"But no Government, however enlightened, can combat disease without knowledge, and were they prepared to lay out vast sums on the public health, their efforts would be nugatory without the contributions of medical research. Both sanitation and medical relief are based on the findings of medical research, and are powerless to advance except as a result of advances in the branches of science dealing with disease. The vastness of the problems at issue should not be ignored."

This leads me to the value of laboratory investments in the West Indies. They are very badly off in this direction: even clinical laboratories do not exist in the hospitals of some of the smaller islands. How, then, can disease be properly diagnosed? A disease not properly diagnosed leads to a waste of time, of medicine, of food—in short, of money. Everywhere the laboratories want strengthening and expanding. Nowhere in the British possessions bordering on the Caribbean are they really up to date and efficient. Research is very largely neglected. Yet we see the strange anomaly of a fine College of Agriculture, with research departments, arising in Trinidad. There parasites and diseases of plants will be studied and remedies devised, while nothing comparable exists for dealing with human pathology. At the same time, the College of Agriculture itself deserves every credit for the step it has taken, along with the International Health Board of the Rockefeller Foundation, to give its students instruction in hygiene.

"Comparisons are odorous," says the buffoon in *Much Ado About Nothing*, but I cannot refrain from directing your attention to the public health activities of the Americans in Porto Rico. I confess, when a patriotic Briton considers the record there and compares it with the conditions obtaining in Jamaica, the Bahamas, Dominica, and half a dozen other colonies, he must feel humbled and ashamed. It will be said at once that Americans are full of money, they can easily afford to spend thousands on such work. Very true, but the American is a keen and astute business man. He is, I admit, in many cases more of an idealist than the Britisher, but I have never heard that he disdained the dollar or cared nothing about a return for his outlay. The American, knowing that hygiene pays, and knowing in part why it pays, has set out in Porto Rico to find out how it can be made to pay more, although, at the same time, he is influenced by humanitarian considerations and an anxiety, very proper, very patriotic, to show what the

United States can do in the field, the great and honourable field, of hygienic endeavour.

Now it is no use our sitting still and saying we are poor, we can't do anything like this, we must jog along as best we can. Such an attitude spells decadence, and, as I have said, there is no room in the world nowadays for decadent people. Some of the islands have no excuse for a policy of masterly inactivity. Barbados and the Bahamas in the West Indies, and Bermuda in dignified isolation are, if not as rich as Croesus, very comfortably off. To do Barbados and Bermuda justice, they are waking up to a sense of their responsibilities, and will doubtless reap their reward. The Bahamas seem to be past praying for, and are at present reaping a fitting reward in the shape of malaria, enteric fever, mosquitos, and the ubiquitous fly. Other colonies suffer grievously from financial depression, but in such cases the situation should be reviewed, possibly with the help of experts, to see if anything can be done in the way of a re-allocation of funds. We may well ask, Is the money available being spent to the best advantage? We know that, even in the wealthy Bahamas, it is not, for the principal medical officer in one of his reports complains about the establishment of a library which scarcely anyone uses, while he cannot obtain the wherewithal to prevent and combat the prevailing typhoid fever.

Again, are we certain that full value is being obtained for what is spent on education? It is true that the curricula embrace lessons in hygiene, but, as taught, they are almost useless. Would it not be possible to make a big change here and to devote some of the money spent on education to sanitary work designed to improve the attendance of scholars in the school, to quicken their intellects, and to make them cleaner and better citizens? I have little doubt there are other directions where the robbing of Peter to pay Paul would not only be feasible but justifiable—not only justifiable but wise.

The mention of education should remind us that Education Stock contains the best of the hygienic shares. To get the best results you must carry your people with you, and you can only do so when you have developed in them a sanitary conscience, made them realize that hygiene pays, and understand how it pays and why it pays. The return on these shares is never immediate, but the investment is sound, and, while some of the money goes to Education Stock, the rest can profitably be expended on hygienic measures which are not quite so dependent on the co-operation and goodwill of the inhabitants. For example, it is rarely that you have to force people to drink a pure water brought to their doors, and you can do much in stamping out malaria without the help of the proletariat. Still, the more you get of this help, provided it be intelligent, the better. It is more likely to be forthcoming if you can convince the people that hygiene will benefit their pockets as well as their minds and bodies. Hence, in conclusion, let me cite some examples which you can employ when, as apostles of Hygieia, you return to the West.

In the case of malaria I propose to take my illustration from Malaya, where Sir Malcolm Watson and others have worked wonders which can, thanks to their researches and enthusiasm, be expressed in terms of hard cash. A Commission not long ago contrasted the value of expenditure on hygiene (a) when the measures employed were crude and the main effort was directed to curing infected coolies, and (b) when the steps taken were guided by a knowledge of prophylactic principles and the main effort was the prevention of disease. The estate chosen was, and is, potentially as unhealthy as any estate in the Federated Malay States.

In 1911 the staff consisted of seven unhealthy Europeans, constantly sick, given to liquor, and taking no interest in bungalows or gardens. In 1923 there were four healthy Europeans (three married and one engaged), three healthy children, pretty gardens, comfortable bungalows, no drinking, and no absences on account of sick leave.

In 1911 there were 870 coolies with practically no dependants. They were miserable, crawling wrecks with narrow shoulders and prominent bellies. They lived in squalid, dirty lines, void of gardens. They possessed no livestock and, saddest thing of all perhaps, no children born alive—a miserable and degraded folk without hope, without

ambition. In 1923 there were only 450 coolies, but these were doing thrice the work accomplished in 1911. Their dependants were represented by 220 healthy old people and young children. Births, as the report puts it, have become a chronic habit. The coolies were fat, well liking, and clean. They had fine gardens, over sixty head of cattle, hundreds of goats, and thousands of chickens.

In 1911 the tappers (it was a rubber estate) were sent out to new tasks every day, and one-third to one-half of the tasks had to be completed in the evening, as the coolies returned sick or too weak to finish the work. In 1923 a coolie was not taken off his task for months, and never had to finish his work off in the evening. In 1911 a gang was sent out to dig graves every day, yet never dug sufficient for requirements, as coolies were constantly dying in the field. In conclusion, the estate in 1923 had become one of the cheapest producers in the Federated Malay States and the cost of production compared favourably with Ceylon and Java.

[In addition to malaria, the lecturer dealt with ankylostomiasis in India, enteric fever in North Carolina, tuberculosis, and dengue in Texas.]

Surely enough has been said to indicate what a fine field exists in the West Indies for economic and humanitarian endeavour! As has been indicated, it is not altogether a virgin field. Here and there we see notable signs of activity, solid evidence of sound work, and indications of a quickening and regeneration—as, for example, the work in Port of Spain, already cited, the extensive water supply and drainage schemes in British Guiana, certain new developments in Jamaica, the stirrings of a sanitary conscience in Bermuda and Barbados, the provision of good drinking water in Dominica, the recognition of the importance of infant and child welfare work in several places. On the whole, however, one must admit that these colonies are sadly behind the times, and that some of them scarcely realize that of recent years the whole outlook in tropical hygiene has changed. I admit the solution of health problems is not so simple as it sounds. There are various difficulties. Above all things it is essential to have good men to initiate and control the reforms. Yet, for the most part, medical officers in these possessions are paid a mere pittance. Nowadays it takes six years to make a doctor, and when he is made he has yet to learn a great deal of his life's work. Not until two years have elapsed after his registration as a medical practitioner can he proceed to a degree or diploma in public health, even though the actual study for such a diploma only occupies one year. If he wishes to qualify in tropical medicine and hygiene he has to undergo a special and intensive five months' course of instruction. All this means a great deal of expenditure. It is a very costly education, and why should a man thus trained, thus equipped, accept a beggarly salary? He may, even if he is first class, provided there are possibilities and opportunities for getting something done; he may, if there is a chance of carrying out research and he is a born research worker; but, in the great majority of cases,

he will not, for he can do better elsewhere, and will go elsewhere, even though, as compared with other parts of the tropics, the West Indies possess some advantages. For example, you can make a permanent home in them in a way impossible in many parts of tropical Africa, India, Ceylon, or Malaya.

Remember, however, that satisfactory and sufficient salaries are not everything. A really good man will not be tempted to stay merely by considerations of filthy lucre if he finds his hands tied for lack of funds, and what should be his life's work crippled and hampered at every step. If he does remain he will cease to be a good man, and joins the ranks of those who say, "I've done my best; it's not my fault, let things rip." How often has that happened! I have seen it myself again and again, and it is a state of mind fatal to the individual and to the advancement of health. Hence well paid medical officers and an active and progressive, but non-extravagant, policy are alike essential. If these be forthcoming there should soon be a change for the better. Yet we must remember that the medical officer is not the only cog in the health machine. Well trained and qualified sanitary inspectors are absolutely necessary if it is to work smoothly and efficiently. In some places these men are available locally—for example, in British Guiana and Trinidad, where there are some first-class inspectors—but very often it will be found better to introduce a man of the right stamp from this country, or, better still perhaps, from one of our other tropical colonies, promoting a junior official to a senior post.

The inspector should be the health officer's eyes and ears; he is the essential intermediary, he is the non-commissioned officer of the sanitary force, and therefore its backbone. Without him it is apt to lack cohesion, and in his absence can never get properly to grips with the populace. Adequate clerical help must also be accorded the Health Office. Too often the wasteful and disheartening process of employing razors to cut wood is adopted. In other words, the medical officer of health spends his time making out returns, and the sanitary inspector is turned out to keeping books when he should be out in the field. This kind of thing is supposed to spell economy. As a matter of fact, it leads to loss of money and possibly also to loss of lives.

So much for personnel, on which practically everything depends. Let us not forget that the more mobile the Sanitary Force the more satisfactory will be its work. There should be no niggling over transport allowances. Epidemics can very often be nipped in the bud, but to accomplish such a desirable abortion the nipper must be on the spot at the earliest possible moment. This has long been recognized in Egypt, where the Epidemiological Section of the Public Health Department is fully equipped as a mobile unit. There are many other points to which I might refer, but I must not weary you, and have probably already provided more than sufficient mental pabulum for the lay digestion.

Let me only say that these matters we have considered—and I esteem it a privilege to have had this opportunity of addressing you—are not vain imaginings or flights of fancy or the ideas of an idealist. They are facts which merit most careful consideration; they are the principles on which action must be based; they are, in a very special sense, matters of life and death. Hence I would express the earnest hope that they will not be lightly regarded or looked upon as impracticable, but that this discussion may prove the means of giving modern hygienic methods a fair and fighting chance in the West Indies. Other British possessions have done so, and have reaped and are reaping the reward, a monetary reward as well as a reward in other directions. The West Indies, fair and fruitful, are amongst the oldest of our colonies. They have had a great past, their very names spell romance and recall glorious and stirring times. Such days may not come again, but there seems no reason why most of them should not have a rosy future, if only they will remember that rosiness is, under certain conditions, a sign of health, and that health, though nowadays readily attainable, can only be obtained by concerted effort and by following those guiding principles which have been enunciated and which have proved, and are proving, beacon lights to many tropical communities.

A British Medical Association Lecture ON RECENT ADVANCES IN THE SURGERY OF THE CHEST.

DELIVERED BEFORE THE BRADFORD DIVISION, APRIL, 1926,

BY

H. S. SOUTTAR, C.B.E., M.Ch., F.R.C.S.,

SURGEON, WITH CHARGE OF OUT-PATIENTS, LONDON HOSPITAL.

(With Special Plate.)

SURGICAL procedures in connexion with the chest differ from those in other regions of the body in the peculiar mechanical difficulties which they present. On the one hand, the chest and its contained viscera are in constant motion; on the other hand, in the pleural cavity alone of all regions of the body is there a constant negative pressure. The latter is by far the most important consideration in dealing with the thorax, since it means that unless very special precautions are taken an opening into the pleural cavity will generally be followed by the immediate collapse of the lung on that side.

This pleural suction, as it might well be called, varies between 6 mm. of mercury in expiration and 30 mm. on deep inspiration, but it must be remembered that on closing the glottis and coughing it may be converted into a positive pressure of 100 mm. or more of mercury. So long as the thorax is closed the mechanical conditions are not affected by the existence of a potential pleural cavity, but the moment it is opened the conditions on the two sides of the chest become entirely different. If the opening is large the viscera on this side are subject simply to atmospheric pressure, whilst on the opposite side they are subject to pressures which may vary, as we have seen, between -30 mm. and +100 mm. of mercury.

If the two sides of the chest were separated by a rigid partition no great harm might result. It would simply mean that one side was thrown out of action so far as respiration was concerned. They are, however, separated not by a rigid partition but by a very mobile mediastinum, and, moreover, this mobile mediastinum contains the heart, the great vessels, and a mass of important nervous structures. Such variations in the pressures on its two sides, often as sudden as they are violent, will literally throw the mediastinum from side to side, producing the condition known as flapping of the mediastinum. The dangers of such a condition need scarcely be stressed, and yet it is the immediate result of a large opening made into the chest without due precautions. Such a state of affairs is of common occurrence in the ordinary treatment of acute empyema. Its recognition and the elaboration of means to avoid it form an important advance in thoracic surgery.

ACUTE EMPYEMA.

Acute empyemata occur in two forms—the adherent and the non-adherent. The former are usually pneumococcal, and will often show pneumococci in pure culture. They are often loculated and limited to one portion of the pleural cavity; they contain thick pus which can only be aspirated with difficulty; the pleural surfaces are covered with thick layers of plastic lymph, and floating in the cavity itself are large masses of soft fibrin. In direct contrast to this the non-adherent form is usually due to streptococci or to a mixed infection; it is necessarily complete, the pleural cavity is full of thin pus, and as gas-forming organisms are frequently present the condition is generally one of pyopneumothorax. In this form the intrathoracic pressure may be very high, the intercostal spaces bulge, the mediastinum is pushed over to an excessive degree, and the diaphragm and liver are pushed downwards. Obviously the two forms involve surgical and mechanical considerations of a very different nature, and they demand very different methods of treatment.

In the first or adherent form there can, in my opinion, be no doubt that the best method of treatment is to open the cavity freely, evacuate the pus, clear out all solid masses of fibrin, and drain by a closed method. The adhesions will prevent collapse of the lung and the forma-

tion of a complete pneumothorax, and the free opening, by giving adequate access to the interior of the chest, makes it possible to remove the large solid masses whose presence retards sterilization and induces the formation of massive adhesions. A large tube is now inserted at the lowest point of the cavity, and the tissues are carefully closed around it, so that it fits quite airtight. A large cork or a perforated sheet of rubber is threaded tightly over the tube, and when the dressings are applied this holds the tube in place. It projects through the dressing, and it is connected to a long rubber tube the end of which hangs below fluid in a jar on the floor beside the patient's bed. As the fluid trickles down it, this exerts a slight suction which assists the expansion of the lung.

In the non-adherent form, on the other hand, a free opening into the pleural cavity is exceedingly dangerous, involving as it does gross disturbance of the equilibrium of the thorax, and producing in an acute form the "flapping mediastinum" to which we have already referred. It is far safer to relieve the pressure by repeated aspiration, until sufficient time shall have elapsed for the formation of a certain amount of protective adhesions. Once these have been formed the pleural cavity can be opened without the danger of an immediate collapse of the lung, but even then it is much better to adopt the method of closed drainage we have described. With open drainage an initial pneumothorax is inevitable, and it may lead to such thickening of the pleura as will seriously interfere with expansion of the lung, whilst there is always a grave risk of secondary infection of a large cavity. Closed drainage is quite easy to arrange—it is more comfortable for the patient, it avoids these risks, and the constant slight suction assists the lung to expand.

SUPPURATIVE BRONCHIECTASIS.

The importance of these mechanical considerations in connexion with the treatment of suppuration in the pleural cavity will be seen. Let me now direct attention to their bearing on suppuration in the lung itself. Sooner or later this is certain to resolve itself into a suppurative bronchiectasis, and for the sake of brevity I shall consider it solely from that aspect.

Suppurative bronchiectasis may have its origin in some mechanical interference with the bronchi, or in infection of the parenchyma of the lung—as, for instance, after an unresolved pneumonia. In either event a very similar state of affairs ultimately results, for the bronchi become dilated from weakening of their walls and obstruction to the egress of air, whilst there is always a greater or less degree of destruction of the lung tissue itself. A ragged abscess cavity may be formed, into which open widely dilated bronchi; or in the more chronic cases the bronchi themselves may form the cavity in which pus collects. In both cases the patient coughs up large quantities of foul pus, and suffers from a severe degree of septic absorption. The problem for the surgeon is the draining of these cavities, and the prevention by adequate ventilation of the growth of the anaerobes for which these cavities provide such a perfect soil.

It is well, however, that we should recognize how often these conditions have a mechanical, or, unfortunately, even a surgical, origin. The commonest cause of bronchiectasis is mechanical interference with the passage of air through the bronchi, and of this one of the commonest causes is the inhalation of a foreign body. This may be any small object, such as a button, a tin-tack, or a collar stud; or it may be a fragment of bone from food the patient was eating, as in a case I shall presently describe. The frequency of such an event, and the gravity of the results, are not sufficiently recognized, but thanks to the pioneer work of Chevalier Jackson the conviction is steadily gaining ground that a large number of cases of obscure pulmonary sepsis are traceable to this source. The following is a striking example.

I was asked by Lord Dawson to see one of his patients in the London Hospital, a woman of 20 with an obscure condition in the right side of the chest. She told me that five months previously, when eating a mutton chop, she suddenly choked, and thought that a fragment of bone had gone down the wrong way. This was followed by intense coughing and retching, which gradually subsided, leaving her with a dry cough.

One month later she began to feel ill, her temperature rose, and her doctor, on exploring the right side of her chest, found pus. She was admitted to a hospital, where her chest was again needled and creamy yellow pus was aspirated, containing many organisms and offensive in smell. She ran a very irregular temperature, ranging between 98° and 102°, rising on one occasion to 104°. She had a loose cough, and brought up sputum containing yellow mucoid masses. Over the right lower chest the percussion note was dull, and breath sounds were absent. Under the impression that the case was one of empyema a rib was resected, the pleural cavity opened, and one ounce of pus was evacuated. This was followed by the drainage from the wound of quantities of very foul pus, but her temperature remained irregular, ranging between 96° and 102°.

When I saw her in the London Hospital she was a very ill looking woman, coughing up enormous quantities of horrible pus. There was an open wound in the right side of the chest

from which pus was pouring, but this periodically closed. She felt better when it was open. The right side of the chest showed marked collapse, and there was some dorsal scoliosis with the concavity to the right. The movements of the right chest were poor, the percussion note was diminished, and the breath sounds were weak. There was increased vocal resonance and bronchophony over the right base. Repeated examinations had failed to show the presence of tubercle bacilli in the sputum. A blood count showed 7,320 leucocytes, of which 70 per cent. were polymorphs. X-ray examination showed a cavity containing fluid in the right lung, whilst the whole of the lower portion of the right lung was opaque and the diaphragm could not be seen.

In view of the long history of the case arrangements were made for a full exploration of the chest, but bronchoscopy was first attempted. It was rendered difficult by the masses of purulent sputum which were being constantly coughed up. I found the right bronchus intensely inflamed, the wall looking like red velvet, and about three inches beyond the bifurcation of the bronchi a cavity was entered containing pus and debris. The thick pus was removed with some difficulty, and finally the bottom of the cavity, formed by red granulation tissue, was reached at a distance of fourteen inches from the teeth. In this granulation tissue a minute white spot could be seen, and on gradually clearing away debris it became a white ridge across the tube, which a probe revealed to be a hard rough structure. On seizing it with alligator forceps it proved to be some object larger than the tube, through which it could not be drawn. The whole instrument was therefore withdrawn, with the forceps holding what was evidently a foreign body. It proved to be a piece of mutton bone of irregular formation, about half an inch across. The immediate improvement in the patient's condition was remarkable, and though her chest was not entirely cleared and she still coughs up a little pus, she considers herself too well for any further operation.

The aspiration of a foreign body is only too likely to occur during a surgical operation, unless the greatest care is taken to avoid it. Particles of vomited material, or plugs of mucus from the mouth, may easily reach the bronchi, and there can be no doubt that many cases of post-operative pneumonia are due to this cause, whilst fragments of teeth or of tonsils may give rise to very serious trouble. It is only recently that attention has been called to the pulmonary complications from this source which may follow tonsillectomy, but the statement of Frederick Moore that pulmonary abscess occurs once in every 3,000 tonsillectomies shows how serious a matter it may be.

The pressure of tumours outside the bronchi may give rise to bronchiectasis and the formation of a pulmonary abscess, and this frequently occurs in carcinoma involving the hilum of the lung. In a case recently referred to me by Dr. Rowlands I drained an enormous abscess of the right lung only to find *post mortem* that a carcinoma had destroyed the right bronchus, invaded the hilum of the left lung, and actually penetrated into the left auricle of the heart.

The diagnosis of bronchiectasis is the realm of the physician, but the average case can unfortunately be diagnosed from very obvious symptoms, by the large amount of pus which the patient coughs up, and by the horrible fetor which distinguishes it. Naturally there is some febrile disturbance, often an irregular swinging temperature, and the patient is ill. But there is not as a rule marked emaciation, and the disease may pursue its course over a long period, whilst the patient is a misery to himself and a terror to his friends. The x-ray appearances are fairly characteristic. There are dense opacities due to infiltrated and fibrotic lung and to bronchi filled with pus, and from these opaque areas shadows radiate out towards the periphery. Occasionally an area is seen, roughly circular

in outline, the upper portion transparent, the lower filled by a dense shadow with a horizontal upper margin. If, on moving the patient, this margin is seen to remain horizontal, moving relatively to the patient, it is evident that we are looking at a cavity containing fluid, a true abscess cavity in the lung. In a typical case the picture contrasts with that of empyema, since the opacity is surrounded by a zone of more transparent lung.

The outlook for these cases apart from surgical intervention is poor. It is true that they may be taught to empty the cavities by postural methods, and that under careful hygiene they may improve. But in most cases, in spite of remissions, the progress is steadily downward, continued sepsis produces its inevitable results, and at any time acute haemoptysis, a secondary empyema, or a cerebral abscess may occur. Until a few years ago it was thought that little could be done for these cases by surgical means, but new methods seem to point to a much more hopeful future.

It is understood that every effort has been made to determine the exact situation and extent of the disease, and that the possibility of a foreign body, or perhaps the foreign body itself, has been eliminated. The next procedure is probably a full surgical exploration of the chest. Under a combination of regional and intratracheal anaesthesia an incision is made in the seventh intercostal space, and unless dense adhesions are encountered it is extended through almost the whole length of that space. A rib spreader is now inserted and the ribs separated to a distance of perhaps four inches. In the absence of adhesions a full view of the lung can now be obtained, it can be fully palpated, and its condition can be completely investigated.

In general, unless an aspirating needle has been used and the pleura infected, the lung will be found free of adhesions. The affected lobe will be found to be somewhat rigid from infiltration, and it will often be of a darker colour than the normal lung. If the air pressure in the intratracheal tube is reduced the normal lung shrinks at once, but the diseased lung only to a less extent. It must be remembered that it forms a sponge-work, with dilated bronchi filled with pus and prevented from collapsing by the infiltration of their walls, and this conception must be borne in mind in considering the problem of treatment. Occasionally the mere opening of the thorax and the letting in of air may produce a sufficient degree of collapse in the diseased lung to effect a cure. But this must be a rare event, and can only occur in early cases where the degree of infiltration is slight.

The obvious surgical course is to drain away the pus, but here we are faced by two serious difficulties. In the first place, if we incise the lung we inevitably infect the whole of a widely open pleural cavity, and we produce a septic complete empyema which communicates with the bronchi, making matters ten times worse. In the second place, you cannot drain a bronchiectatic lung by simply incising it. As Lillenthal neatly puts it, there is a great difference between emptying a vessel by knocking a hole in its bottom and trying to get the liquid out of a water-soaked sponge by incising it. So much, indeed, is Lillenthal impressed by this difficulty that he advocates complete excision of the affected lobe. In his hands this drastic procedure has given wonderful results, though even he finds a mortality of nearly 50 per cent. The operation itself is not difficult, but in dividing the root of the lobe infection of the pleura is inevitable, and all that can be done is to limit its effects. After the age of 35 Lillenthal himself rarely considers that the operation is justifiable, brilliant though its results may be at an earlier age.

A less ambitious but much safer procedure has been devised by Evarts Graham of St. Louis, and as I have carried it out myself with conspicuous success I feel some confidence in the soundness of the method. The first thing is to explore the chest and to see whether or not adhesions are present. If the lung is free adhesions must be produced by artifice, and this is done by packing gauze over the area selected for attack, to be removed at the end of a week. A fortnight later, when the lung has become densely adherent to the chest wall at this point, sufficient ribs are resected over this area to give a really wide exposure of the affected lobe of the lung, a corresponding

flap of chest wall being turned up. A soldering iron at a dull heat is now plunged straight into the bronchiectatic lung, and the septic sponge-work is widely destroyed. A large cavity is left into which open numbers of dilated bronchi, from which pus is thus drained in a really effective manner. A large slough of course comes away, but considerable bleeding is rare, and any that may occur is readily controlled by pressure. The cavity is gradually obliterated by collapse of the chest wall, by expansion of the lung, and by the formation of granulation tissue.

The following case, referred to me by Professor Ellis, illustrates the facility of the operation and the dramatic recovery which may follow.

A woman, aged 31, dated her illness from an attack of pneumonia two years previously which had never quite cleared up. Nine months after this attack she had a slight hæmoptysis and was admitted to Brompton Hospital. No tubercle bacilli were found in her sputum, but she was sent to a sanatorium, where she remained in bed for four months. For a time she was better, but for the last six months she had had a troublesome cough, severe dyspnoea, and an evening temperature running up to 102°. She was a thin, wasted woman and said that she had lost 2 st. in the last six months. There was marked clubbing of the fingers. Over the right base there was marked dullness, with diminished vocal resonance and absent breath sounds, whilst an x-ray photograph showed a dense shadow in this region, suggestive of empyema. She constantly coughed up large quantities of foul pus, often blood-stained, and her temperature oscillated between 97° and 102°.

A needle withdrew streptococcal pus, and an exploration of the chest was therefore carried out. The pleural cavity was found empty and clear of adhesions, except at the point where the needle had been inserted. The right lower lobe gave the impression of being almost solid at its lower pole, which was dark purple in colour. Gauze was packed in between the lung and the chest wall with a view to obtaining adhesions round this area, being withdrawn a week later.

A week later bronchoscopy showed that the right bronchus and the branch leading to the lower lobe were intensely engorged, resembling red velvet, and a cavity of some size was entered; it contained pus. An attempt was made to wash this out, and was repeated on several occasions, but without much success. The trachea was so irritable that bronchoscopy without an anaesthetic led at once to violent coughing and the evacuation of the abscess up the tube. As emptying the abscess had no effect on the temperature it was determined to drain the cavity through the chest wall. A large opening was therefore made over the adherent area, and through this a large cavity in the lung was entered. The opening was enlarged with a heavy copper cautery at a low heat, and by this means the outer wall of a cavity about 3 in. in diameter was destroyed. Into this cavity opened several bronchi as large as a finger, and from these pus poured.

The result was immediate, for her temperature fell at once, her cough stopped, her appetite returned, and she said that she had not been so well for months. After a few days the discharge ceased to be foul and became greatly reduced in amount. She was sent to a convalescent home, and at the end of two months the opening had closed, she had put on a stone in weight, and appeared in perfect health.

PULMONARY TUBERCULOSIS.

To the thoracic surgeon pulmonary tuberculosis presents the widest field of all, and, though its surgical treatment is still in its infancy, in recent years great advances have been made. The underlying principle is that which is universally adopted in the treatment of tuberculosis in other regions—to place the part at rest; but here, in contrast to the limbs, we are dealing with an organ whose movement is essential to life. In the solution of this apparent contraindication lies the whole surgical problem.

The selection of cases is the field of the physician, but perhaps I may refer to a few important points. Of the more acute cases the most suitable are those in which, after two or three months of conservative treatment, the disease is still advancing, and where the advance is more marked on one side. Cases of acute bronchopneumonia or pneumonia disease localized to one lung can be so treated, and the advance may be checked. In chronic cases of long standing with extensive fibrosis and cavitation, where perhaps the disease has come to a standstill, but where the patient is incapacitated by a chronic cough and frequent exacerbations, much can be done for his relief.

The surgical treatment of all these conditions can be summed up in the one word "collapse." It may be obtained by introducing air into the pleural cavity, by introducing packing of some sort between the parietal pleura and the chest wall, by removal of the ribs, or by paralyzing the diaphragm, but in every case the final object is the same. Two methods stand out as of very general application, artificial pneumothorax and thoracoplasty, and

the two are in many ways complementary to each other. Where it is possible to produce a complete pneumothorax this is undoubtedly the method of choice, but in many cases, and especially in those chronic cases to which we have just referred, adhesions between the layers of the pleura make it impossible, and we may then have to fall back on thoracoplasty.

In producing an artificial pneumothorax any of the standard forms of apparatus may be employed. The essentials are that it should be possible to introduce a known quantity of air and to keep under close observation the resulting intrathoracic pressure. The latter is of extreme importance, since, except in very special circumstances, it is essential that the lung should be allowed to collapse by its own elasticity, whilst as a rule it is best to finish with a small negative pressure. The whole procedure can be carried out under local anaesthesia. The site of puncture should be chosen with a view to avoiding adhesions, and therefore at a distance from the chief foci of disease. In the majority of cases the seventh space in the post-axillary line will be satisfactory. The amount of air introduced on the first occasion will vary between 250 and 450 c.c.m., enough to produce definite symptomatic relief, but not enough to run any risk of overstraining the other lung, upon which, of course, additional work is thrown, both circulatory and respiratory. Perhaps two days later more air is introduced, and the operation is repeated at intervals depending on the symptomatic response, until if possible complete collapse of the diseased lung is obtained. If this ideal is reached it will still be necessary to introduce air at intervals of perhaps two weeks, in order to compensate for air which has been absorbed and to maintain the collapse.

Such in briefest outline is a method which has now developed a highly specialized technique. But, like any other operative method, it must only be regarded as an adjunct to full hygienic control, without which it is doomed to failure. Its success depends upon the possibility of producing a more or less complete pneumothorax—that is to say, upon the absence of adhesions. When these are at all extensive other methods must be adopted, and of these the most effective is thoracoplasty.

Thoracoplasty consists in the removal of so much of the bony structure of the thoracic wall that the remaining soft structures collapse upon the underlying lung. The work of Sauerbruch has reduced it from an exceedingly dangerous to a comparatively safe procedure, and in the hands especially of Bull and Saugman it has given brilliant results. Sauerbruch's operation depends upon the fact that if the posterior portions of the ribs are removed the remaining portions can bend inwards on the costal cartilages, and can virtually obliterate the chest cavity. Through a vertical J-shaped incision behind the whole of the posterior half of the thoracic wall is readily exposed, with very little damage to the muscles which cover it. The ribs are exposed in turn and resected subperiosteally, the length removed varying from 3 cm. for the first rib to 12 or 15 cm. for the eighth. The total length of rib removed in a complete operation may be as much as 120 cm., or about 4 feet. The operation may be limited to one portion of the chest, but it is not then nearly so effective, or it may be done in two stages. It is best accomplished under local and regional infiltration anaesthesia, perhaps accompanied by gas and oxygen. The nerve block is here of the first importance in reducing shock, and with its use the condition of the patient the day after this very extensive operation is quite remarkable.

This is undoubtedly the most powerful method we possess of collapsing the lung, and it is equally applicable to cases where the disease is not in the lung but in the pleura. Of this the following is an example among my own cases.

The patient was a man, aged 25, whom I was asked by Dr. Miller to see in the London Hospital. He gave the history that five months previously he had noticed a splashing sound in his chest, and soon after found that he was short of breath on exertion. His doctor found fluid in his chest, and a few weeks later he was admitted to hospital. Large quantities of milky fluid were aspirated from the left side of his chest on many occasions, but it always re-collected. It contained tubercle bacilli. When I first saw him he was a thin, pale man, slightly cyanosed, only able to breathe when propped up vertically in bed. He ran an oscillating temperature, and he was desperately ill. The left side of his chest was full of fluid. As it was evident

that the immediate cause of his trouble was mechanical I had first to consider how this could be relieved. Something more than aspiration through a needle was required, but drainage, from the risk of secondary infection, was out of the question. Under local anaesthesia, and without even moving the patient in bed, I made a small opening in the eighth space, into which I fitted a smooth silver obturator as a plug. Through this opening, which remained perfectly clean, we removed every morning from one to two pints of fluid. At the end of a fortnight his condition had so far improved that I was able to resect a rib and to explore the chest. On opening the pleural cavity twelve pints of milky fluid escaped. Both surfaces of the pleura were covered with tubercles. The wound was closed in the hope that adhesions might form. Six weeks later, fluid having been repeatedly aspirated in the meantime, the whole of the left dorsal region was blocked with novocain, and the posterior portions of the ribs from the fifth to the eighth were resected. As the ninth and tenth had previously been resected a satisfactory collapse of the lower part of the chest was thus obtained. The result was very remarkable. He made an uninterrupted recovery, and a year later he was in perfect health, doing full work on a farm. He has remained perfectly well, there is no sign of fluid in his chest, and the external deformity is trivial.

CONCLUSION.

The thorax thus presents to the surgeon peculiar difficulties and great opportunities. The difficulties are largely mechanical, and they can be overcome by mechanical means. Given the necessary appliances, and the still more necessary experience, there is no region which can be explored with more safety or with greater thoroughness. Many of the conditions have already been brought under our control, and the conquest of many others is only a matter of time. But this of all the branches of our art is the one in which co-operation between physician and surgeon is the most essential, and I therefore welcome this opportunity of bringing it before a body of practitioners who are meeting with these cases every day. I have only touched on a few features in a very large field, but I hope that I may have enabled you to realize the great opportunities, the brilliant hopes, and above all the safety, of modern thoracic surgery.

An Address

ON

GASTRIC DIAGNOSIS.*

BY

L. R. BROSTER, O.B.E., D.M., M.Ch., F.R.C.S.,

ASSISTANT SURGEON, CHARING CROSS HOSPITAL; SURGEON, QUEEN'S
HOSPITAL FOR CHILDREN.

(With Special Plate.)

THIS paper contains an analysis of the diagnosis of four related gastric conditions of similar symptomatology, based on operation findings. From the patient's point of view the stomach is the most plaintive organ of the body, and we all know that our methods of diagnosis and treatment of it are not yet so standardized as to meet the requirements of each individual case.

Having been personally interested in the correlation of the x-ray diagnosis and the operative findings, I wish to direct attention chiefly to this aspect, and, with the aid of a series of plates supplied by Dr. S. Cochrane Shanks, to distinguish the finer points of diagnosis.

I will, so far as possible, limit myself to the analysis of some 140 cases treated at the Charing Cross Hospital; these include 51 cases of gastric ulcer, 33 cases of duodenal ulcer, 27 cases of carcinoma of the stomach, and 26 cases mimicking these lesions, but due to other causes.

PROPHYLAXIS.

We have not been able as yet to determine the exact causative factor in gastric and duodenal ulcer. There is no doubt that predisposing causes exist. The patient who early seeks medical advice can expect amelioration of his symptoms from judicious treatment, while in the later stages he can be saved much pain and bouts of semi-invalidism, and fear less the complications which threaten his life.

* Delivered to the Southampton Division of the British Medical Association.

The practitioner whose aim it is to prevent the occurrence of these lesions has to devise a daily routine for those who seek his guidance. Such questions as diet, the treatment by drugs, the restriction of smoking, proper rest, the elimination of oral sepsis, and of foci of infection must be attended to.

When the disease is established examination by means of the x-rays and the fractional test meal should be employed. It is not until such treatment has been tried and has failed to prevent recurrence of the symptoms that the need for surgery arises. It then becomes a question of co-operation between the physician and surgeon, and the best results are obtained when this partnership is continued after the operation. The patient is prone to think that an operation means an end to his disabilities. It is true that most patients are cured, but some are only improved; a few with gross lesions cannot expect to become entirely normal again, while in a small percentage of cases jejunal ulcers will develop. It is to this small minority that continued after-care is so important.

DIAGNOSIS.

With regard to the efficacy of the diagnostic means at our disposal, opinions differ. M'ynihan and the Mayos base most reliance on the x-ray findings, Walton stresses the clinical history, while others place their faith in the fractional test meal. The necessity for such indirect methods indicates a very varied symptomatology, and a lack of definite physical signs.

This being so, I am convinced that when taking the patient's history it is necessary to eliminate, as far as possible, matters of fancy, and to consider only the bald facts. For this purpose I use a chart, which is comprehensive and standardizes the results. I prefer to take clinical histories myself, and am often struck by how materially they can differ from those taken by my assistants. In reviewing the x-ray and operative findings they are found to agree in the majority of cases, and in this series the margin of error worked out as follows:

Gastric Ulcers.

Of 49 cases—

History and x rays disagreed in 13—	
History correct, x rays wrong or doubtful in	8
History wrong, x rays correct in	4
History doubtful, x rays wrong in	1

Duodenal Ulcers.

Of 28 cases—

History correct, x rays wrong or doubtful in	8
History wrong, x rays correct in	4
History and x rays wrong in	3

Carcinoma.

Of 22 cases—

The x-ray findings were wrong or doubtful in	5
--	---

Whatever the merits or demerits of these various forms of investigation may be, the main point is that we each evolve our own particular lines of thought and action, and are best fitted to carry these into effect. Personally I consider a good x-ray examination a necessity. Apart from the diagnostic point of view, it is an invaluable guide to the surgeon in planning his operation, and revealing such complications as a small coexisting ulcer. Should there be any doubt, or should the x-ray examination and the clinical history disagree, then positive evidence from the test meal becomes a deciding factor.

SYMPTOMATOLOGY.

1. General.

Perhaps the most striking features of gastric and duodenal ulceration are its selectivity for the male sex, and the definite periodicity of its symptoms. Bouts of pain lasting generally from two to three weeks are followed by intervals of complete freedom ranging from a few months to a year or more. In duodenal ulcer these remissions are most constant; the patient has one or two attacks a year, and knows sometimes exactly when the next one is due.

In the early stages the intervals are not so marked as when the ulcer is established. In the later stages any change in this periodicity becomes significant; the painful attacks become prolonged, while the periods of freedom

become shorter. Such a change is invariably associated with some complication, such as pyloric stenosis, hour-glass contraction of the stomach; or adhesions to the pancreas. When the change is sudden, and the attack lasts much longer and the pain is constant, the onset of carcinomatous change in the ulcer must be suspected.

What happens to the ulcer in these symptomless intervals? Operation at these times reveals the ulcer still active or in a smouldering condition. Occasionally the scar of an old healed ulcer is found, and it is fair to assume that healing has occurred when a painless interval has lasted an inordinately long time.

2. Age and Duration.

Although ulcers may appear at unexpected ages, the average age of incidence lies between the third and fourth decades. The average for duodenal ulcers is a little earlier than for gastric ulcers, and carcinoma follows after the forties. In this series the age incidence and duration of the symptoms work out as follows:

	Age.	Duration.
Gastric	44	6.5 years.
Duodenal	41	6.6 "
Carcinoma	53	5.0 "
Non-ulcers	38	5.7 "

In women the onset is slightly earlier than in males, and the ratio of females to males is: gastric 7:51; carcinoma 9:27; duodenal 7:33; non-ulcers 7:26.

3. Pain.

Although pain is popularly regarded as a *sine qua non*, it is important to remember that certain ulcers are unassociated with pain, and manifest their presence by a sudden perforation or haemorrhage. I have recently met with two perforations of this type, where a careful interrogation failed to elicit any previous history of dyspepsia. One patient was a workman, who twisted himself on a scaffolding, and walked into hospital with slight rigidity of the right upper rectus and a pulse of 72. The other patient experienced slight pain for the first time, which he relieved with oil, and perforation occurred the next morning. Apart from slight rigidity and a pulse of 80, he had no symptoms of dyspepsia.

The intermittent character of the pain has already been referred to. It seldom occurs within half an hour after a meal, but may appear at any time up to the next meal. As a general rule, in uncomplicated cases the time of onset is delayed the farther away the ulcer is from the cardia, and a two-hour limit is roughly the dividing line between the pyloric and duodenal ulcers. Each has a food fluctuation. In gastric ulcer it is food, comfort, pain, comfort; whereas in duodenal ulcer it is food, comfort, pain. The relief afforded to a duodenal ulcer by taking more food is often referred to as the "hunger pain."

The pain varies in intensity—sometimes dull and aching, at other times sharp, boring, or burning. It is determined partly by the acidity of the gastric contents, by the nature of the food, and by spasm. The time of onset coincides with the crest of the acid wave of the fractional test meal. The localization is in the epigastrium. With posterior and adherent ulcers it spreads to the back, and may be referred to the point of the shoulder. In duodenal ulcer the tendency is to spread to the right iliac fossa, and in jejunal ulcer to the left side. Radiation with a more constant pain is indicative of complications, while the sudden acute stabbing pain is pathognomonic of perforation. Relief of pain is more often occasioned by vomiting in gastric ulcer, and by more food in duodenal ulcer. The ingenious methods of obtaining relief devised by patients are as numerous as they are inconstant.

The feature of carcinoma following on an ulcer is the change from a fluctuating to a constant pain, which is not relieved by the ingestion of more food; whereas in the primary carcinoma the pain may be so insidious that it is merely described as discomfort, and in a man over 40 should arouse suspicion. The pain caused by non-organic lesions of the stomach is more variable, and tends to come on earlier after food. The average time of onset of pain after food in this series was: In gastric ulcer, 1.7 to 2.4 hours; in duodenal ulcer, 2 to 2.4 hours; in carcinoma, never later than 1½ hours; in non-ulcers, 3/4 to 1½ hours.

4. Vomiting.

In gastric ulcer vomiting is a common feature and occurred in 88 per cent. of the cases; it was almost equally common in the cases of carcinoma. In the duodenal ulcers and non-ulcer cases it occurred in about 50 per cent. of the cases. Walton states that vomiting in duodenal ulcer occurs in only 8 per cent. of cases. It is a reflex act conditioned by the pain, and becomes a more constant feature with the onset of complications. The fact that emptying of the stomach so often relieves the pain has encouraged patients to devise various means of inducing it. The incidence of vomiting to the number of cases was: Gastric ulcer, 43/51; duodenal ulcer, 16/33; carcinoma, 20/27; non-ulcer, 14/27.

5. Haemorrhage.

Haemorrhage from a chronic ulcer is always an alarming occurrence, and more so if it is duodenal in origin. Cases are published from time to time where it has been so severe as to warrant immediate operation, and the base of the ulcer has been found eroding one of the larger arterial branches. Death seldom occurs from haemorrhage. Medical treatment is invariably successful, and operation is better deferred. Blood transfusion has enabled us to deal far more effectively with this condition than hitherto. In severe and repeated haemorrhages it should always be resorted to, although I would add that special care is necessary in dealing with Group II cases.

Most perplexing are those cases of gastrostaxis, first described by Hale-White, in which the mucosa literally weeps blood and no demonstrable lesion can be found. I recently treated a young woman for this condition. Her x-ray examination showed a large filling defect on the greater curvature which was reported as an ulcer. The test-meal acidity was low. At operation no sign of ulcer could be found, but the whole mucosa oozed with blood. This patient was subsequently treated with hydrochloric acid. She remained fairly comfortable on 12 minims thrice daily, but any reduction of this amount caused her pain and haemorrhage to reappear.

Haematemesis occurs in about 30 per cent. of gastric ulcers. In duodenal ulcer regurgitation of blood may take place through the pyloric sphincter, and the more common feature of melaena may be overlooked when the blood is passed in small quantities.

Altered blood in the vomit, the so-called "coffee grounds," is found with carcinoma. I can offer no adequate explanation of the cause of the haematemesis or melaena associated with such cases as fibrosis of the appendix, Lane's kinks, adhesions, gall stones, and tuberculous mesenteric glands which have occurred in this series.

	Cases.	Haemat- emesis.	? Haemat- emesis.	Melaena.	? Melaena.
Gastric ulcer ...	51	15	3	5	2
Duodenal ulcer ...	33	4	2	7	2
Carcinoma ...	27	7	1	6	1
Non-ulcers*	26	8	—	2	—

* Haematemesis and melaena in 4.

6. Physical Signs.

It is rare for physical signs to be of any importance in the diagnosis. Of them, tenderness in the epigastrium is by far the commonest, and rigidity of the upper recti comes next in frequency. The most helpful signs when present are visible peristalsis, a succussion splash, dilatation of the stomach, or a tumour. As would be expected, they are most commonly found in carcinoma.

	Tender.	Splash.	Peri- stalsis.	Rigid.	Lump.
Gastric ulcer ...	17	8	4	6	—
Duodenal ulcer ...	14	2	—	4	—
Carcinoma ...	10	2	2	7	9
Non-ulcers ...	11	2	—	—	2

7. Appetite and Loss of Weight.

Appetite is so capricious that loss of weight is a more reliable index of the patient's general condition. Macbeth's dictum, "Now, good digestion wait on appetite, and health on both," would be qualified in these more scientific days by saying that good digestion depended more on the free hydrochloric acid in the gastric juice. Thus we find that where the acid is high the appetite is good; where it is low the appetite is poor, as also with the onset of complications. Cæsar, quite apart from his mistrust, may have had in his mind the dyspeptic type when he said:

"Let me have men about me that are fat: . . .
Yond' Cassius has a lean and hungry look."

The majority of these patients are certainly of the lean type, and many of them are afraid to eat. That this is so, the following average loss of weight shows:

Gastric ulcer	1 st. in 9 months.
Duodenal ulcer	1 st. in 21.5 "
Carcinoma	1 st. in 5 "
Non-ulcers	1 st. in 8 "

8. Teeth.

The occurrence of septic teeth as a focus of infection is a diminishing factor, even in the hospital type of patient, since the general public and the medical profession are becoming increasingly alive to its consequences. There is thus little justification for it ever being overlooked in the class of case under consideration. The dental examination should not be confined to septic gums or teeth, but should include radiography of the roots for hidden apical abscesses. At this point the tonsils and accessory sinuses should also receive attention.

9. Constipation.

Constipation *per se* as a symptom of ulcer does not exist, unless there is an organic delay, or an association with some cause of stasis in the lower alimentary tract. That patients frequently suffer from constipation must be regarded more as a direct result of the habitual taking of bismuth.

10. X Rays.

I consider the x-ray examination of the patient after the administration of an opaque barium meal to be the most accurate means of investigation, when performed by an expert radiologist; and it must be remembered that evidence is often obtained by screen examinations which is not always recorded on the films. In unskilled hands the results are often useless and misleading.

Walton estimates that in gastric ulcer the results are correct in 90 to 95 per cent. of cases. In duodenal ulcers this standard is not so high, and the early cases of growth are difficult to distinguish from ulcer. The evidence is either direct or indirect. The classical direct evidence is an ulcer crater on the lesser curve filled with barium, the so-called niche, with a notch on the greater curvature opposite it, or a filling defect, an hour-glass stomach, an obvious delay, or an irregular duodenal cap. With indirect evidence we find such signs as rapid emptying, active peristalsis, spasm, and local tenderness to pressure. Occasionally the evidence may be misleading, the symptoms being due to conditions other than ulcer.

In all the cases under consideration the x-ray reports or films have been checked by the operative findings.

(a) *Gastric Ulcer.*—In this series there were 36 cases, of which the diagnosis was correct in 29—an average of 83 per cent. Of the 7 wrong, 3 were posterior ulcers, 2 being diagnosed as caecal stasis; 1, thought to be a lesser curve ulcer with delay, was a pyloric diverticulum; 1 diagnosed as duodenal ulcer was found to be pyloric; in 1 there was no evidence of ulcer; a recent ulcer had perforated and then healed; 1 showed rapid exit of food for a lesser curve ulcer with severe hæmorrhage. The chief difficulty in diagnosis is, therefore, the posterior ulcer, and it is probable that with the improved technique of taking photographs obliquely or laterally in order to silhouette the posterior wall of the stomach, more of these ulcers will be demonstrated.

(b) *Duodenal Ulcer.*—The evidence is less precise in the case of the x-ray reports of duodenal ulcer. Rapid emptying and peristalsis, the classical textbook syndrome, do not figure so prominently as do delay, irregular cap, no cap, or a combination of delay with abnormalities of the cap. Out of 20 cases, 14 were correct—an average of 70 per cent.

(c) *Carcinoma.*—Of 18 cases of carcinoma, 12 were correct and 6 wrong—a percentage of 66. Of the 6 wrong, 4 showed no definite deformity; 1 showed duodenal obstruction; 1 showed duodenal ulcer. It is not uncommon for duodenal lesions to be confused with those of growth.

(d) *Non-Ulcers.*—It is of more interest to study those cases in which the x rays showed some evidence of an organic lesion which was not confirmed operatively. It is impossible to classify these, so I give the results *seriatim*.

	X-Ray Examination.	Operation.	Test Meal.
S. M.	Seven hours' delay and caecal stasis	Appendicectomy and Lane's kink	
W. L.	Rapid exit (? gastric or duodenal ulcer)	Appendicectomy and Lane's kink	Ulcer.
S. C.	Duodenal ulcer	Appendicectomy and adhesions	
H. D.	Duodenal ulcer	Appendicectomy and visceropexia	
W. B.	Hypertonic and irritable stomach	Appendicectomy and adhesions	Ulcer.
N. C.	Abnormal pylorus (? ulcer)	Appendicectomy and adhesions to gall bladder	
M. S.	? Lesser curve ulcer	Adhesions; post-gastro-enterostomy	
F. C.	—	Appendicectomy and adhesions	Ulcer.
W. R.	Eight hours' delay; tender pylorus	Appendicectomy and nodule on pylorus	Ulcer.
S. W.	Lesser curve crater and spasm	Nothing found	
E. W.	Hour-glass	Gall stones and band across stomach to splenic flexure	
J. C.	Seven hours' delay; low dilated	Gall stones and tubercle of ileum	
R. J.	Filling defect; seven hours' delay	Hypertrophic tubercle of ileum with omental band fixed in pelvis	
M. F.	Big ulcer on greater curve	Gastrostaxis	Low.

GASTRIC ANALYSIS.

The diagnosis of gastric lesions by means of the fractional test meal alone is apt to be misleading, but it often gives very valuable corroborative evidence. This is due to the fact that the acidity is subject to a wide range of variation. Ryle and Bennett, in a study of 100 healthy students, found this variation of free hydrochloric acid in the majority of normal stomachs. In those cases where there is any doubt in the diagnosis or a conflict of other evidence, the test meal may be very useful in coming to a conclusion, more especially in cases of duodenal ulcer and carcinoma. In about 75 per cent. of these cases curves are obtained which conform to a fairly uniform standard. In duodenal ulcer the acid content is high, and the feature of the maintenance of its secretion after the second hour is characteristic. In carcinoma there is little or no free hydrochloric acid present. This low type of curve, however, may be found with the anæmias, gall stones, visceropexia, and achlorhydria gastrica.

The curves in gastric ulcer are most variable. Here the acid rises quickly after the meal, but is not continued as in duodenal ulcer. In the majority of cases the acid is increased, but it may be normal, or even low. Curves similar to this group are sometimes found associated with chronic appendicitis, with or without adhesions, a Lane's kink, and occasionally cases of carcinoma will retain their ulcer acidity.

In pyloric stenosis there is a wide disproportion between the free and total acids, the latter being high as a result of fermentation processes.

OPERATIVE TREATMENT.

When a chronic ulcer fails to heal after continued medical treatment, surgical treatment becomes necessary. The operation of gastro-enterostomy has been most frequently practised for this condition. This procedure has a mechanical purpose, the anastomosis enabling the stomach to be more readily drained, and a physiological value, the acidity of the stomach becoming slowly neutralized by the alkaline bile, and the secretions of the pancreas and small intestine. The rest afforded to the ulcer by these means permits it to heal, and, it is said, delays the onset of malignancy. In cases of pyloric stenosis, for which the operation was primarily designed, the results are excellent; and in cases where the ulcer is distal to the anastomosis the results are good. Unfortunately it has been allowed to fall into disrepute through being performed for other conditions which do not warrant it.

Various methods have been practised from time to time which are directed against the ulcer itself, and these should be combined with gastro-enterostomy. They consist

in infolding of the ulcer, excision, or destruction by means of the cautery. This line of attack should be pursued in all cases of haemorrhage. In America Balfour excises the ulcer by means of a diathermy knife, and this destruction of the ulcer is an additional safeguard in forestalling the onset of malignant change. More recently a bolder technique has been employed in the form of partial gastrectomy; the ulcer-bearing portion of the stomach is removed, and the remainder united to the jejunum. This method is particularly advocated by Sir Berkeley Moynihan and the Mayo brothers. Other operations have been devised to meet special contingencies, and many modifications of the technique have been suggested, into the details of which I do not propose to enter.

In dealing with the grosser complications, such as hour-glass stomach and adhesion of the ulcer to the pancreas and to the surrounding structures, no hard-and-fast lines can be laid down. Most of these patients, whose general condition is very poor indeed, have to be treated according to their special requirements, and the ingenuity as well as the finer sense of judgement of the surgeon may be taxed to their utmost limits. Finally, every operation should include a thorough exploration of the abdominal cavity, especially of the gall bladder and appendix, for it is useless to operate on an ulcer and leave such a focus of infection untreated.

Operative Findings.

There were 22 cases of ulcer of the lesser curve of the stomach. Of these, 2 were kissing ulcers, 2 were associated with duodenal ulcers, 4 were posterior, and 2 were hour-glass.

There were 23 cases of pyloric ulcer. Of these, 3 were posterior, 4 were multiple, 3 were pyloro-duodenal, 3 were adherent, and 5 were associated with stenosis.

There was one case of jejunal ulcer; this was due to a silk stitch.

BRIEF REPORTS OF CASES.

Case 1.—C. S. for some years had had intermittent attacks of epigastric pain radiating to the back; it was of a drawing or burning character, and came on one to two hours after food; it was relieved by bismuth. The appetite was good, but the patient was afraid to eat; had lost 8 lb. in four months. There was tenderness over the epigastrium. X-ray examination suggested pyloric ulcer. Test meal showed delayed secretion for one hour, then hyperchlorhydria. At operation an ulcer was found just beyond the pylorus.

Case 2.—Mrs. F. C., aged 60, had suffered from indigestion for fifteen years. Immediately after food there was an intermittent heavy feeling in the epigastrium which radiated to the right iliac fossa; it was relieved by vomiting and hot drinks. Haematemesis had occurred on several occasions. The appetite was poor, and the general condition feeble; she had lost 4 st. in the last few years. X-ray examination revealed an hour-glass stomach. At operation a chronic ulcer was found on the lesser curve; sleeve resection was performed. (See Plate, Fig. 1.)

Case 3.—T. G., aged 63, for twelve months had had a gnawing pain three hours after food; it was relieved by taking food. The patient was awakened between 2 and 3 in the morning, and had been much worse in the nine weeks previous to seeking advice. Vomiting sometimes accompanied the pain. The appetite was good; there had been slight loss of weight; splash. X-ray

examination: seven hours' delay; ulcer crater on lesser curve; notch on greater curve. Operation, partial gastrectomy, revealed an ulcer on the lesser curve and a coexisting ulcer on the anterior inferior portion of the first part of the duodenum. The history suggested duodenal ulcer, but the x rays showed only gastric ulcer. (See Plate, Fig. 2.)

Case 4.—R. J., male, aged 57, had for two years had dull aching pain across the epigastrium and colicky pain across the lower abdomen. The pain came on two hours after food and was relieved by vomiting. The vomitus resembled coffee-ground. He was afraid to eat, and had lost half a stone in three months. There was general tenderness over the abdomen. The x rays showed a filling defect of the stomach, with seven hours' delay. A test meal was not estimated owing to the presence of bile in each specimen. Operation showed that the filling defect was caused by a rolled up piece of omentum fixed to the pelvis and dragging on the stomach; the ileum and mesenteric glands were tuberculous. (See Plate, Fig. 3.)

(a)

(b)

(c)

Typical Test Meal Curves: (a) Duodenal ulcer; (b) gastric ulcer (no radiographic signs); (c) carcinoma of greater curvature.

Case 5.—E. A., male, aged 51, complained of pain of a tingling and later of a boring character localized to the left epigastrium and radiating downwards; it was relieved by various means. For the past twelve months it had come on once in every twenty-four hours, and he had induced vomiting to relieve it. His appetite was good, but he had lost 2 st. in three months. X rays revealed a typical lesser curve ulcer. The test meal showed very low acidity. At operation a large chronic ulcer was found high up on the lesser curve. (See Plate, Fig. 4.)

Case 6.—J. F., a woman aged 40, had for seven years had intermittent attacks of pain, lasting about a fortnight, with intervals of freedom lasting for several months. Pain of a sharp nature coming on half an hour after food, and aggravated by food, was relieved by vomiting; the pain extended to the shoulders. She had lost a good deal of weight; there was resistance in the epigastrium, and rigidity. Occult blood was present. X rays showed a stomach of small capacity; over seven hours' delay; large filling defect of pyloric antrum. Inoperable carcinoma. (See Plate, Fig. 5.)

Case 7.—Mrs. F., aged 53, for two years had had constant dull aching epigastric pain conducted to the back; it was increased by taking food and relieved by medicine. There was almost daily vomiting after food. The appetite was poor, and she had lost a stone in six months. She was anaemic and wasted, and had enlarged glands in the axilla and groin. A blood count showed lymphatic leukaemia. X-ray examination suggested an ulcer on the lesser curve. A test meal showed hypochlorhydria (see chart). At operation (lesser curve ulcer), posterior gastro-enterostomy, an indurated mass was found in the caecum. Microscopy of appendix—lymphatic leukaemia. (See Plate, Fig. 6.)

Note.—Many of these cases were collected while I was surgical registrar, and I am indebted to the surgical staff, especially Mr. H. S. Clogg, for their kind permission to publish them. Also to Dr. Russell Reynolds and Dr. S. Cochrane Shanks for their willing co-operation in the radiological examination, and to Mr. Jocelyn Patterson for the test meal results.

METHOD OF TREATING ASTHMA BY RADIATION.

(Preliminary Note.)

BY

S. GILBERT SCOTT, M.R.C.S., L.R.C.P.,

D.M.R.E.CAMB.,

RADIOLOGIST TO THE LONDON HOSPITAL.

THE amount of medical literature on the subject of asthma, and the number of methods of cure advocated from time to time, illustrate the humiliating fact that little is known of its pathology, and that no satisfactory line of treatment has been discovered. There are patients who pin their faith to one pet drug, which they hold in reserve, as they have found from experience that it gives some temporary relief of their distressing symptoms; others ever ready to try any new remedy; and lastly, those who have given up all remedies and simply "grin and bear it."

Let me state at once that I have no new theories as to the causation of asthma, but the results obtained from the

method about to be described lead me to believe that the primary cause will eventually be found to be metabolic, with or without some local irritation reflex.

As treatment by radiation is not based on any theory, it may be asked how the beneficial effects came to light. My attention was accidentally drawn to them some years ago while treating patients for carcinoma of the breast by a new method of application of x rays. Realizing that in malignant disease, unless efforts were made to prevent the formation of metastases, the patient would reap little benefit by concentrating on destruction of the primary growth, the question arose whether the patient could stand an efficient radiation over a large area, for the whole trunk at least would have to be covered. I therefore devised an apparatus, which was installed at the London Hospital, by means of which it was possible to subject the patient to what was, practically speaking, an x -ray bath. It was found that the dose could be administered up to certain limits without bad effects. Full details of this method were published in the *BRITISH MEDICAL JOURNAL* in 1921 (vol. i, p. 771). To explain its application to the treatment of asthma it will suffice to say that its essential details are a radiation field large enough to embrace the whole trunk, and the use of one tube in front and one at the back, both energized at the same time, followed by radiation in the same way from side to side. The results obtained in cases of breast carcinoma have been very gratifying, but do not concern me here. I intend to publish a report on them shortly.

Among the patients being treated in this way for malignant disease were some suffering from chronic bronchitis. Many of them volunteered the information that the treatment eased their breathing. Little notice of this was taken until one day a female patient became very profuse in her thanks, and insisted that the treatment had completely cured her asthma, to which she had been a martyr for some fifteen years. This aroused my interest, and I set about getting together some true asthmatic patients in order to test the method; this was slow work, but it was evident after the first few cases that radiation possessed some very definite influence on the disease. Beneficial results were experienced within a few hours of the first treatment—increased expectoration and decrease in the "tightness" of the chest.

So many organs and tissues are included in the radiation field by this method that it was impossible to suggest off-hand which organ or tissue was directly affected; radiation might be influencing the secretion of the ductless glands, or it might be setting up some complex influence on the spleen.

I have said enough to make it clear that I believe the influence of radiation on asthma to be complex, that it is not a direct influence on lung tissue, but some profound indirect or secondary change affecting the whole body. The patient, however, is naturally more interested in the practical results than with theories about them.

Technique.

Technique has been slightly modified from time to time. Experience with increasing numbers, however, has established certain factors.

(a) *Small Dosage.*—Originally the dose administered was the same as that for carcinoma of the breast—that is, 20 X through 4 mm. of aluminium measured on the skin, with 25 mm. spark-gap. This was found to be the maximum or tolerance dose. A certain amount of nausea and sickness usually followed, but this I considered unavoidable when patients were undergoing treatment for so serious a disease as cancer; but the question arose whether this disturbance was necessary in asthma. I reduced the dose gradually, and was surprised to find that half that originally used—namely, 10 X through 3 mm. aluminium—gave as good results in asthma, and did not cause any general disturbance.

(b) *Low Voltage.*—The large radiation area necessary, the general upset and risk of damage to deep structures, rendered high voltage undesirable.

(c) *Large Radiation Field.*—The necessity for the field to include practically the whole trunk must be emphasized, for I have demonstrated that radiation of the thorax alone does not give the results. I am not yet certain that there

is any special benefit in radiating with two tubes at once—one in front and one at the back—but it certainly saves time.

This dual dose of 10 X through 3 mm. of aluminium measured on the skin is administered once a week to the average case—twice a week if the case is severe. After the fourth dose an interval of two weeks is allowed, then it is repeated once a month for four months; after that the patient is instructed to come up as soon as any wheezing or "tightness" of the chest is noticed, when a further dose is given.

A general history of the case should be taken, and should embrace the family history; asthma is frequently found in other members. The type of patient and type of chest are noted, and a general radiological examination of the thorax made. Practically all cases so far examined have had a definite fibrosis of the roots of the lungs, but whether this is the cause or effect is doubtful.

Immediate Effects.

The immediate effects are experienced within a few hours of the treatment. The patients state that relief of the "tightness of the chest" is the first thing they notice. This is followed in twenty-four hours by an increase in phlegm. With the small dosage now used no nausea is experienced. So far all patients treated have obtained very definite relief and no bad attacks have occurred, but no doubt failures will occur as the numbers increase. No blood changes have been noted. A general improvement in the patient's condition is apparent. A definite increase in weight in most cases is an interesting secondary effect noted. A few of the earlier cases—those receiving the heavier dosage—developed what they described as attacks of acute bronchitis after the first course of treatment, but without any signs of asthma. I do not know whether this is to be looked upon as mere chance, or whether the heavier radiation was in some way responsible for the attacks. High voltage radiation is known to give rise occasionally to some form of fibrosis of the lung, but this is usually a gradual process, and not acute as in these cases. The fact that the later patients—those on the reduced dosage—have not experienced this complication rather strengthens the supposition that radiation had something to do with its production.

Later Results.

Of the twenty-one cases of chronic asthma of various types so far treated by radiation over a period of two and a half years, all except the two youngest had tried every form of treatment with little or no effect, and had given up all. As previously mentioned, all obtained relief of their symptoms, although the number of treatments necessary to get rid of the wheezing varied. The nearest approach to failure was with a patient of great size—he weighed about 19 st.—with a thorax like a barrel. I have heard from him recently that his asthma has greatly improved.

The youngest patient, aged 4 years, responded to an even smaller dose than that already mentioned.

Two sisters—martyrs to asthma for twenty and twenty-two years respectively—who had given up all work for many years as they expected to be in bed six to eight months in the year, made an immediate response. They have put on weight rapidly, and have once again resumed normal life.

A few weeks ago an ex-police constable was sent to the London Hospital. He had been discharged from the force as incurable. Cyanosed, painfully dyspnoeic, he presented a pitiful spectacle. His appearance a week after the first radiation was remarkable, for his colour and breathing were to all appearance normal. He is still under treatment, and it is hoped eventually to get him well enough to resume his duties.

A boy, aged 12, subject to hay fever, which apparently acted as the irritant factor to his asthma, had undergone various forms of treatment with no benefit. His worst time was during the summer months. He has so far had no attacks of hay fever or asthma, but as treatment was only commenced at the end of last summer the efficiency of radiation has yet to be put to the test.

These cases have been quoted to give some idea of the type so far treated.

It has been possible to keep in touch with practically all those treated up to date, as the majority of them are so afraid of becoming chronic invalids again that they readily carry out instructions and report themselves regularly.

I wish it to be clearly understood that what I have here written is but a brief summary of beneficial effects so far obtained in asthma by means of radiation applied in a manner not usually adopted. The number of cases so far treated (21) is too small and the time too short for any statement as to the permanency or true efficiency of the method to be made. It is hoped, however, that those who have access to a larger number of patients will give it a trial, so that a true valuation may be reached.

So far radiation applied as described has proved a valuable palliative agent; time will indicate its true curative value. Radiation attacks this distressing complaint from an entirely new angle, and while at present it is not based on any theory more light may be thrown on the cause if we eventually find out what influence small radiation doses over a large body area have on general metabolism.

Radiation, of course, has been tried before in asthma, and the results reported have on the whole been disappointing. Ramirez and Cole come to the conclusion that radiation offers no particular advantage over other methods, but that definite effects noted in some of their cases would indicate that a modification of technique might yield a more encouraging result. I believe the fault in the methods so far tried lies in the limited radiation field—that is, the lungs alone are looked upon as the site of the trouble. This, combined with overdosage, accounts for the poor results.

This preliminary note may encourage others to give the method a trial, but careful attention to essential details is necessary.

HAEMATOMA IN THE ABDOMINAL WALL SIMULATING PELVIC NEW GROWTH.*

BY

W. E. FOTHERGILL, M.D.,

PROFESSOR OF CLINICAL OBSTETRICS AND GYNAECOLOGY, VICTORIA UNIVERSITY, AND SURGEON TO ST. MARY'S HOSPITALS FOR WOMEN, MANCHESTER.

HAEMATOMATA in the lower part of the abdominal wall sometimes present such close resemblances to tumours of pelvic origin that very nice diagnostic problems may arise. Cuthbertson¹ has recently collected forty-one cases in women of which no fewer than twelve were diagnosed as ovarian cysts and ectopic gestation. In only three of the forty-one cases was the haematoma recognized before operation, while in two others it was suspected. Thus the recognition of this condition is clearly a matter of some difficulty, and one which has points of special interest for those who deal with the diseases of women. This is illustrated by a recent case.

A lady, aged 57, was quite well until she had a day of severe abdominal pain. She sent for Dr. Bennett of Hyde, who found a considerable swelling rising above the pubes on the right side. The pain subsided under treatment; but, two days later, diffuse black bruises appeared upon the surface of the lower abdomen. When I saw her during the following week there was a discoloured area, measuring about eight inches by four, containing many patches of subcutaneous haemorrhage. There was a rounded swelling above the pubes, mainly to the right of the mid-line. It resembled a four and a half months pregnant uterus in shape and size, but was more like a fibroid in consistency. The cervix was pushed forward by a cystic swelling, which could be felt in the pouch of Douglas. Thus the physical signs suggested the presence of a fibroid above and an ovarian cyst below. But when the patient was asked to sit up, and so brought the recti into contraction, the swelling above the pubes could still be felt, and it became quite fixed. This showed that it was really in the abdominal wall. The sudden onset of pain accompanied by the appearance of the lump and followed by the extravasation of

blood under the skin indicated that rupture of some fibres of the right rectus had occurred. The diagnosis, therefore, was haematoma of the abdominal wall, together with ovarian cyst in the pouch of Douglas.

The abdomen was opened through blood-stained tissues to the left of the swelling, the linea alba being displaced towards that side. A simple cyst of the left ovary was then removed. The uterus and right tube and ovary were normal. The appendix was removed, as it was involved with a portion of omentum, which was adherent near the internal abdominal ring. The haematoma lay within the right rectus, with a thick layer of muscle over it. The mass of blood clot projected into the abdominal cavity, with a thin layer of muscle and the peritoneum under it. The clot was turned out through a cut in the edge of the muscle. The wound was then closed in the usual way, a strip of gauze being left in the cavity of the haematoma for one day. Healing occurred quickly.

I once saw a case in which someone had diagnosed ovarian tumour in the absence of the patient's usual medical adviser, Dr. Robertson, then of Rawtenstall.

The patient was a stout, healthy woman, past the menopause, and she told us that the pain and swelling dated from a fall over a clothes-basket, which hurt her very much, but did not prevent her from finishing her washing. The right lower abdomen was quite dull and solid, as if the right iliac fossa was filled by a mass which rose above the umbilicus and crossed the middle line. The mass could still be felt, and became fixed when the patient sat up, and this sign, with the history of the fall, gave the diagnosis of haematoma. Expectant treatment was employed.

Later there was some constitutional disturbance, and the mass became softer. When I saw the patient again the physical signs were those of a large cyst adherent to the abdominal wall, and it was clear that the blood-clot had become infected and liquefied. An incision through the right rectus liberated a great quantity of chocolate-coloured pus mixed with blood-clot which had been distending a cavity walled in front by the rectus and separated from the abdominal cavity by peritoneum below and by peritoneum and the sheath of the rectus above.

I subsequently saw a similar case, and, in the light of previous experience, recognized it as an infected and liquefied haematoma, and arranged for the patient's admission to hospital. When she came in the lapse of time had introduced a new and disconcerting feature which rather shook the diagnosis, for the swelling, previously cystic, was now tympanitic. I remember the horror of some of those present when I incised this resonant area, and their relief when a blast of foul gas was followed by a gush of chocolate-pudding pus.

I once watched an operation after a very sporting diagnosis had been made—namely, myoma of the round ligament. The outcome was that the surgeon struck pus before he had cut through the abdominal wall. No doubt when he examined the patient the mass felt solid and closely resembled a fibroid. Infection and liquefaction must have occurred in the time that elapsed between the making of the diagnosis and the operation.

Infection does not always occur. Dr. J. W. Stenhouse had a patient, a healthy elderly lady, with a firm fixed swelling above Poupart's ligament which appeared suddenly with pain. We concluded that this was a haematoma, and it disappeared entirely in the course of a few weeks. When I was house-surgeon to the late Sir A. R. Simpson two students brought their old landlady to see him in the Buchanan ward of the Edinburgh Royal Infirmary. She thought she had strained herself while leaning out to clean a window. There was a lateral solid mass which seemed to rise out of the left iliac fossa and to be attached to the iliac bone. Simpson did not consider it suitable for operative treatment. He told us to strap her well up with strips of belladonna plaster. This gave her much comfort, and after a time she came back saying the plaster was too loose. It was renewed, and this happened two or three times. In the end the lump disappeared. These two cases stand out in my memory as the only disappearances of considerable lumps other than inflammatory deposits which I have personally observed. I believe they were both haematomas, though this was not proved by incision in either case.

As to the general aspects of the condition but little has been written; it is hardly mentioned in some textbooks and is treated briefly in others. Numerous cases have been recorded in the medical journals, most of which would seem to be the results of strains and accidents in men of active habits—cavalry soldiers, acrobats, and others whose occupation or sport demands violent effort. In women, on the other hand, the lesion occurs, apart from obvious

* Read before the North of England Obstetrical and Gynaecological Society, April 16th, 1926.

trauma, in those of middle or advanced age. It is sometimes associated with coughing or vomiting. In the cases I have mentioned the patients were all past the menopause. There was a history of a fall in one case and of a strain in another. Out of Cuthbertson's¹ forty-one cases, thirteen were over 50 years of age; seven were between 40 and 50; six were under 40. Twelve of the patients were pregnant or had recently been delivered.

Haematomata which simulate pelvic growths are below the umbilicus, and are thus due to the rupture of muscular branches of the deep epigastric artery. Being impressed by the marked lateral extension of the swelling in these cases I consulted Professor Stopford on the point. He says that if the haemorrhage occurs below the fold of Douglas, owing to the formation of the sheath of the rectus at that level, there is nothing to prevent the lateral extravasation of blood deep to the aponeurosis of the oblique muscles. This explains the relatively limited character of haematomata higher up in the rectus muscles. The extravasation of blood cannot cross the linea alba, but the swelling can extend beyond the middle line by pushing the linea alba over toward the sound side of the body.

The most interesting thing about these cases is the diagnosis. The patient complains of pain and the medical man finds the swelling. The trouble is that he seldom knows how long the swelling has been present; for patients frequently have masses of various kinds in the pelvis or abdomen whose presence is not suspected until they complain of pain and submit to examination. The main point is the recognition that these swellings are part and parcel of the abdominal wall. This is generally made by noting that they can still be felt when the recti are in action, and that they become fixed as the muscles contract. Another point is that, when a mass in the abdominal wall is not too large, a resonant note may be obtained right through it by deep percussion. But these signs are not infallible, for a mass within the abdomen that has become adherent to the wall gives the same signs as one which is a part of the wall. Even physical signs can tell lies, and must be checked.

This point decided, the next question is, What other swellings may be found in the wall of the abdomen? My first employment after qualification was to do duty for the house-surgeon of a hospital in a country town. He called my attention to a girl with a so-called ovarian cyst who was being prepared for operation next morning. The girl told us that the swelling was there sometimes, but not always. It was cystic, in the mid-line, and reached just to the umbilicus. It was still felt, and was fixed when the recti were in contraction. Being very young then, and full of book learning, I suggested that it might be a cyst of the urachus communicating with the bladder. Strange to say, it was, and we massaged the contents into the bladder and drew it off with a catheter.

A girl, aged 13, was brought to the Northern Hospital, Manchester, with a swelling above the pubes, which was part of the abdominal wall. The mother had been told that it was a pregnant uterus, and, when assured that this was not the case, she took the child away. But, later, the patient reached the Children's Hospital at Pendlebury, where the late Mr. Joseph Collier opened an abscess and found in the centre of it a rusty needle.

The commonest swellings in the abdominal wall are new growths—namely, those masses of spindle-celled tissue called desmoids. They are generally single, but I have seen three in the recti of one patient. Slow-growing and painless, they are easily recognized. They were frequently excised formerly, but they yield to treatment by irradiation in most cases.

Another new growth in the abdominal wall was seen in a patient from whom I had removed an ovarian cyst-adenoma six years previously. She came back saying she had another tumour upon which her corsets pressed uncomfortably when she sat down. It was a solid encapsuled mass under the scar of the former operation, and, on section, its structure was that of the solid portions of a cystadenoma.

Thus, before completing the diagnosis of a haematoma, it is necessary to exclude new growths, inflammatory masses, developmental errors; for they can all produce swellings

in the abdominal wall which simulate tumours of pelvic origin. As to treatment, a small haematoma in this position may doubtless be left alone. But should we wait for the larger ones to become infected before opening and emptying them? I think not. If the mass of blood-clot is of considerable size the patient will be sound and well again much sooner under active surgical than under an expectant treatment.

RECTAL ANAESTHESIA.

BY

ROBERT B. COLEMAN, M.B., CH.B.,
MEDICAL OFFICER, C.M.S. HOSPITAL, OLD CAIRO.

FROM the course of the correspondence on rectal anaesthesia appearing in the BRITISH MEDICAL JOURNAL during the last few months it appears that few surgeons practise it, and from communications received by me it would seem that some failures have been encountered. Such failures must, I think, be due to faulty method of administration, and it may probably be useful to describe that used at the C.M.S. Hospital at Cairo, where it has invariably proved perfectly safe. It has been the routine method since I first saw it used by Dr. Stiven at the Government Hospital, Port Said.

We confine it almost entirely to operations on the head, neck, chest, or upper extremity. Spinal anaesthesia by stovaine, which we find so eminently satisfactory, with an experience of nearly 8,000 cases, as described in the JOURNAL of March 21st, 1925, is our routine procedure for all operations up to the costal margin. Naturally, however, the ether method can be used for most operations.

The mixture used is three parts of ether to one part of olive oil, and the amount given is regulated by the weight of the patient, the allowance being one ounce of the mixture for every 20 lb. body weight. In actual practice we find this estimate is rather on the conservative side, and in cases requiring more perfect anaesthesia we often order a small quantity in excess of this, up to half an ounce for an average adult. We consider that about eight ounces is a maximum dose; this means six ounces of ether.

The anaesthetic is given to the patient in the bed, but some care is necessary in choosing a suitable room. The ideal condition is to have a small private ward, the windows of which can be darkened by shutters or blinds. It should be in a quiet place, and if possible not too far from the theatre, and preferably on the same floor, to avoid disturbing the patient by lift or stairs. If given in a general ward this should be darkened and quietened if possible, and screens kept round the bed. The stretcher and the macintoshes, etc., are put under the patient previously, so that he may be moved to trolley or carried without risk of waking.

An enema and rectal washout having been given some hours previously morphine with atropine is injected hypodermically an hour and three-quarters before the time fixed for the operation; fifteen minutes later administration of the mixture is commenced.

The mixture, slightly warmed, is run into the rectum high up by a catheter attached to a tube and glass funnel, which should not be raised to any appreciable height. All the apparatus should be well warmed before use to avoid cooling of the mixture. It is important that this should be given slowly, and it is reckoned that the administration should take twenty to thirty minutes. This is by no means always an easy matter, especially as sometimes the patient attempts to strain and return it, but with patience and tact it can generally be accomplished. It is found to facilitate the giving of the whole dose if it is preceded and followed by just a little olive oil. The administration can safely be entrusted to a competent sister, nurse, or orderly. At the completion the catheter is clipped, and great care is taken to withdraw it gradually, so as not to excite straining. A damp cloth is put over the patient's face to prevent excessive evaporation, and he is allowed to lie quietly till required for the theatre. With the above

timing the administration should be completed an hour before he is removed to the theatre, which must be done as noiselessly and as smoothly as possible.

In the great majority of cases nothing more is needed. The surgeon finds the anaesthesia very satisfactory, and it lasts for several hours if need be. Often there is a little corneal reflex, but in these cases, beyond perhaps a light movement on the part of the patient when the first incision is made, usually there is no further difficulty. In a few cases it is found necessary to give just a small amount of general anaesthetic on an open mask at the commencement of the operation. This would naturally be either in most countries, but in this climate we seldom use ether for general anaesthesia, preferring chloroform, which is remarkably safe here. A few drops are usually sufficient, and then it can be discontinued.

At the end of the operation, before the patient leaves the theatre, a rectal speculum is passed and the excess of the mixture run out, and, immediately on return to the ward, very thorough and repeated washing out of the rectum and colour is carried out, and finally saline solution is left in. This cleansing of the rectum is very important, and should not be delayed. Probably neglect of this point has been responsible for the report of gangrene of the rectum which is stated to have occurred in some hospitals. We have never seen rectal complications in any case. Our patients have been of both sexes, and we have used the method in quite a number of children from about 8 years upwards, who take it very well. The cases have included goitre, glands of neck or axilla, mastoid operation, malignant disease of tongue, lip, upper and lower jaw, plastic operations on

nose, face, or ear, amputation of breast, operations on arm, and plating fractures.

It is not our custom to use the method for very small operations, in order to avoid the extra work for the ward staff. One great advantage of spinal anaesthesia for operations below the costal margin is the saving of time in the theatre and lessening the work afterwards in the ward. Rectal anaesthesia means considerably more work in the ward, both before and after.

The advantages of the method are marked both for the patient and for the surgeon. Those for the patient include the absence of apprehension and absence of coughing, straining, and vomiting, both at the operation and afterwards. For the surgeon it is a tremendous advantage to have a clear field in head and neck operations, when so often the anaesthetist is much in the way. In operations on the neck the face can be covered up at the start and not uncovered again. In operations on the nose and mouth the naso-pharynx can be well plugged with a stout tube for respiration through the middle of the plug, and there need be no time lost in continually mopping out the blood or anxiety in keeping the airway open. Also the surgeon has plenty of time. This might possibly be a doubtful advantage if it tended to make the surgeon slow in his work—never a good thing for the patient—but it is a great boon in some ticklish plastic operations on the face. The only real disadvantage is the extra work on the ward staff and the preliminary time involved, as described above.

My colleagues, Mr. F. O. Lasbrey and Mr. J. E. Bateman, are equal advocates of the method with myself.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

SEROUS MENINGITIS: REPEATED LUMBAR PUNCTURE: RECOVERY.

THE following case, recently under my care, seems of sufficient interest to warrant publication.

The patient, a boy aged 9 years, was first seen on March 18th. There was a history of a rash resembling measles four days before (a sister developed typical measles the following week), and on March 17th the child complained of pain in the back of the neck, though he was playing as usual all day. When seen on March 18th he was unconscious and breathing stertorously, all reflexes were abolished, the plantar response being dorsiflexion, the pupils widely dilated, and urine and faeces passed involuntarily. There was very slight rigidity of the back and neck muscles and at times there was nystagmus of a slow rotatory type. There was some bronchitis. The temperature was 103°; the pulse (100) varied greatly in quality, at times being full and strong, at others weak and thready. The urine was normal.

Next day the coma seemed deeper, and there was definite rigidity of the neck. There was no vomiting and the optic discs appeared normal. After lumbar puncture the child could be roused by strong stimuli. Next afternoon he was seen by Dr. Beaumont of Wimpole Street, who removed about 5 ounces of perfectly clear cerebro-spinal fluid under enormous pressure. He showed this to be sterile, and cells

improved for thirty-six hours, but on March 22nd he was again deeply comatose, and the chest full of moist rales; he was apparently drowning in his own secretions; 2 ounces of cerebro-spinal fluid were removed, still under increased pressure, and after the child had been fed by stomach tube he was placed on his face for the rest of the day with the foot of the bed raised; a considerable quantity of mucus drained away from the lungs. The next day the breathing was much easier and he could be roused, but as there was still great rigidity of the neck another ounce of cerebro-spinal fluid was removed, and immediately he was able to swallow for the first time for six days. The improvement was maintained, and the next day, when the last lumbar puncture was done (half an ounce being removed), he showed resistance. Convalescence was rapid, but he became so irritable and restless that three days later he was transferred to a nursing home, from which he was discharged quite well a week later. As there was a vague history of a possible fracture-dislocation of the cervical region of the spine three years previously he was x-rayed, but nothing abnormal was found. He has remained perfectly well since. The case seems to have been one of serous and not tuberculous meningitis, as we provisionally diagnosed.

Peacehaven.

DOROTHY M. ANDERSON, M.D., D.P.H.

TREATMENT OF YAWS BY NOVARSENOBILLON.

DURING the past year, when stationed in Nigeria, West Africa, where yaws abounds and also large ganglia on the hands, I have treated successfully many cases of yaws, some of them serious, with injections of novarsenobillon, and have been struck with the rapidity of recovery—generally in four or six days, and after one injection.

One patient had large ganglia on the back of the hand, and as the yaws disappeared so did the ganglia, and did not return. When I last saw him, ten months afterwards, there was no sign of either yaws or ganglia. Another case of ganglia on both hands without yaws received one injection and in less than a fortnight was completely relieved of both pain and swelling.

I have used this drug also in contracted tendons, and one patient, who had complete contraction of both knees and was quite unable to walk, recovered complete use of his legs and was doing his ordinary farming after two months. He received two injections.

ACUTE INTUSSUSCEPTION SUCCESSFULLY TREATED BY RECTAL INFLATION.

THE treatment of acute intussusception by inflation with air by the rectum receives such scant notice in any of the textbooks to which I have referred that it will be worth while to record the following case.

A male child, aged 9 months, perfectly healthy, was suddenly seized with acute pain and vomiting at 11 a.m. on April 2nd. I saw him at 12.30 p.m. He was evidently suffering from paroxysms of severe abdominal pain, as evidenced by the drawing up of his legs and loud screaming, at intervals of a few minutes; his colour was ashen, and he showed the ordinary symptoms of severe shock. The abdomen was quite soft, and he only showed signs of tenderness on palpating the right side; by the rectum nothing abnormal could be felt. Acute intussusception was considered to be the cause of the trouble. At 2 p.m. an anaesthetic was given, and a sausage-shaped tumour extending across the abdomen from the right side, above the umbilicus, could then be distinctly felt. With an ordinary Higginson syringe air was injected slowly into the rectum, until the abdomen was appreciably distended, care being taken to prevent the air escaping by the side of the nozzle of the syringe. The syringe was withdrawn, and a cigarette-holder, the nearest available and suitable article in the house, was inserted into the rectum, to allow of the escape of the air. On examining the abdomen after this had been done, no sign of a tumour could be felt. Half a pint of warm soap and water was now injected into the rectum, and

was returned accompanied by a quantity of blood and mucus. The child, on coming round from the anaesthetic, was apparently much easier and free from pain, and soon went off to sleep. There was no return of the pain or vomiting; a quantity of blood and mucus was passed during the next twenty-four hours, with some faecal matter, and by the end of the second day the baby was taking his usual feeds again.

This case serves to show the importance of administering an anaesthetic for the purpose of diagnosis in suspected acute abdominal conditions in infants and children, and also that in cases of acute intussusception, taken in hand sufficiently early, we have a simple and efficient means, especially in remote country districts, of treating a dangerous and often fatal condition, without resorting to a major surgical operation.

OCULAR MALFORMATION.

The following cases must be so extremely rare, I think, as to merit their being recorded.

A Tamil woman from a neighbouring rubber estate brought her three children to me to be treated for worms. The mother and a female child, aged 8 years, presented the following interesting ocular conditions. In both: (1) Both corneae were almond-shaped, with the long axis placed vertically. (2) The pupils were pear-shaped, apex downwards, situated eccentrically in the lower nasal quadrant of the cornea. The apex was at the periphery of the cornea at 7 o'clock in the left eye (5 o'clock in the right). The rest of the pupil lay along a line from this point towards the mid-point of the cornea, and extended about two-thirds of this distance. They were equal on each side.

(3) They did not react to light stimulus, either direct or consensual. (4) They reacted slightly and slowly with convergence (only noted in the mother's case). (5) They dilated well with mydriatics, retaining their pear shape. Vision was good, except in the case of the child's left eye, where it was somewhat impaired by a few small white opacities in the lens. Ophthalmoscopic examination revealed normal discs. I could not make out the macular regions definitely. The child's eyes were in a state of constant lateral nystagmus. Its intelligence seemed average.

A second child, aged 9 years, which was being carried in arms, was an emaciated and very undersized little girl, cyanotic and dyspnoeic, with well marked clubbing of the fingers. Examination revealed a congenital malformation of the heart. Her eyes were normal.

The third child, aged 6, a bright, intelligent boy, with normal eyes, and apparently normal in every way, completed a very interesting family.

No history or evidence of syphilis was obtained in the mother's case, and none of her children showed any of the usual stigmata of the congenital variety.

TWISTED OVARIAN PEDICLE IN A CHILD.

A girl, aged 4½ years, complained of severe pain in the lower part of the abdomen about 3 p.m. on April 4th, 1926. The pain came on at intervals and got worse. I saw her for the first time at 10 p.m. on the following day and made a diagnosis of an acute abdominal condition. She was taken to hospital that night and operated upon. At the operation a twisted ovarian cyst of the left side was found. The pedicle showed three turns clockwise. The ovarian cyst weighed 11 oz.

The child made an uneventful recovery and left hospital on April 24th.

J. MORRIS, M.B.

GANGRENE IN THE NEWBORN.

The article by Dr. W. R. Grovo on gangrene in an infant, published in the *JOURNAL* of April 24th (p. 738), has been the means of other cases of this very rare condition being recorded—in one instance twins were affected.

I delivered Mrs. T. on March 26th, 1925, of twin girls. Within forty-eight hours of birth the toes and fingers, in varying degrees, of both infants showed signs of gangrene. Both were puny and premature. One died before the gangrenous portions separated, but the other, in due course of time lost several toes and fingers (including the phalanges of the big toe of one foot) and is now a very large and bonny baby.

RESISTANCE TO INFECTIOUS DISEASES.

At a meeting of the Edinburgh Medico-Chirurgical Society, held in the Hall of the British Medical Association Scottish Headquarters on May 5th, with the President, Professor RUSSELL, in the chair, Dr. A. JAMES read a paper on the power of resistance to infectious diseases.

Dr. James said that in the development of disease two factors were at work—the virulence of the infection and the resistance of the patient, or the store of constitutional strength and fitness in relation to environment possessed by the individual. He wished to consider the second factor with reference to infectious disease; it was quite obvious that a good constitution was not enough, for a strong, healthy man from the country might quickly succumb to an infection received in a town. A child brought up in a town might resist certain infections, and the question to be considered was: Did this power of resistance to one particular infectious disease operate against other infectious diseases, and if so, to what extent? In order to study this Dr. James had collected 918 cases of scarlet fever, 610 cases of diphtheria, 238 cases of measles, and 111 cases of diphtheria carriers, all over 6 years of age, and examined their histories. The infectious diseases of 1,000 school children were also studied and the results tabulated. His tabulation showed that the proportion of those who had had no previous infectious disease was high in measles and low in diphtheria. Since measles was a very common disease this might seem to show that those who could resist measles could resist other diseases better than their fellows. To study constitutional fitness the cases were divided according to their severity into two groups and the number of previous infectious diseases recorded for each group. Of 918 cases of scarlet fever, 877 were mild or moderate, 41 severe and fatal. In the group of mild cases the number of previous infectious diseases was 1.73 and for the severe cases 2.12. Furthermore, in the second group there was no case without a history of previous infectious disease. Other diseases gave similar results. Dr. James described a case to illustrate the particular susceptibility of certain individuals. A boy, aged 7, was admitted to hospital suffering from measles; he contracted successively diphtheria, scarlet fever, and chicken-pox, while all the others in the wards he visited remained free. The speaker suggested that if one generation received adequate medical treatment there should be less needed in the succeeding generation. The figures showing that the demands for hospital beds had risen out of all proportion to the increase of the population proved that this was not so. Dr. James suggested that the doctor was not to be blamed for this, but rather the politician in his eagerness to correct the tardiness of Providence in improving the health of the community.

The Tuberculous Diathesis.

Dr. C. McNEIL said that the term "tuberculosis" was of recent origin, and dated from the time of Laënnec; it included glandular and pulmonary tuberculosis, which types were described as scrofula and phthisis in the days of Greek medicine. It was curious that the idea of "constitution" was associated with scrofula and phthisis from the earliest time, and its present survival was the direct tradition from the Hippocratic doctrine of a phlegmatic humour or disposition. In the Middle Ages scrofula appeared under a new guise as "the king's evil," and for a period of nearly 800 years the cure of scrofula by the royal touch was practised by the kings of France and England. In the early period of Greek and Latin medicine scrofula and phthisis were not associated with one another, though in each the doctrine of a "constitution" was taught. But with the revival of a scientific study of medicine, and notably by Cullen, who definitely proclaimed a kinship between scrofula and phthisis, an approximation between these two great clinical types of tuberculosis developed. Laënnec's doctrine of the tubercle as the cause of phthisis was a further and very important stage in progress (1820). But the doctrine of constitution, and especially of a scrofulous constitution, still dominated

medical thought, this constitution being regarded as the direct cause of the manifestations of scrofula and phthisis; the idea of contagion in phthisis was deliberately rejected by Cullen, Laënnec, and even as late as 1875 by Watson. With the discovery of the tubercle bacillus by Koch (1882) the identity of scrofula and phthisis was established, Laënnec's doctrine of the tubercle was vindicated, and the word "tuberculosis" became supreme. Scrofula fell at once from its high position, and had gradually disappeared from the everyday vocabulary of medicine. It was now, indeed, an obsolete and almost forgotten word, surviving merely in such forms as the scrofulous child, scrofulous conjunctivitis and keratitis, and scrofuloderma. The theory of constitution in tuberculosis persisted after Koch's discovery in the changed form of an hereditary predisposition or tendency, but even so had steadily receded. The recent investigations of Bernard showing that the children of tuberculous parents, if protected from infection, did not contract the disease, and showed fully average health and vigour, had supplied further important evidence against it. But the idea of a scrofulous constitution still survived, especially in Germany, in connexion with certain types of tuberculosis in childhood, gland and bone tuberculosis, and those obstinate relapsing catarrhs of the eyes called scrofulous and strumous. It was taught (Heubner, Czerny, Escherich, Moro) that in such cases tuberculous infection was associated with an abnormal constitution, lymphatism, or status lymphaticus, and that in them the tuberculin reactions were unusually severe. Slides were shown illustrating the stigmata of the scrofulous child, the occurrence of severe tuberculin reactions in scrofulous conjunctivitis, and the morbid anatomy of status lymphaticus. Thyroid hyperplasia was shown to accompany the lymphoid hyperplasia in status lymphaticus, and was claimed to be an essential part of its morbid anatomy; if this were established the morbid anatomy of status lymphaticus in the child was comparable with that of exophthalmic goitre in the adult. These facts supplied some anatomical evidence of the existence of an abnormal constitution in certain cases of tuberculosis in childhood, but this abnormal constitution was independent of tuberculous infection, for it was also found along with, and probably explained, certain rare fulminant types of many other infections in childhood such as pneumonia, scarlet fever, measles, chicken-pox. The suggestion was made that this abnormal constitution in the child termed "status lymphaticus" might be the counterpart of exophthalmic goitre in the adult, both being dependent upon some unknown disorder of general metabolism. Whether this view was right or not, there was no evidence for the very ancient doctrine of an abnormal constitution, or diathesis, peculiar to tuberculosis. If the old word "scrofula" were to be retained in medicine it should only signify glandular tuberculosis, which was a definite and important phase of tuberculous infection in childhood, and should not imply any idea of constitution.

SANOCRYSIN IN TUBERCULOSIS.

At a meeting of the Royal Medico-Chirurgical Society of Glasgow on April 9th, Professor JOHN H. TEACHER in the chair, Dr. MARY F. NANNETTI read a paper on the use of sanocrysin in the treatment of pulmonary tuberculosis.

Dr. Nannetti explained that owing to the nature of the tubercle bacillus, and the small amount of tuberculous tissue in blood vessels, a chemical substance introduced into the blood must diffuse a long way to reach the interior of the tubercle. Professor Moellgaard of Copenhagen, after much experimental work, had claimed that sanocrysin complied with the necessary conditions for the treatment of tuberculosis. For effective therapeutic action an agent must be soluble and quickly diffusible, and provide an adequate margin between the dose which killed the bacillus and that which was poisonous to the infected person. It must be stable, and decompose very slowly in the organism except when attached to the bacillus. Chemical compounds are not found in any amounts which are poisonous to the organism. After describing the chemical and physical properties of sanocrysin Dr. Nannetti stated that this

salt penetrated the lipid substance of the tubercle bacillus, and carried gold into its body, killing and dissolving it with an immunizing effect. If the antigen liberated was very toxic or liberated in too large amounts, or if the patient had not the power to build up antihodies, injection of sanocrysin caused severe toxæmia. Formerly serum prepared from animals injected with an emulsion of formalin-treated defatted bacilli was given as an antidote; it was now used to combat shock, and as a prophylactic in advanced disease. The most suitable type of case for sanocrysin treatment was the exudative—that is, the recent caseous pneumonic type with nodular foci breaking down with cavity formation, and presenting a woolly flocculent appearance when examined by x rays. In these cases the results of treatment were sometimes very striking. In the chronic type with fibrous tissue and production of real tubercles, the gold salt could not penetrate easily; it was of service in clearing up any coexistent active foci. In the early days of sanocrysin too large doses were given—a half to one gram—and fever, albuminuria, rashes, anorexia, and other complications followed. Since 1925 Dr. Gravesen of Vejleford Sanatorium, Denmark, had begun with much smaller doses—one-fifth gram, rising gradually to one or one and a half grams; a hypodermic of caffeine was given after every dose of sanocrysin. Digalen was given in some sanatoriums in England instead. The temperature was taken four-hourly or more often, the urine was tested daily for albumin, the sputum examined weekly for tubercle bacilli, and the patient was kept in bed. After one course of injections the patient continued ordinary sanatorium treatment without sanocrysin for about six weeks. A second course of injections was often required to allow the gold salt to reach those bacilli which were protected by fibrous tissue. The dangers to be guarded against were: shock, which was treated by intravenous injections of 20 c.cm. of serum and cardiac stimulants; fever, due to too short intervals between the doses; albuminuria, which disappeared when sanocrysin administration was suspended; temporary loss of weight; exanthema of all degrees; and local reactions in the lungs. In suitable cases the results were often highly satisfactory; the general condition improved, the temperature showed a more regular curve, the feeling of tiredness disappeared, moist râles cleared up or became dry and crepitant, while the number of tubercle bacilli decreased and gradually vanished. After subcutaneous injection there was apt to be a focal reaction and formation of abscess.

PREGNANCY COMPLICATED BY POLYCYSTIC DISEASE OF THE KIDNEYS.

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on April 30th, the President, Dr. D. G. MADDILL, in the chair, Dr. J. S. QUINN gave an account of a case of polycystic disease of the kidneys complicating pregnancy. The clinical details were as follows.

The patient was a 5-para, aged 35; she had been married for twelve years, and came in February, 1925, with a history of three months' amenorrhoea. She said she had had albuminuria in all the pregnancies except the first, and that in the last pregnancy, three years before, she had been very seriously ill, the infant being born spontaneously at seven months. On examination her urine was found to be free from albumin, and, apart from restricting her diet and ensuring a regular daily action of the bowels, no more active treatment was considered necessary. A fortnight later she complained of some bleeding with considerable discomfort and bearing down, as well as great frequency and difficulty in micturition. There was still no albumin in the urine, but vaginal examination revealed an ulcerated and oedematous cervix protruding from the vagina, with a retroverted fundus enlarged to correspond with the length of pregnancy (three and a half months). Two large tumours were easily palpable—one on each side of the lower abdomen: the one on the right was globular and cystic, the size of a melon, and quite freely mobile in all directions. On the left side a hard irregular mass with a limited range of mobility appeared to arise in the region of the pelvic brim, and extended upwards and laterally to the costal margin. No pain or discomfort was felt other than that due to the prolapse of the uterus. The uterus was replaced in position and a pessary inserted to retain the cervix at its normal level, and allow of a reduction of the swelling and oedema of the tissues. A diagnosis of double ovarian tumour was made, but it was decided to postpone operation on account of the possibility of a miscarriage, the septic condition of the cervix, and because it was considered that there would be less chance of interrupting

the pregnancy at a later date if double ovariectomy had to be performed.

The patient was kept under observation for the next four weeks, during which time the haemorrhage ceased, and the pregnancy appeared to be continuing on normal lines. There was no albuminuria at any time. However, she began to complain of pain in each flank, and the tumours, which up to this had been palpable without discomfort, now caused her considerable pain when handled. Eventually these attacks became more frequent, more severe, and as she was now four and a half months pregnant an operation was performed. The enlarged fundus was found lying in the normal mid-line position, with two large retroperitoneal cystic masses—one on each side. The left tumour consisted of a cyst, the size of a melon, resting on a bed of much smaller cysts, which sprang from the lower pole of the left kidney. The remainder of the renal tissue on this side was dotted with countless minute cysts, and the rest of the organ was considerably enlarged. The base of the tumour, consisting of the lower pole of the kidney, was cut across, the cyst removed and the raw area oversewn to control bleeding; the suture line was covered with a pad of the surrounding fat. The right kidney was completely disorganized, and consisted solely of grape-like cysts, no kidney tissue being evident to the naked eye. Some of the cysts were haemorrhagic, and it was decided to remove the entire mass. This was done and a tube brought out to the right loin, through a small incision in the posterior wall. The peritoneum was closed on each side, and the pregnancy was then terminated by an incision through the fundus, the ovum being removed, and the uterine incision sutured as in a Caesarean section. The tubes were finally tied and cut, and the abdomen closed.

The patient did quite well, and was passing normal quantities of urine within twenty-four hours; at no time during convalescence did her condition give rise to any anxiety. Her condition since operation had been quite good, and she had been free from any pain or discomfort. Her blood pressure was 205 and she was passing a very slightly increased amount of urine, of specific gravity 1014.

Dr. Quin said that the condition was progressive, and would eventually terminate in uraemia, but he thought that this result might possibly have been postponed by the treatment adopted.

The PRESIDENT said that he had never heard of a case of double polycystic kidneys in which the kidneys were so large as those described. He did not understand why an operation was not decided upon immediately the tumours had been felt.

Dr. QUIN, replying, said that when the condition was diagnosed the cervix was septic, oedematous, and ulcerated, and there was a certain amount of bleeding. It seemed possible that the pregnancy would have terminated spontaneously. He at first had diagnosed the case as one of ovarian tumour. Pain had only started after the fourth month, and there was less chance of pregnancy terminating after removal of both ovaries when the fourth month was past.

Abdominal Fibroma.

Dr. LOUIS CASSIDY showed a specimen of fibroma of the anterior abdominal wall. The patient, a woman of 40, had been six years married, had had no abortions, and her last pregnancy had occurred six months before admission to hospital. Menstruation since then had been normal. She had a swelling on the left side below the umbilicus, the nature of which it was difficult to determine. The pelvic contents were normal. It was decided to perform an exploratory laparotomy in order to determine the nature of the tumour. A large solid mass covered with peritoneum was found.

The PRESIDENT asked whether the growth was a fibroma or a fibromyoma. The former might grow anywhere, but it was very rare to find a fibromyoma growing in the abdominal wall, although he had seen one growing in the vagina.

Dr. BETHEL SOLOMONS asked what the exact extent of the tumour was; this might be a help in finding out the possible origin of the tumour.

Dr. D. J. CANNON said that tumours of this kind were occasionally met with in children. He had found one recently in a child aged 5, and six months later the same child was brought back to him with a pelvic tumour growing from the bladder, and containing involuntary muscle.

Dr. CASSIDY said that the tumour was entirely embedded in the abdominal wall; sections had been cut, and it had been found to be a fibromyoma. The tumour had grown within six months, and the patient had had no pain or discomfort whatsoever. It was only the size of the tumour which led her to go to hospital.

Reviews.

THE HISTORY OF PEDIATRICS.

THE once neglected subject of the history of medicine has been studied in this country more and more since the formation of a section devoted to it in the Royal Society of Medicine, and recent publications have shown that it is arousing more and more interest in the United States. Conspicuous among those who have written about it are Dr. FIELDING H. GARRISON and Dr. JOHN RUHRÄH, of whom the former has written an introduction to the work of the latter now under notice. Dr. Ruhräh wisely calls his book *Pediatrics of the Past*,¹ for had he entitled it "Pediatrists" some might have found fault with his definitions, since many of the authors noticed by him were by no means specialists; and their interest in the treatment of diseases and injuries of childhood was not great. But every clinician must at some time have had child patients, and nearly every medical author must have something to say about them. Therefore these two score or so of biographical sketches, together with some other essays on ancient medicine, are fitly named by their author.

Beginning, of course, with Hippocrates, in whose pages, as in those of Shakespeare, enthusiasts can find the whole of medicine and surgery, Dr. Ruhräh goes on to Soranus Ephesius, who is now thought by good authorities to have described rickets in the second century after Christ, and then introduces us to some of the worthies who are well-nigh forgotten, but who deserve to be quoted even for their mistakes as well as for their wisdom, and whose fates should suggest to us that many contemporary verdicts are liable to reversal by the High Court of Posterity. The author does well to claim a place in the medical Valhalla for Thomas Phaer (1510?-1560) as the author of the first book on pediatrics in the English language, although it is more as a translator than as an original contributor to the stock of knowledge that he can claim to be remembered. How many readers of this review have heard of his translation into English verse of "The XIII (sic) Bookes of Æneidos"? The *Dictionary of National Biography*, to which Dr. Ruhräh owes more than he sometimes acknowledges, tells us that Phaer only lived to translate rather more than nine of the Æneids.

Felix Würtz of Basle (1518-1574) was a far more notable paediatricist on the surgical side, and one of the earliest orthopaedic surgeons. His work was translated by Abraham Lebertson Fox, who appears to have been a Dutchman. But Würtz, although he claims to have cured club-feet and other deformities with splints and plaisters, and gives very sensible general advice, does not descend to such particulars as would enable us to judge of his knowledge and skill in orthopaedics.

The quotations from Pemell, who wrote during the Commonwealth, are instructive, but we are quite at a loss to guess what king is meant by "Good King Charlie," who is referred to thus between quotation marks. We have never heard any British monarch thus alluded to. Among the quotations from the Swedish physician Rosenstein (1706-1773) it is surprising to find one headed "Diphtheria." We are under the impression that this name for what had been before described as "putrid sore throat" was the invention of Bretonneau some half-century later, who, by the by, surely deserved some notice as a paediatricist. We appreciate the difficulties which Dr. Ruhräh must have met in selecting the subjects of his biographical sketches, but we cannot quite understand on what principle Richard Wiseman is included, while Andy and the describer of Little's disease are left out.

The scope of such a work does not admit of originality, and much of the information about the better known authors contained in it is somewhat hackneyed; but the amount of industry and patience required to produce such a book claims our admiration, and the profession is in debt to Dr. Ruhräh for making some of the less known writers

¹ *Pediatrics of the Past*. An Anthology compiled and edited by John Ruhräh, M.D. With a Foreword by Fielding H. Garrison, M.D. New York: P. B. Hoeber, Inc. 1925. (Roy. 8vo, pp. xxv + 592; illustrated. 10.10 dollars.)

accessible. If we may seek for hlemishes, which might be removed in those futuro editions which are sure to be needed, we would remark that the provenance of the portraits might be indicated more completely and generally, and that the many photographic reproductions of title-pages, etc., would be far more acceptable were they printed upon a smooth-surfaced paper. The rough paper which admirably suits the text gives only blurred reproductions of these photographs, and the result is to convey a quite false idea of the merits of the typographers of the sixteenth to the eighteenth centuries.

A curious error is to be found at page 276, where two pages—one of the text and one of figures—from Mayow's *Tractatus Duo* are reproduced in facsimile as being taken from Glisson's *De Rachitide*. This is the more remarkable in that an appreciative article on Mayow follows at pages 341 et seq. It should be stated that the frontispiece facing page 258 does not appear in the original edition of Glisson's treatise, but in the third edition published in Holland. We are jealous of the full glory of Whistler's "alphabetical procession" *Paedoplanchnosteocaces*, which Dr. Ruhräh has docked of its fair proportions by omitting four letters from the midst of it.

We notice some printer's errors. On page 255 *Aiken* should be *Aikin*, as it is correctly printed on the preceding page. On page 334 "Cundlo in Northampton" should probably be "Oundle" in that county.

DISEASES OF THE DIGESTIVE ORGANS.

IN the sixth series of his *Leçons de pathologie digestive*,² Dr. MAURICE LOEPER publishes eighteen lectures delivered at the Tenon Hospital, Paris, on various points connected with diseases of the stomach and liver. The first three deal with gastric leucopedesis or the passage of haemic leucocytes into the gastric contents; this, he considers, exerts both enzyme (proteolytic, amylolytic, and lipasic) and protective (bacteriolytic and antitoxic) functions, for he believes that anaphylaxis depends, at least in part, on the absence or insufficiency of this leucocytic migration. Various eruptions (erythema, eczema, urticaria, and angioneurotic oedema) may thus result, and as remedies small quantities of peptone, atropine, and sugar are recommended. In gastric cancer the leucocytic diapedesis is usually exaggerated, whereas in peptic ulcer it is below normal. In a systematic review of gastric syphilis he describes several forms: that with haematemeses simulating peptic ulcer but with hypochlorhydria and lymphocytes in the gastric contents (of this he has seen four examples); that resembling gastritis; with a definite tumour which rapidly disappears on specific treatment; and the stenosing form which may produce an hour-glass stomach or narrowing of the cardiac or pyloric orifices; but another article mentions the rarity of syphilitic bilocular stomach and the great preponderance of simple ulcer in the hour-glass stomach, which, he says, is most often to be observed in women. The possible relation of syphilis to the simple round ulcer is discussed, but the difficulties of coming to a positive conclusion are recognized and set out. In the chapter on gastroneuritis Dr. Loeper returns to a subject which he has previously elucidated in lectures given in 1919 and 1922, showing that nerves may be implicated in the cicatricial tissue of ulcer and by carcinoma. In this lecture a neuroma of Auerbach's plexus in a case of painful ulcer and carcinomatous infiltration of the vagus are figured. There is a full discussion of subcutaneous metastases in visceral carcinoma—a rare event—and a case primary in the stomach is recorded; it appears that gastric cancer heads the list in producing metastases, and Loeper regards the spread as haemic and not lymphatic, thus differing from Mr. Sampson Handley, whom he does not quote. The dyspepsia associated with erythraemia is discussed, and then follow lectures on haematoma of the rectus abdominis muscle in hepatic disease, on methods of reducing the cholesterol content of the blood, and on the treatment of gall stones and infection of the biliary tract

by diet and one fasting day a week. These lectures are stimulating, and are obviously the outcome of much clinical observation and thought.

ASTHMA.

DR. JAMES ADAM has not only added a book to the voluminous literature of asthma, but, what is more, he has produced a second edition.³ The thesis he put forward in his first edition some thirteen years ago was that asthma resulted from two factors—a toxæmia and a lesion in the respiratory tract, most often in the nose. This view he still supports and elaborates at length in his new edition, laying great emphasis on the toxæmia. In the interval between the two editions the theory of anaphylaxis in its relation to asthma has been the subject, not only of much brilliant speculation, but also of laborious and painful research, but Dr. Adam sweeps aside those who have been so engaged under the scornful name of "anaphylactophiliasts." For Dr. Adam the toxæmia is the underlying basal cause which renders the subjects sensitive in a variety of ways, so that anaphylaxis has been given an exaggerated importance, and if this toxæmia and the nose are appropriately treated what he calls the "vulnerance" is abolished.

The chief sources of toxæmia are, he holds, nasal, oral, and intestinal sepsis, but above all the last, so that dietetic treatment forms the principal weapon in his therapeutic armoury. Unfortunately, Dr. Adam uses the word "toxæmia" very vaguely and still more frequently. It is to be found on almost every page, and the reader inevitably calls to mind that blessed word Mesopotamia, which is credited with having brought much comfort to a certain old lady. The author can scarcely claim to have added anything to our scientific knowledge of the pathology of asthma. The views which he puts forward in a forcible if somewhat intolerant style are based on long and large clinical experience, but they are too indefinite for him to expect them to be received at the present time with an unhesitating and whole-hearted welcome. If his views are clear, then he lacks clarity of expression; for the reader, after reading, for example, pages 103 and 109, is left wondering what he believes is the true relationship between asthma and hay fever.

Putting aside, however, vagueness in the more theoretical aspects of the subject, it is evident that the writer has studied a large number of cases, following them up over a long period of years with great clinical acumen. In his directions for the treatment and general management of cases of asthma—one of the bugbears of the practitioner—Dr. Adam displays a store of valuable experience and practical observation. Those at whose disposal he has placed this record of patient clinical research should be deeply grateful.

BIOLOGICAL PHYSICS AND CHEMISTRY.

PHYSICAL chemistry has come into biology to stay. If we had any doubts of the reality of this invasion they would surely be dispelled by the number and the authority of the writers who are attempting in comprehensive treatises to point the new way. The latest attempt is represented by *Physical Chemistry in Biology and Medicine*,⁴ written from the Minnesota Medical School by Professor J. F. McCLendon and his associate, Dr. GRACE MEDES. It is not the least ambitious, though by no means the most comprehensive, of its kind. Indeed, its method is sufficiently distinct to make it difficult to appraise by comparison.

The first part of the book deals with the physico-chemistry of atomic structure, the colloidal particle, osmotic and surface forces, and electrolytic dissociation. Only the latter is adequate and self-contained, the treatment of the other subjects consisting of little more than bald definitions of the fundamental principles involved.

³ *Asthma and its Radical Treatment*. By James Adam, M.A., M.D., G.M. Second edition, revised and enlarged. London: Henry Kimpton. 1925. (Demy 8vo, pp. vii + 224; 2 figures. 10s. 6d. net.)

² *Leçons de pathologie digestive*. Par M. Loeper. (Sixième Série.) Paris: Masson et Cie. 1925. (Demy 8vo, pp. xi + 274; 47 figures. 22 fr.)

⁴ *Physical Chemistry in Biology and Medicine*. By J. F. McClendon, Ph.D., and Grace Medes, Ph.D. Philadelphia and London: W. B. Saunders Company. 1925. (Demy 8vo, pp. 425; 34 figures. 21s. net.)

Part II develops the significance to biology of some of the principles defined in the first part. Here we derived greatest satisfaction from the discussions of the ionic equilibrium of the blood and of some of the problems of permeability. The treatment of such subjects as the relation of atomic structure to physiological action, thermochemistry in the body, colloids in organisms, secretion, oedema, and the relation of surfaces to vital phenomena offered much that was of interest, but was on the whole inadequate and somewhat unbalanced. Where space has been so ruthlessly economized the authors should have been at particular pains to prevent their personal interests usurping an amount of attention out of proportion to the perspective of the whole subject. Such matters as the hydrogen ion concentration of the soil and of the sea are special problems demanding no extensive treatment in a treatise of this sort. Medicine receives little direct attention—wisely, we think, for its problems also are special problems—though acidosis, gastric secretion, anaesthesia, and the relation of calcium to epilepsy are touched on.

The work has been nobly conceived, but it must be acknowledged that the authors fail frequently to drive home both the fundamental principles and the implications to biology. The explanation is not far to seek. One-third of the 390 pages are devoted to sectional bibliographies embracing references to over 1,700 authors. Many of the chapters occupy little more space than the bibliography, to which they are in truth but prefatory notes. Now it may be argued that this is a sound method, but in the present case it is contended that it would be justified only if the introduction were to a critically selected literature and if the reader were constantly guided through the literature by a physical argument whose biological implications were made very plain. If you would persuade your reader into mathematical and physical ways of thought you must treat him very gently, else you will scare him from the field. While this book does not achieve all that we would ask of one bearing its title, and while we feel that it has fallen short also of the authors' own intention, it nevertheless offers much of value to the diligent student, particularly to him who can use judiciously the extensive bibliography.

The biochemical department of the Harvard Medical School has performed a very particular service to physiology and to experimental medicine. Under the enthusiastic guidance of Dr. OTTO FOLIN there has been developed a comprehensive series of analytical methods adapted to biochemical purposes, which have found wide favour in European laboratories as well as in those of the United States. Dr. Folin's *Laboratory Manual of Biological Chemistry* needs no introduction to these laboratories, so that the service of the reviewer of a new edition¹ is performed when he has passed on the information of a revision and extension of a book which has proved its own usefulness. The present edition is marked, apart from the clarification of certain passages, by the introduction of improvements in the methods for phosphates, uric acid, and sugar. In form the book represents the course in biological chemistry given in the Harvard Medical School. As such it is open to argument that the emphasis upon analytical methods has distorted the true perspective of the subject. But in substance the book is a manual of a system of blood and urinary analysis which is in wide use. Such methods as are not taught to the author's students are introduced into a supplement, and the supplement forms more than one-third of the whole volume! It is to the laboratory rather than to the teacher that this book will appeal.

The first point which must be explained about Dr. ALFRED J. LOTKA's *Elements of Physical Biology*² is what is meant by the title. The term "biophysics" should, the author thinks, be used to denote that branch of science which treats of the physics of individual life processes as exhibited in the individual organism—for example, the conduction of an impulse along nerve or muscle. The term

"physical biology" is used by him to denote the broader field of the application of physical principles in the study of life-bearing systems as a whole. Thus in this sense physical biology includes biophysics as a subordinate province. The province of physical biology, on the other hand, is practically unlimited, since it embraces all the phenomena of life.

The book is divided into four parts, headed general principles, kinetics, statics, and dynamics. Almost every subject that is dealt with is discussed from the mathematical point of view, and in many sections only the trained statistician will find himself at ease. An amazingly varied selection of material is analysed by the author, so that any scientifically minded reader with a mathematical bias is likely to find something to interest him somewhere in the book.

REFLECTIONS OF A FRENCH MEDICAL OFFICER ON THE GREAT WAR.

Dr. LOUIS BARRAS is a student of psycho-physiological problems the vigour of whose literary style is beginning to attract a considerable amount of attention in France. His *Souvenirs of the great war*, or, as he calls it, the greatest war,³ are a series of historical and psychological reflections written during his service with a regiment and with a field ambulance. He purports to lift the mask off realities, bare the souls of those who took part in the war, and fix on the pages of his book situations which he describes as more extraordinary than the most creative imagination has ever been able to conceive. He lived the life of the soldier in the trenches, in billets, and in rest stations. His descriptions are intensely realistic, and his pictures of horrors, drawn with the mind and eye of a doctor, are reminiscent of the writings of Barbusse and Philip Gibbs. The volume is in two parts, the first being a series of nine word-pictures of incidents in the life in the front line of a medical officer, named Auguste, together with reflections on the scenes which passed before his eyes. In the second part Dr. Barras, still in the character of Auguste, indulges in psychological commentaries on the soldier, his chiefs, various political and other influences, national characteristics, and love.

In the opening chapters he describes how his battalion at the beginning of the war crossed the frontier into Lorraine, where his poetic sense was stirred by the beauty of the fields, forests, and rivers, the freshness of the air, the red roofs of the houses, and the music of the village bells. He came from the south, and the landscapes of Lorraine were new to him. Then follow vivid descriptions of the life in the trenches, during battle, and in rest billets. We live with Auguste through all the vicissitudes of war, share his dug-out, work in his aid posts, relish such comforts of food and wine as come his way, and sink into the luxury of a good bed when the battalion is withdrawn from the line for its four days' rest. The scene shifts from Lorraine to the north. Villers-Cotterets, Compiègne, the forests, châteaux, and parks of Picardy and Artois pass in review, and then Flanders, with a tale of wine and love in an estaminet at Poperinghe. Auguste's experience with a field ambulance leads him to make some scathing remarks on its commanding officer and the principal medical officer of the division, especially on the former's fear of initiative or taking responsibility, and the latter's bureaucratic spirit in ordering the ambulance to open in a position exposed to hostile fire, and in preventing measures to remove the wounded in it to places of safety. It is all very realistic and intensely interesting reading.

Equally interesting are the three chapters of the second part of the volume. The first contains reflections on men at the head of affairs and others in high positions, the *plurigaçons* and the *pluriétoués*, for whom Auguste expresses great contempt. Some were amiable, good fellows, but weak men of the world; others who tried to be strong only displayed provocative brutality. If a man became thoroughly conversant with the duties of his post, the

² *Elements of Physical Biology*. By Alfred J. Lotka, M.A., D.Sc. Baltimore: Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1925. (Roy. 8vo, pp. xxx + 450; 72 figures. 25s. net.)

³ *Souvenirs d'un Médecin sur la plus grande Guerre*. By Louis Barras. Paris: A. Maloine. 1925. (Imp. 16mo, pp. 206 7.50 fr.)

chances were that he would be sent elsewhere. Confused and contradictory orders emanated from the administrative bureaux. The whole of the chapter is, in fact, a violent attack on those in high places, and on the attitude of the regular army medical officer towards his civilian confrere.

The second chapter contains various comments on military life, and the third reflections on the psychology of the soldier and of the British and the German troops, together with a brief reflection on the psychology of love and the urge of sex relations in war, a subject which many French, and some English writers nowadays, seem incapable of leaving alone. Auguste—that is to say, Dr. Barras—formed a high opinion of the British. He first came into close contact with them in Flanders in October, 1914, and noted how well they understood war and how much they helped the French. They did not waste time, he says, in words—they acted; and he describes instances of this trait in their character, in contrast with that of his own countrymen.

British medical officers who went through the war on the Western Front will live their life over again in reading these souvenirs; they form a wonderfully true and skilfully drawn picture of war. Our medical officers probably had experiences similar to those of Auguste, but it is hoped that their reflections on them are not quite so bitter. We feel, too, that while the author writes on the psychology of others his own psychology must be taken into consideration.

PERSONALITY.

THE author of this book *Personality*¹ is a practising physician who tells his readers that he has approached the study of the subject from the practical standpoint. He brings to the elucidation of its manifold problems a variety of physiological and psychological observations. Such a study is necessarily hedged around with difficulties. Dr. Gordon has avoided the inadequacy of a purely materialistic interpretation of personality by his adoption of Lloyd Morgan's doctrine of emergent evolution. In discussing, therefore, the physical foundations of personality he does not lose sight of psychological values. Personality he defines as the emergent synthesis of the bodily and mental attributes of the individual in relation to the environment in the most comprehensive sense. The problem of the relationship of body and mind is skilfully handled. Semon's mnemonic laws are utilized in the description of mental and bodily phenomena as the two manifestations of engram activation. The temperamental factor in personality is discussed in the light of the present-day knowledge of endocrine activity.

Dr. Gordon deals at some length with the contributions made to the study of personality by the exponents of the "dynamic psychology." The theories of Freud, Jung, and Adler are carefully outlined and correlated with Semon's mnemonic laws. The author considers that the Freudian school has successfully delineated definite personality types, but he is not prepared to accept the Freudian explanation of their origin. He finds in Jung's classification a more satisfactory delineation. Jung's function types (the thinking, feeling, intuition, and sensation types) and his general attitude types (extrovert and introvert), which are determined by the prevailing function, are well described. It is refreshing to find an author referring to the clarity of Jung's work.

Instability of the personality is discussed in relation to the neurotic and the delinquent. There are chapters on the dissociated personality and the retarded personality; and in conclusion an interesting section in which the spiritual aspects of his study are envisaged.

Dr. Gordon has made a significant contribution to the study of personality, and does not forget that, however painstaking any analysis may be, the core of the problem remains unsolved in the indivisibility and uniqueness of personality.

¹ *Personality*. By R. G. Gordon, M.D., M.R.C.P.Ed. The International Library of Psychology, Philosophy and Scientific Method. London: Regan Paul, Trench, Trubner and Co., Ltd.; New York: Harcourt, Brace and Co., Inc. 1925. (Demy 8vo, pp. xiv + 302. 10s. 6d. net.)

NOTES ON BOOKS.

Dr. HENRI STÉVENIN's little book on whooping-cough,⁹ which forms the latest contribution to the series entitled *Bibliothèque des connaissances médicales*, edited by Dr. Apert, is divided into seven chapters devoted respectively to the symptoms, varieties of the disease, complications, bacteriology, pathogenesis, prophylaxis, and treatment, preceded by an introduction containing a short historical sketch. Like most practitioners who have had much experience of whooping-cough, the author is convinced that there is no form of treatment which has a constant action on the course of the disease. The book is essentially practical, and can be recommended as an excellent summary of present knowledge of whooping-cough.

The little work on infectious diseases,¹⁰ by Drs. O. HUNTEMÜLLER and H. KLEWE, is a concise guide for students and practitioners, and is not intended to take the place of a textbook. The work contains a general part dealing with notification, microscopical diagnosis, the technique of vaccination and serum therapy, disinfection, and sterilization, and a special part devoted to the various acute and chronic infectious diseases, including not only the common infectious disorders, but also tropical infections, dermatomycoses, contagious eye and ear diseases, and the varieties of helminthiasis. A short bibliography of German works on infectious diseases is appended.

Causeries d'urologie,¹¹ by R. UTEAU, is, as its title suggests, neither a treatise nor a manual on urology. It is rather a collection of axioms, isolated observations, and practical points which the author has found of importance in his work. Like the majority of French textbooks, it is written in concise and epigrammatic language. There is little that is superfluous within its pages, and conflicting opinions, theories, and quotations from different authorities find no place. It is essentially an epitome, and to those wishing to revise rapidly their knowledge of genito-urinary surgery it should be of great use. Only a few essential illustrations have been inserted.

It is not only when driven by showers into the pavilion that cricketers like to look through the records of famous matches of the past. Many of us, even in winter, have enjoyed dipping into a collection of match scores; it is part of the spell exercised by the national game. Such a book is *Oxford v. Cambridge at the Wicket*,¹² compiled by a great Oxford and All-England cricketer, Mr. P. F. WARNER, and another authority on the game, Mr. F. S. ASHLEY-COOPER. It contains the scores of all matches played between the universities from 1827 to 1925, with brief but entertaining notes on each game. The early matches were informal affairs. Any sort of costume was worn; byes and wides often proved top scorer; it was not at all unusual for a player to be "absent" without any stated reason when he should have been helping to save his side; and on one occasion at least "the tent and table were open to all comers." Up to 1850 the matches were sometimes played on one or other of the Oxford grounds; since then they have all been played at Lord's. The volume closes with an index giving the name of every player, with dates of birth and death, and the school from which he was sent to Oxford or Cambridge.

PREPARATIONS AND APPLIANCES.

The Tungstone Accumulator.

A NEW accumulator for motor cars and wireless sets, stated to be a British product, British made, has recently been introduced by the Tungstone Accumulator Company (3, St. Bride's House, Salisbury Square, London, E.C.4). To the motorist who is not expert in things electrical the great merit of this battery is the ease with which the plates can be removed from the containers. If the nuts of the main terminals are taken off, the plates, which are attached to the lid of each cell, can be lifted out, and a damaged plate replaced without disturbing the rest of the accumulator. In addition to this, the container of each cell is of seamless, indestructible metal; the die-cast grids and plates can withstand unusual stress; and the paste is very securely fixed into the interlacing holes of the grids. The result is a very strong and powerful battery, which, after prolonged

ill usage in testing, shows no buckling in the plates and no loss of efficiency. The ease and force with which the self-starter controlled by a Tungstone accumulator will turn the engine, even on a cold morning, is certainly remarkable. The only small trouble experienced has been a slight tendency to splashing of acid. To prevent this it is necessary to take great care that the level of the acid is not too high, and that the vent plugs are very securely screwed down.

THE EYE AND EVOLUTION.

PROFESSOR ELLIOT SMITH'S CAVENDISH LECTURE.

THE Cavendish Lecture, under the auspices of the West London Medico-Chirurgical Society, was delivered by Professor G. ELLIOT SMITH, M.D., F.R.S., on May 28th, to a large gathering at Kensington Town Hall. Dr. H. W. ARMSTEAD, president of the society, was in the chair.

Professor Elliot Smith took for his subject "Vision and evolution." He set out to show that the faculty of vision had played the most important part in making possible those achievements which distinguished man from other creatures. It was principally by vision that human beings apprehended the world around them; moreover, it was the visual control of the hands which made possible the art of learning; it was due to vision almost entirely that the mind appreciated beauty in form, colour, and perspective; and vision also played an important part in sexual selection. Very largely by means of vision human beings learned to understand one another. The faculty played a significant part in human behaviour. By watching movements, gestures, facial expressions, and especially the changes in the eye itself, persons learned almost unconsciously to appreciate the distinctive qualities of others, to interpret motives, and to communicate information, understanding, and emotion. The fundamental importance of vision as the foundation upon which man's intellectual superiority was built was found in the texture of the language, witness such expressions as "insight," "foresight," "vision," and "perception," and even some slang expressions illustrated the same thing. Speech itself was really the outcome of this higher visual endowment, for in that stage of evolution when visual discrimination between objects became possible the need arose for an auditory symbolism to express what were thus differentiated to communicate with others.

Among primitive animals, the lecturer continued, smell was the dominating sense. The sense of smell was the means by which the animal began to appreciate continuity of experience—a fundamental factor in existence. Animals learned, on the basis of experience, to anticipate by smell the taste of various foods, and in every animal group smell was depended upon, not only in the search for food, but in the recognition of sexual mates and rivals. But the sense of smell gave no indication of the position in space of the exciting object such as vision provided, and in every group of vertebrate animals there were certain members which specialized in vision, and in consequence became extremely expert along certain lines of activity, though this very specialization restricted their activities or development in a wider respect. Thus ungulate animals, horses for instance, became fleet of foot, having limb and hoof developed for this particular purpose. Carnivorous animals developed a paw equipped for the particular function of seizing their prey. In bats the arm became transformed into a wing, and in marine mammals into a flipper. But while these creatures became expert in particular modes of life they lost their ability to adapt themselves to new needs and conditions.

Certain creatures, however, like the jumping shrews of South Africa, had been able to avoid definite life, and their limbs did not undergo any degree of specialization but retained a primitive structure, with plasticity and adaptability to various purposes. One of these groups of shrew-like animals, as the result of an arboreal existence, lost their dependence upon the sense of smell, while their sense of vision and their muscular agility were enhanced, so that while the brain of the ground shrew showed an enormous olfactory area, and above it

a comparatively small territory concerned with visual, auditory, and tactile impulses, the brain of a similar creature living in trees showed a great reduction in the size of the olfactory area and an enormous expansion of the rest of the brain. As this process continued there was brought into existence the order of primates, to which the lemur, the apo, and man belonged. In this order the significant change was the enormous increase in the visual territory of the brain. This was evident in the lowest creatures of this order—the lemurs and those lemuroid animals, the tarsiers. The tarsier, which still existed, a living fossil, in Borneo and Java, was almost identical in structure with a creature that existed before the beginning of the Tertiary period; it still retains many of the most primitive features of the earliest primates. In the tarsier, for the first time in mammals, vision replaced smell as the dominant sense. The main difference between the tarsier and the monkey was that the monkey had greatly extended the range and precision of the conjugate movements of the eyes, whereas the tarsier had not, but this latter creature had evidently felt the need for such a development, and had compensated for its lack by developing an astonishing range of head and neck movement such as no other mammal possessed. In all vertebrate animals other than mammals the eyes can move independently the one of the other, but in most mammals one eye could not be moved without the other being moved also. But the power to make conjugate movements of wide range and precision began with the monkey, and the lack of it held back the tarsier.

In the monkeys and in man, when these delicate movements were made possible by the special development of the cortex, the macula lutea developed, and the animal thus gained the power of discerning the details of objects, of practising a nicer discrimination between colours and textures, of distinguishing between objects of similar shape which to an animal without a macula was impossible. All this had a profound influence in stimulating the development of the cerebral cortex. The animal had its curiosity excited so that it handled and examined objects, cultivating also in this way its power of skilled movement, guiding its hands with amazing dexterity; its auditory and vocal powers and its tactile capacity also increased, and all this again expressed itself in the structure of the brain, which showed a great frontal expansion. By comparing the lemur or the tarsier with the marmoset it could be seen that the enhancement of muscular skill was acquired at the time that the power of stereoscopic vision originated.

From all this (Professor Elliot Smith continued) it was possible to build up a theory or hypothesis to explain how the high powers of discrimination began. The cultivation of vision started a cycle of further changes, which themselves led to still other changes, all in the direction of greater power and refinement. There was reason to believe that the development of the prefrontal area, which grew out, so to speak, from the motor territory, was itself an expression of the increased powers of skilled movement. In the course of this evolution it became possible to apply these increased powers automatically, so that the animal was able to concentrate its vision upon things seen rather than upon the motor act of seeing. When an animal learned to converge its eyes upon a particular object it was also fixing its attention and acquiring the ability to concentrate the mind for a particular purpose. The lecturer added that when one came to the fossil remains of man one found still other stages in the development of the prefrontal and parietal areas. These regions were smallest in the Pithecanthropus of Java, considerably bigger in the Piltown man, bigger still in the Rhodesian man, and showed further progress in Neanderthal man. The brain continued this progressive expansion until it reached the more equable stage of development in *Homo sapiens*. Man's mental superiority was really based upon the seeing eye and the dexterous hand.

In proposing a vote of thanks for a fascinating lecture, Mr. McADAM ECCLES said that one lesson to be learned was that anatomy was not a science of water-tight compartments, and that physiologists must beware lest anatomists overran their field.

British Medical Journal.

SATURDAY, JUNE 5TH, 1926.

THE NOTTINGHAM MEETING: THEN AND NOW.

ONCE a year, at the height of summer, the British Medical Association shifts its centre of gravity. The headquarters machinery in London does not stop, but for a week or so the Association makes its home elsewhere, usually in some English or Scottish city, though Ireland and Wales also have received several visits, and twice the Annual Meeting has been held in Canada. In this sense the Association is a peripatetic body, and has been so from the time of its foundation ninety-four years ago. The custom was broken by the war, but was revived with great success in 1920 at Cambridge; and since then Newcastle, Glasgow, Portsmouth, Bradford, and Bath have shown in turn, and each in its own way, how valuable a part of the life and work of the Association its Annual Meeting can be made. This summer it will meet again, after an interval of thirty-four years, in the great industrial centre that has grown up within and around the ancient town of Nottingham.

When the Association met, for the second time, at Nottingham in 1892 the only direct part its 14,267 members had in the conduct of their collective affairs was the right to speak and vote at the statutory "general meetings," which had come by then to be looked upon almost as the preserve of a few stalwart debaters. Although our membership is now more than twice as large, the democratic organization of the Divisions and the Representative Body enables every member who wishes to do so to take his or her share in the determination of professional policy. We say "or her" because it was not until a general meeting in 1892 that the sex ban disappeared and a previous resolution excluding medical women from admission to the Association was rescinded. The last Nottingham meeting was memorable also for the announcement, made at the annual dinner, that the Council intended to set aside some £50,000 for purchasing a freehold site and erecting suitable buildings to form a metropolitan home for the Association. It was upon the site thereafter acquired and inhabited that the fine house arose in the Strand in 1907. That building is now about to become the London headquarters of the Dominion of New Zealand, the Association having entered last year into possession of its new and beautiful home in Tavistock Square, which was opened by His Majesty the King on July 13th.

The range and variety of the British Medical Association's ever-widening interests and activities to-day are reflected in the Annual Report of Council for 1925-26, published in the SUPPLEMENT of April 24th, which will form the foundation for the work of the Representative Body during its forthcoming session at Nottingham. It was the custom of the nineties to let medical politics and domestic administration share with science and social enjoyment the four crowded days of an Annual Meeting. The result was what might be expected—overlapping, and dissipation of

energy and interest. More time is now available, and the business is so distributed that the Representative Body can complete its task before the sectional meetings open and the festivities begin, and it is therefore possible for any one member to take part in all that goes on. This is a great advantage, because the work of the scientific Sections, the deliberations of the various conferences, the addresses and social features of the gathering, together with the annual exhibition and the pathological museum, fall into place as integral parts of a conception which touches at many points the interest of every member of the profession.

By the year 1892 sectional organization of the scientific and clinical work of the Annual Meeting had been established for some time, and there were ten Sections on that occasion. But the set debates, judged by modern standards, were rather sketchy, in arrangement and not very comprehensive in scope, while the sectional programme was strewn with a multitude of disconnected papers; there were 200 of these in all, which contrasts strangely with the half-dozen independent communications notified for next month's meeting. We are less miscellaneous nowadays, and general interest, instead of being diffused, is focused by the careful planning of compact discussions in which each aspect of a disease or a mode of treatment or investigation is introduced by some well known worker in that field. A further development of this idea is the joint debate between two or more Sections. These have proved most attractive in recent years, and three such combined meetings will be held next month. In 1892 the ceremonial spirit of the Victorian age demanded that besides the President's Address three formal addresses—in medicine, in surgery, and in pathology—should be delivered in full session; and here and there a sectional president would feel moved to preface his first day's heterogeneous proceedings with something in the nature of general oratory. Thus not only is the scientific work better planned in 1926, but strict attention to a limited amount of business on prearranged lines is the order of the day. The practical nature of the subjects to be discussed at the meetings of the thirteen Sections will be gathered from the full programme of the Nottingham Annual Meeting printed in the SUPPLEMENT this week. Most of the topics are of interest, not to specialists alone, but to everyone engaged in general practice who wishes to keep abreast of recent work and to make himself familiar with fresh ideas on matters which are engaging the attention of the most active minds in various departments of clinical and scientific medicine.

It is not with any idea of glorifying the present at the expense of the past that we have drawn these contrasts. Our predecessors were building up the great organization we inherit. They had to face many obstacles within and without, and it is because they overcame them that the Association stands where it does to-day. Two things they had which make all other things possible—good will and faith in the future. There was a family spirit about the old Annual Meeting: it was a rallying-point for the whole profession. This spirit is with us still, as the growing number of oversea members who attend our gatherings will testify. Immense progress has been made in the past thirty-four years, but neither the Association nor its Annual Meeting is a perfect instrument. When we think there is no more room for improvement then our faces will be turned away from the future.

HOW TO MAKE HYGIENE PAY.

THE history of the public health development of our own country shows convincingly the need of periodic stimuli to accomplish the awakening of the nation's sanitary conscience. Had it not been for the recurring outbreaks of cholera we should probably have taken much longer to reach the stage of appointing medical officers of health, and, by the successive steps of a Royal Sanitary Commission and a Local Government Board, arrive at a culminating point in a Ministry of Health.

Even with the example of the homeland ever before their minds, there are British colonies which lag far behind modern requirements in matters hygienic, and some of them still remain in the lethargy of embryonic sanitary life. Dr. Andrew Balfour, the director of the London School of Hygiene and Tropical Medicine, has wisely taken advantage of an invitation to address delegates to the West Indian Conference in London to apply a fresh and much needed stimulus to West Indian hygienic effort. His pungent address, slightly abridged, is published this week (p. 929). The climate, the environment, and the general mode of life tend in many tropical countries to foster the *dolce far niente*; or, after the summoning up of energy to start and perhaps carry through one important hygienic scheme, there follows a lull, "a little folding of the hands to sleep," and the effort necessary for continued improvement is allowed to slacken, conditions return to their former state; the money has been not merely spent, but wasted. Unhygienic conditions so act and react upon one another that there must be sustained effort for general improvement on as many lines as possible if satisfactory results are to be maintained, and not an aim, however well directed, to remedy one particular defect. In Dr. Balfour's happy simile, there are several sound investments for capitalists with money to lay out in measures hygienic, but, to paraphrase his words, they are investments to hold on to; the returns may not be quick, but they are always sure. Among these, worthy of special mention, in fact trustee securities, are prevention of soil pollution, antimalarial and antituberculosis measures, and education.

This last is a much abused word. Many schools in the tropics have health teaching as part of their curriculum; but what can it avail to teach in a native school the dangers of flies and mosquitos and the advantages of cleanliness, when that school is surrounded by removable bush and refuse or half-drained marshland, and has no latrine accommodation for the pupils? Sums spent on education such as this (these sums are large and these conditions very frequent, as every worker in the tropics knows) would far better be expended on the more potent, unwittingly absorbed education afforded by example of adequate conservancy and latrine accommodation, proper drainage, mosquito-proof buildings, and so on. The constant presence of a sanitary environment will do infinitely more to engender hygienic habits than talking about health, cleanliness, and the benefits of fresh air, in hot, ill-ventilated schoolrooms. This will appear a trite commonplace, but in many tropical countries we find an extraordinary upset of values. There is some excuse for this, since the application of scientific knowledge acquired in a temperate climate needs to be modified to meet tropical conditions. In other words, there is a need—nay a necessity—for local investigations for solving the hygienic problems which exist abroad. Hence the paramount importance of engaging properly qualified scientific workers in the first instance, and of providing them with properly

equipped laboratories in order that they may test and adapt to the best advantage the experience gained on the spot. Not only is a good health officer a necessity, but he must be provided with a reliable, and therefore a properly trained, personnel—that is to say, sanitary inspectors. The money spent on a small army of uneducated natives, one or two to every little village, as we have seen in some colonies; to "look after the local sanitation," would more than suffice to pay for sanitary inspectors properly trained, and that there is a need for such was recognized by the Royal Sanitary Institute some years ago, as mentioned in *Health Problems of the Empire*,¹ a work which deserves to be more widely known, in which occurs the following passage: "Quite recently the Royal Sanitary Institute, which has for many years held examinations in general sanitation for sanitary inspectors abroad, went a step further, and commenced to hold in Great Britain examinations in tropical hygiene for inspectors working in, or destined for, the tropics. This is a matter of considerable importance, as there has been a tendency in many colonies not to apply practically the knowledge gained. Such practical application is pre-eminently the business of the sanitary inspector acting under the medical officer of health, and the manner in which tropical hygiene in certain respects differs from sanitation in temperate climes makes it necessary that sanitary inspectors in, or proceeding to, the colonies should be specially qualified."

What happens not infrequently is this. The Government of a colony awakens to the idea that all is not well with the health of the people or the sanitary condition of the island, the additional stimulus being that in consequence of this the tourist traffic is diminishing, so the homeland is asked to choose and send out an energetic well qualified medical man as health officer. This is done. He arrives, makes his survey, and sends in a report stating what is needed to improve the conditions. Then comes the tug-of-war. His every suggestion is met with the inquiry, "What will it cost?" followed soon after by the minute, "Regret no funds available," though vast amounts are being spent in other ways. Disease breaks out, and the cry goes up, "We are paying for a man sent out with a good record as a first-class hygienist, and he does not stop the epidemic." He will tell how it may be stopped, but the waving of a magic wand does not suffice, and a little money is grudgingly doled out, half-measures are taken, and the plague is stayed—for a time. Finally, the disease becomes endemic, or is uprooted at a cost vastly greater than would have been necessary had the work been timely undertaken. But there is another aspect. After repeated vain requests for the necessary means to carry out what he knows to be essential, the heart of the health officer grows sick with deferred hope, and he applies for a transfer, which he will probably succeed in obtaining if his importunities have been frequent enough to make his removal desirable for the comfort of the authorities; or he may, tired by rebuffs, offer up a heartfelt prayer for a "really good epidemic" as a last resource to arouse the local powers, before remarking, as Dr. Balfour says in his address, "I have done my best; let things rip," and he will no longer oppose, at least with any vehemence, the fatal policy of *laissez faire*.

This leads us to the gist of the whole matter—the need for placing such a man in a financially independent position, with security of tenure if he does his

¹ *Health Problems of the Empire: Past, Present, and Future.* Empire Series, edited by Hugh Gunn. London: Collins and Co.

work, for providing him with proper assistance and facilities for research, and for allowing him administrative control of his own personnel. The best trained man is not the most extravagant; on the contrary, he is the most economical; while the advantages of a properly trained sanitary inspector are incalculable, and the two, working together in harmony, will repay a hundredfold their cost in the betterment of the people's health, the consequent improved quality and output of the people's work, and the concomitant and lasting happiness of the people's lives. A good health officer will become better by lengthened experience of his district, and, if properly paid, properly equipped with facilities for research, and properly assisted, he will not wish to change. A good chief can do but little if badly supported, and very little more with good assistance if he is crippled by lack of funds; whereas, worst of all—a conduit leading to a bottomless pit of inestimably wasteful extravagance—is a bad health officer, however well supplied with funds.

We have in the past and the present had abundant examples of the first two terms of the sequence, "Does hygiene pay?" and "Why hygiene pays," and, now that everyone knows that it does pay handsomely, the future question will ever be, not merely on humanitarian grounds, but on the business grounds of sheer economy and profit, "Why, then, has hygiene been neglected?"

AMBULATORY TREATMENT WITH TUBERCULIN.

No one can justly deny to Dr. Camac Wilkinson the meed of praise he has fairly earned by the enthusiasm and perseverance with which he has advocated the use of tuberculin in the treatment of pulmonary tuberculosis. In the letter published elsewhere in this issue (p. 967) he tells us that he has used it continuously since it was introduced by Koch in 1891, and as a matter of fact a very full paper by him on the subject was published in our columns nearly a quarter of a century ago.¹ At that time he was lecturer in medicine in the University of Sydney. Recently he was for some years director of a tuberculin dispensary in south London; he has published accounts of his work there, but, unfortunately, he was compelled for, as we understand, private domestic reasons, to give it up some two or three years ago. It is now, as appears from his letter, to be resumed in Fitzroy Square. His experience entitles him, he considers, to claim: (1) That in the earliest stage (physical signs and suggestive symptoms) the disease can be prevented from passing on to the later stages, at any rate for many years, in 95 to 100 per cent. of the cases. (2) That even in Turban's third stage some patients may survive for fifteen years or more, leading ordinary lives. (3) That tuberculin used in proper doses, properly timed, properly administered, and carefully controlled by constant clinical observations, benefits 75 per cent. of those suffering from consumption and tertiary manifestations affecting other organs than the lung. These are strong claims, but Dr. Camac Wilkinson believes them to be justified by his experience, even among working-class patients in London, who have gone on with their work during treatment. We cannot, of course, venture to express any opinion upon his conclusions, for, as he says, a judgement can only be formed after long and painstaking observation. But we may venture to say that the tests he enumerates in his letter seem to be formulated in a true scientific spirit, and that he is wholly sincere and wholly above-board in his methods. He invites practitioners to send patients to the dispensary he is now opening, and it would seem well worth while to do so if sanatorium treat-

ment cannot be obtained. He also invites practitioners to go to the dispensary to see how the treatment should be applied, and probably personal conviction on its value could be reached after observation of a few cases for a year or so. But more than this will be necessary to convince others. It is not easy to understand why his method of using tuberculin has not attracted more attention from the medical profession and from the public, including the approved societies. It may be due partly to the fact that he seems always to have worked more or less by himself, and partly to the circumstance that his books are not easy to read; if we are right such obstacles as these could be removed without very much difficulty. It is rather saddening to have to add that another cause may be his punctilious insistence on strict scientific method, which means the lapse of long periods, extending to several years, before he will allow others to formulate for themselves the conclusions of whose truth he is himself so thoroughly convinced: in other words, he will not have premature agreement.

THE AIMS AND METHODS OF EXPERIMENTATION.

LECTURERS at the Royal Institution have the difficult double task of interesting the experts, whose knowledge of the chosen subject is almost as great as their own, and of pleasing the "gallery," to whom science is always a fairy tale with fascinating illustrations in the shape of experiment. Sir Almroth Wright, in his lecture on Friday evening, May 28th, on the aims and methods of therapeutic research, managed to maintain the interest of both sections of his audience by being at once profound and simple. In the great task of experimentation, he said, it was necessary to take into consideration not only those things which could be seen and heard, but those which he termed "subperceptive," and the knowledge of which required method and technique in its pursuit. Bacon had laid it down that there were two kinds of experimentation—experiments of light, which afforded information, and experiments of fruit, which were capable of practical application. The lecturer confined his remarks to experiments in connexion with diseases arising as a result of bacterial infection, and he devoted a large part of his time to discussing and demonstrating the bactericidal action of the blood, remarking at the end of a series of interesting experiments that these all belonged, nevertheless, only to the first class of experiments within the Baconian definition; they might suffice for a Royal Institution lecture, but so far as his own utilitarian profession was concerned the question inevitably arose as to the good of them. Discoveries in the laboratory did not count at all unless they could be directed to the saving of a patient. Sir Almroth Wright then proceeded to discuss the general question of prophylaxis, reminding his audience that the mere putting of a drug into the body which would be eliminated by the following day could be of no possible avail. The great thing which had to be done was to increase the resisting power of the blood by increasing the efficacy of the white blood corpuscles. The more the protective power of the blood was tested the more did the observer become interested in the enormous capacity which it revealed. When Darwinians spoke about man having evolved through his brain capacity, they might with equal truth point to the importance of the great bactericidal power of the blood in the story of survival. In demonstrating how more white blood corpuscles might be brought into wounds in order more effectively to fulfil their function, Sir Almroth Wright showed what could be done in this respect by the action of common salt—a phenomenon to which little attention had been devoted by the physicist. Sodium chloride had extraordinary properties in connexion with blood fluid. If water was put into a wound no serum

¹ BRITISH MEDICAL JOURNAL, 1902, vol. 1, p. 1389 (June 7th).

came out to meet it, but if a 5 per cent. salt solution were used the serum appeared from all sides. The lecturer went on to illustrate the result of the application of antiseptics to wounds, experimenting for this purpose with several specimens of blood to which the same amounts of staphylococci had been added, and gave a short account of the researches which had been carried out on the effect of carbolic solutions, cresosote, and the drug known as optochin, which would have found an application in destroying the micro-organisms in pneumonia but for the fact that it caused patients to go blind. He spoke also of the efficiency of inoculation by modern methods, and the degree and period of protection obtained, reminding his audience that vaccination was possible, not only with micro-organisms, but with all disintegration products of the body. It was a great thing to have found substances availing for protection for a time against micro-organisms, and bringing about such protection almost instantaneously, by a dose of the necessary vaccine. Incidentally he touched on light therapy, and mentioned the curiously divergent results in lupus cases according to the varying susceptibility of the patients.

BRITISH JUSTICE.

SINCE the United States ambassador to this country has informed his President that we are down and out, any little testimony to the contrary from one of his countrymen is very welcome. Dr. John Rathbone Oliver, chief medical officer to the Supremo Bench of Baltimore, has lately published a paper on criminology and common sense,¹ in which he contrasts American with British criminal procedure and treatment of criminals, much to our advantage. It appears that the sentimentalists who have poured out much gushing sympathy over evildoers in the United States hold the erroneous opinion that British law and British treatment of lawbreakers is hard and unfeeling. After a personal study of our ways and of those of some Continental countries Dr. Oliver is able to assure his countrymen that this is not so, but that, on the contrary, they have much to learn from us, not only as regards philanthropy, but still more as regards the detection and punishment of offenders. No doubt many of the defects of the police methods of the United States are not so much due to deficient appreciation of right and wrong as to the amateur type of organization on which in many States the law still has to rely. The fact also that every one of the forty-eight States has made and administers its own criminal laws must be taken into account in comparing the two countries. Dr. Oliver says nothing of Canada, yet a fairer comparison may be drawn between that Dominion and the United States, since both are new countries rapidly developing, and both are democratic. In Canada, which has grown up under a central government, police is not a merely sectional matter, and the long arm of the law has generally managed to reach the criminal. The contrast, for instance, between the state of affairs in the early days at Klondyke and that in a typical Western American gold rush is illuminating, and shows the restraining effect of a certainty or strong probability of punishment on the lawless mind. Dr. Oliver denounces the morbid sentimentality which makes some hardened gunman or unnatural domestic murderer an object of sympathy, or at least of paramount interest. We wish that we could honestly pride ourselves on the absence of such feeling in our own country. Our readers need not have long memories to be able to recall cases in which a like misplaced tenderness has been manifested here. But it is well to remember that, in both countries, for one unbalanced and shrieking sentimentalist who makes himself heard there are many sober, silent persons who loathe the agitation and whose opinions favour calm judgement. Dr. Oliver seems, how-

ever, more concerned with minor criminals and courts of first instance than with grave offences. He was very much impressed with the kindness and common sense which are characteristic of metropolitan police magistrates. He speaks in terms of admiration of the recent book by Mr. J. A. R. Cairns on his experiences as a magistrate,² and had he seen it we feel sure that he would have had nothing but praise for Mr. Cecil Chapman's work on a similar subject, which shows the author to be, as many of his colleagues are, more of a friend than a judge of first offenders, and a kindly sympathizer with what good there may be even in the hardened criminal.

MEAT INSPECTION.

THE necessity for more and better meat inspection in this country was the main topic for discussion before the Section of Comparative Medicine of the Royal Society of Medicine on May 26th. Mr. Wooldridge, professor of veterinary hygiene in the University of London, in an introductory paper indicated the chief aims of meat inspection. He divided the subject into two sections—*ante-mortem* and *post-mortem* inspection. *Ante-mortem* inspection, he declared—and with this all the subsequent speakers agreed—was of the utmost importance, and must be carried out by one who was not only a qualified meat inspector, but also a trained clinician. Meat was inspected *post mortem* for various reasons: bacteria harmful to man, such as tubercle bacilli, anthrax bacilli, and so on; parasites such as *Cysticercus* and *Trichina*; poisons, whether bacterial toxins or chemical preservatives; aesthetic reasons; and for innutritious meat. The greatest danger to human beings, however, was from "fevered" meat (that is, meat from ailing animals which does not "set" properly, and which has often a dark colour and a characteristic odour) and from "emergency slaughter" cases (that is, animals which have been slaughtered *extremis* or when suffering from an incurable condition). It is most dangerous when the animal is slaughtered on account of some pyaemic or septicæmic condition. Slaughter of animals which have been "in contact" with such conditions as foot-and-mouth disease, swine fever, and rabies, and which have not developed any symptoms of these diseases, is perfectly safe. Specific diseases communicable to man are very rarely transmitted by the ingestion of cooked meat, although contact with the flesh of animals suffering from anthrax may cause the infection. Accordingly the main object of a meat inspector is to prevent the sale of meat likely to cause meat poisoning, and, to a secondary degree, to prevent the sale of obnoxious-looking or innutritious meat. The present state of meat inspection is still bad, in spite of many recent improvements, and compares unfavourably with the systems in force not only in foreign countries, but in British dominions and colonies. It was often haphazard, and too frequently entirely in the hands of men who have only a very superficial training. All those who took part in the discussion urged the necessity for improvements in this. Dr. Porter suggested that all butchers should be registered, while Professor Leiper proposed that they should be in possession of a meat inspector's certificate. This, of course, would be subsidiary to a policy which would insist on the provision of central public abattoirs under municipal control, and providing facilities for adequate *ante-mortem* as well as *post-mortem* examination by properly qualified veterinary officials. Such meat would be stamped, and would relieve butchers of any further responsibility as to any abnormalities in the meat, excepting, of course, those due to decomposition. Such public control of slaughter would not only eliminate the disadvantages of the private slaughterhouse, but would

¹ *Journal of Criminal Law and Criminology*, February, 1926.

² *The Loom of the Law*. By J. A. R. Cairns. Third edition. London: Hutchinson and Co. 1925.

enable more adequate use to be made of by-products, and so provide for more economical working and cheaper and better meat.

DÜSSELDORF HEALTH EXHIBITION.

At Düsseldorf there is a health exhibition, which is to remain open until October. It is called the *Gesolei*, the three syllables of this coined word being abbreviations of the German expressions for health culture, social welfare, and physical training. The object of the exhibition is to disseminate knowledge on these three subjects amongst the people; the proposal to hold the exhibition appears to have come from Dr. Arthur Schlossmann, who conducts a children's clinic in Düsseldorf, and has devoted much time to the supervision of the exhibition. The grounds cover an extensive area on the banks of the Rhine, and a "Lilliput" railway runs round the whole enclosure. The exhibits give a very complete display of State and municipal social services in Germany. In one pavilion there are coloured pictures, diagrams, and models arranged to display the activities of the *Krankenkassen* (nearly corresponding to our approved societies) and other bodies under the health insurance schemes. Various coloured cardboard cylinders show the enormous increase in the number of insured persons in Germany, the relative amounts of money contributed by the employers and the employed, and the revenue formerly derived from investments. It is interesting to note that as the result of the period of inflation the whole of the income from investments disappeared; but last year a proportion of the loss was recovered from the State, which does not normally contribute to the insurance fund. The medical profession also has a pavilion, wherein the increase of insured persons is depicted in perhaps less glowing colours. It appears that in Germany the proportion of the insured to the non-insured population has increased from 20 to 80 per cent. during the last decade or two. The pavilion of the trade unions is decorated with much labour literature of various shades of red and pink, and with a statue of a man trying to wield a sickle and a hammer at the same time. There is an interesting little clinic for the treatment of children by sunlight; and a building fitted up as wards for infants, in which real nurses have live infants under their care. The German spas have a pavilion, with pictures of the scenery in which they are situated. There is an exhibition of anatomical specimens prepared by a process which renders the tissues transparent; preparations of this kind were shown in the Pathological Museum at the last Annual Meeting of the British Medical Association. It may be doubted whether these are particularly illuminating to the lay public in search of health; in any case, pictures of hydrocephalus and other monsters do not seem suitable exhibits for prospective mothers. A small room full of obstetric and gynaecological specimens is labelled as unsuitable for the young; but large entrances without doors afford a fair view to the prurient youngster. The rest of the exhibition contains the usual trade articles, from baths to ambulances, which can in any way be associated with health. The buildings of the exhibition and the pictorial representations in the galleries are somewhat uncouth; but perhaps the artistic sense is hardly to be expected in structures and designs which are so ephemeral.

THE INNERVATION OF THE PYLORUS.

A RECENT issue of the *Journal of Physiology* (vol. Ixi, No. 1, p. 28) contains a paper by E. D. McCrea and B. A. McSwiney, from the department of physiology of the University of Manchester, which throws some light on the much vexed question of pyloric stenosis. The research was directed to ascertain the effect of stimulation of the vagi on the pyloric region of the stomach. It was shown that

vagal branches actually reach the pylorus from the hepatic branch of the left vagus. Stimulation of this nerve in both the cat and the dog leads always to the production of peristaltic movements, and such movements, if already present, are augmented. The force of the movements is dependent to some extent on the strength of the stimulus. The movements are always of the peristaltic type, and in this differ from those of the body of the stomach, where they may be of a tonic or rhythmic character, or both. The movement elicited in the pylorus is always of peristaltic type, no matter what may be the degree of distension of this part of the organ. This observation would suggest that the cause of congenital hypertrophic stenosis is to be sought in the factors that bring about an increase of nervous stimulation. This increase could act through the intrinsic nerve plexuses of the stomach, which are as well developed here as elsewhere in the gut. The exact relation of these to the extrinsic nerves is not really known, but the evidence, so far as it goes, suggests that the vagus terminates on both plexuses.

TRUDEAU SANATORIUM.

THE changes that have been introduced into the modern treatment of pulmonary tuberculosis as the result of the careful study of recent years are indicated in the forty-first annual report of the Trudeau Sanatorium, at Saranac Lake in the Adirondacks. When this institution first opened its doors only patients with the disease in its earliest stages were admitted, because these alone were considered to be curable or even susceptible of any marked improvement. In the present day a larger proportion of patients with more advanced tuberculosis can be admitted as suitable for sanatorium treatment, many of them being confined to bed; whereas in the past only some 10 per cent. of the patients at any one time were treated by rest in bed as a regrettable necessity, now at least 30 per cent. are so treated as a valuable routine measure. In early days the sanatorium resembled a boarding-house where boarders were under a mild supervision; it is now more like a cottage hospital, for one-third of the patients are kept in bed. The Trudeau Sanatorium has a daily average of 170 patients, and about fifty infirmaries beds are in constant occupation. The new Ludington Memorial Infirmary was opened on April 9th, 1925, adding thirty-two beds for this type of treatment. Over 500 patients were dealt with during 1925, and 330 were discharged, yet the waiting list continues long and there is serious delay in admission. The total number of patients that have been treated in the institution will soon exceed 7,000. The statistical department of the sanatorium is in communication with over 2,000 old patients, many of whom are in active employment; this indicates the value of sanatorium treatment in resending human lives at a productive age, and not as a merely palliative procedure.

CORNS.

MAN—and still more woman—has chosen for many generations to maltreat his feet, and he has to pay the penalty in the shape of corns, callosities, and too deformities. For although Nature gives each normal infant a fair and undeformed start, boots and shoes soon have their way with most of us. Hence the need of chiropodists, and of instruction for those who would become corn-curers. For such a purpose Mr. E. G. V. Runtig's little book *Practical Chiropody* may be taken as a safe guide. In it the learner will find sound advice and clear statement. Mr. Runtig has also written in the members' diary of the Incorporated Society of Chiropodists a definition of the term and a statement of the aims of the

Practical Chiropody. By E. G. V. Runtig, F.R.S.Ch. London: The Scientific Press, Ltd. 1925. (Cr. 8vo, pp. ix + 164; 7 plates. 5s. net.)

calling. "A chiropodist," he says, "is one who is fully equipped to undertake the surgical and mechanical treatment of such abnormalities as corns, callosities, and warts; to ameliorate the conditions produced by abnormal nails; and by judicious padding and protection to bring comfort to enlarged and misplaced joints." Although the last phrase is rather ambiguous, and we are in doubt as to the nature of a misplaced joint, the modest aims of the chiropodist are thoroughly laudable, as long as he realizes his limitations and knows when to send his patient to the surgeon. We gather from the published statement of the objects of the society that it is the dissemination of just such knowledge with which it largely concerns itself, at the same time as it helps to render valuable services to the poor in the foot hospitals and clinics which are established in London, Manchester, Edinburgh, Leeds, and Yarmouth. The ethical rules of the society breathe the spirit of the Hippocratic oath, and while we wish that an etymologically more rational name than chiropodist could be adopted, the society has our good wishes. This is a literal age, in the sense that the custom is rife and growing of signifying things and people and associations by their initials. For our readers' information, then, we point out that the letters "F.I.S.Ch." stand for "Fellow of the Incorporated Society of Chiropodists."

THE CHARAKA CLUB.

THERE are many medical clubs, some nutritional, others instructional as well as friendly, but few so interesting as the Charaka Club of New York, with its intriguing name, taken from the Hindu sage, the Hippocrates of India, and its appropriate motto, "Posta multa virtus opora laxare solet." The club publishes proceedings in a limited edition of 500 copies, and the sixth volume of these has now appeared five years after the fifth, which was noted in our columns (1920, i, 16). From it we gather that the club contains nineteen members, some of whom come from Boston (Professor Harvey Cushing), Philadelphia (Drs. F. R. Packard and T. McCrae), Baltimore (Professor W. G. MacCallum), and Washington (Dr. Fielding H. Garrison). The club was founded in 1898 by a group of New York physicians to afford opportunities of artistic, literary, and historical recreation. The new volume contains fifteen separate contributions, four of which are short poems, one translated from his native Hungarian by the late Dr. Arpad G. Gester (to whom separate tributes are paid by Dr. L. S. Pilcher and Dr. B. Sachs), a sonnet by Dr. C. L. Dana, to 'Chio as the muse' of historical medicine, and two by Dr. Frederick Petorsen. The last named appropriately contributes an appreciation of Dr. Henry Head's poems, some of which appeared during the war in the *Yale Review*, and apropos of his editorship of *Brain* remarks: "This apt juxtaposition of words to many light-minded among us seemed to be what the American columnist calls 'aptronymic'—like Philpott the brewer, Bowowski the dog-fancier, Mrs. Catt the leader of women." One of the staunchest and most graceful supporters of the club is Dr. C. L. Dana, the contributor of ten articles in its six volumes; writing on Dr. John Ursinus, the Father of Opothecrasy, he sets forth as a proper and pleasant function of a society devoted to the history of medicine and its artistic fringes the recording of men who have done the smaller things in life; he mentions that he read papers on John Mason Good and Thomas Lodge, but the reader has a right to feel defrauded when he learns that these were never published in the club's volumes. Ursinus, "Medical Doctor and Poet Laureate" of Verona, wrote in 1541 "a description of certain animals and their medicinal uses," thus preceding by

120 years J. Belcher's book on similar lines in 1663. Dr. G. L. Walton writes in a humorous vein three articles, the first of which is entitled "The cogitations of a crank who is trying to reform." The story of John Baskerville and his activities, especially his press, is told by Dr. F. S. Moara, who also contributes a scholarly and well written account of Demokedes the Krotoniote and contemporary of Pythagoras and Alkmaion in the sixth century B.C. He practised medicine with such eminent success in Aegina that Athens bid for and secured him until he was similarly lured to Samos by Polykrates, with whom he was taken prisoner, and eventually after various experiences he became medical attendant of Darius. He antedated Hippocrates by a hundred years, and was described by Herodotus as the best skilled physician of all living men. The got-up of this volume is admirable, and well befits its contents.

THE COLYER PRIZE FOR DENTAL RESEARCH.

At the annual general meeting of the Section of Odontology of the Royal Society of Medicine on May 31st a presentation was made to Sir Frank Colyer in recognition of his devoted services as honorary curator of the museum for the past twenty-five years. The president, Mr. Lewin Payne, said that when Sir Frank Colyer commenced these duties the odontological museum was housed in the premises of the Dental Hospital in Leicester Square. Later the museum was moved to Hanover Square, and later still to the Royal College of Surgeons in Lincoln's Inn Fields. Sir Frank Colyer had been most assiduous in arranging and cataloguing the specimens, and the museum might now claim to be the best odontological collection in existence. It was felt among his friends that after a quarter of a century of such service on the part of Sir Frank Colyer some recognition should be made, and as the result of an appeal to members of the Section rather more than £200 had been raised. With this money it was decided to establish a prize, to be called the "Colyer Prize," to encourage research in dental science amongst young dental practitioners—a purpose entirely in keeping with the ideals Sir Frank Colyer had always advocated. He therefore, in the name of the Section, presented the cheque to Sir Frank Colyer, together with a parchment commemorating his services. Sir Frank Colyer, after a suitable acknowledgement of the honour done him in associating his name with the prize, and after recalling some of the early incidents of his curatorship, handed over the cheque to Sir StClair Thomson, president of the Royal Society of Medicine, as representing the council of the society, whose sanction will be necessary for the arrangements for the prize, which have not yet been finally decided. Sir StClair Thomson said that he did not think it would be possible to point to a better example in London than Sir Frank Colyer of a dental surgeon who had been a help to his profession. While it was true that it was the work which counted and not the applause, at the same time, as Charles Lamb said, it was very pleasant to do good by stealth and get it found out by accident, and when in this case the good that he had done had been found out by a man's own colleagues, who were the best judges of the worth of his service, it was all the more gratifying. He would have much pleasure in transmitting to the council of the society the amount collected for the prize.

We deeply regret to receive the news, as we go to press, of the death of Lieut.-General Sir William Leishman, K.C.B., K.C.M.G., F.R.S., the very distinguished Director-General of the Army Medical Service, who was to have presided over the Section of Pathology at the forthcoming Annual Meeting of the British Medical Association at Nottingham. A memoir will appear in our next issue.

¹ The Proceedings of the Charaka Club. Vol. VI. New York: Paul B. Hoeber, Inc. (Roy. 8vo, pp. 145; 6 figures 4 dollars net.) Copies of vols. III, IV, and V can be obtained at 4 dollars each. 500 copies published for members of the club and their friends.

NINETY-FOURTH ANNUAL MEETING of the British Medical Association, NOTTINGHAM, 1926.

THE ninety-fourth Annual Meeting of the British Medical Association will be held at Nottingham next month under the presidency of Mr. R. G. Hogarth, C.B.E., F.R.C.S., senior surgeon to the Nottingham General Hospital, who will deliver his address to the Association on the evening of Tuesday, July 20th. The Annual Representative Meeting, for the transaction of medico-political and administrative business, will open on the previous Friday, July 16th. The sectional meetings for scientific and clinical work will be held on Wednesday, Thursday, and Friday, July 21st, 22nd, and 23rd. The names of the officers of the thirteen Sections are published in the SUPPLEMENT this week, together with the provisional programme of arrangements for the Annual Meeting. On the last day of the meeting (Saturday, July 24th) there will be excursions to places of interest in the neighbourhood, some of which are mentioned in the article printed below. Other descriptive and historical notes on Nottingham and the neighbouring country have appeared in the JOURNAL of December 5th, 1925 (p. 1081), January 23rd, 1926 (p. 158), and March 20th (p. 541).

HOUSES, TOWNS AND VILLAGES IN THE NEIGHBOURHOOD OF NOTTINGHAM.

BY

E. L. GUILFORD, M.A.

GREAT houses always have an attraction for modern people. Perhaps this is because nowadays no one thinks of building a Chatsworth or a Blenheim even if he can afford to do so. We are content with something much more serviceable than the vast series of uncomfortable rooms which so often are better suited to a museum than a dwelling place. In the course of a fairly wide intimacy with the great houses of this country the writer can remember few rooms which have any pretensions to real comfort. Years ago I remember exploring a famous house, and after being shown room after room heaped with the gathered treasures of many centuries, I was allowed to enter a small room in which, I was told, the family spent most of the time. It was quite small, but it was comfortable, and did not give the impression that it had been built round a draught.

Houses are famous for various reasons. Some are renowned for their architecture, some for the beauty of their site, some for their associations. There are a few which are famous for all three, and of these in this district pride of place goes to Haddon Hall, with, perhaps, Newstead Abbey following very closely after. Some, perhaps, will place Chatsworth very high in the list, but, after all, any such order must be determined largely by personal preference, and when all is said and done it is impossible to compare one house with another. Chatsworth and Haddon are both gems, but they differ so much in every way that a comparison is impossible.

It is quite out of the question to attempt any description of even a tithe of the large houses in Nottinghamshire, Derbyshire, Lincolnshire, and Leicestershire. The majority of them are private houses, and are never shown to the public. There they stand, often on the top of a slight slope, looking proudly over a rich green well wooded park. Now and then we come across a park surrounded

by a wall or palings, but though our road seems to take us all round it, yet we never get a glimpse of the house.

Every stranger visiting Nottingham on a sight-seeing holiday takes an early opportunity of going to the Dukeries. This is a part of Sherwood Forest which has been enclosed. Here are the three great estates of Welbeck, Clumber, and Thoresby, owned respectively by the Dukes of Portland and Newcastle, and Earl Manvers. The latter is a descendant of the Dukes of Kingston, so that the title "Dukeries" is not really a misnomer. These great estates are for the most part open to visitors, though of recent years restrictions have been imposed

because of the fact that this valuable privilege has been seriously abused.

Welbeck is a treasure-house, and well worth a visit for its art treasures. Its associations with Horace Walpole, Lord George Bentinck, and the eccentric fifth Duke of Portland would take far too long to tell here. Clumber House and Thoresby have not so much to show as Welbeck, but their associations are of great interest. Rufford Abbey, the seat of Lord Savile, is only a few miles away from the Dukeries,

and is generally included with them in the popular mind. Here there was a great Cistercian foundation, of which the refectory remains incorporated in the present building. Rufford is not open to visitors, but the main Nottingham-Ollerton road passes through the Rufford woods and by the beautiful entrance gateway, from which a glimpse of the Abbey can be seen.

Just on the outskirts of the city of Nottingham stands Wollaton Hall, certainly the most remarkable piece of domestic architecture in this district. Built in the middle of Queen Elizabeth's reign, this extraordinary example of Renaissance architecture is a reminder of the wealth which the great territorial magnates possessed in the past. It is also interesting because it was largely paid for out of

CHATSWORTH HOUSE AND BRIDGE.
(Photograph by Drinkwater, Nottingham.)

the sale of coal from the Wollaton pits. This hall and park have been acquired recently by the Nottingham Corporation, and the hall will be used as a natural history museum.

In the north of the county there are a number of large houses, such as Worksop Manor and Serlby Hall, but these are not in any way show places. Just over the borders of Leicestershire is Belvoir Castle, the seat of the Duke of Rutland. Standing on a well wooded hill which commands wide prospects over the Vale of Belvoir and the valley of the Trent, the castle has been described as the "lordliest place in England" with the exception of Windsor Castle. Here a castle was built by the standard-bearer of William the Conqueror, and here the Dukes of Rutland have lived for many years. There can surely be few more beautiful spots than the Belvoir woods, in which the public is free to wander within certain very wide limits. These woods are full of little nooks and corners beloved of picnic parties, and in the spring and early summer they are certainly a joy to behold. Of the castle itself little need be said. It is not open to visitors as a rule, but since the present Duke has decided to live at Haddon Hall, in Derbyshire, it is possible that Belvoir Castle may be more accessible than in the past.

Four houses stand out pre-eminently in Derbyshire: Chatsworth, Haddon, Hardwick, and Wingfield. The reputation of the first two is national. Both are interesting for themselves, for their contents, and above all for their associations. Hardwick Hall recalls to us Bess of Hardwick, a "character" if ever there was one, while at Wingfield Manor, now a ruin, we meet the memory of Mary Queen of Scots, who spent much time here, as she did at Chatsworth.

In each of these Midland counties there are a large

In Nottinghamshire there is Newark, one of the most picturesque towns in England. The ruins of the castle of the Bishops of Lincoln and the magnificent spire of the parish church, taken together with the quaint narrow streets and the handsome market-place, make Newark a joy to any observant traveller who loves the past. The memories of its loyalty to the King during the Civil War still cling to it, and we are still reminded that it was as a Conservative member for Newark that Mr. Gladstone

first entered Parliament. Here, too, Lord Byron had his first volume of poems printed. Situated on the Fosse Way and Great North Road, Newark has reaped to the full the rich harvest accruing from the all-penetrating motor car. Worksop is another little town that is full of charm. Well known for its proximity to Welbeck Abbey, it has in its Priory Church and perfectly preserved Gateway a relic of the past that is well worth a visit. Mansfield and Retford are modernized out of all

recognition, and have little to show to visitors beyond a display of commercial energy that is causing them to grow with considerable rapidity.

Derbyshire has a large number of towns of interest. Chesterfield has been industrialized, but Buxton is still a very respectable inland watering place of the class of Cheltenham and Leamington, though much more beautiful than either. Standing as it does nine hundred feet above sea-level, it is a favourite resort for winter sports. The Matlocks are very popular, but owing to their proximity to Nottingham and Derby they have become the resort of many excursionists, and are no longer visited so much by those who seek a quiet and peaceful holiday. Melbourne and Ashbourne are two very delightful old-world towns with many historical associations and much that is quaint in their domestic and ecclesiastical architecture. Ashbourne is suitably placed for the exploration of the beauties of Dovedale, but it should be borne in mind that some of the lesser known dales in Derbyshire are very well worth visiting. It is here that the good walker scores over the

NEWSTEAD ABBEY. (Photo by Drinkwater, Nottingham.)

HADDON HALL. (Photo by Drinkwater, Nottingham.)

number of houses, many of them of great size, which are not known to the general public because they are, and always have been, private residences—many of them in the possession of one family over a long term of years. It is impossible to deal with these in the short compass of such an article as this, and readers must be referred to the detailed guide-books which exist.

When we turn to the towns and villages in these Midland counties we find that there is much to say. Apart from the county towns, there are many smaller places which have much to attract the visitor.

WOLLATON HALL. (Photo by F. Frith and Co.)

traveller dependent upon a bicycle or motor car. Derbyshire has very many charming villages scattered up and down its length. There is Baslow, close to Chatsworth and Repton, south of Derby, and Eyam, famous for its connexion with the Plague—in fact, the number is far greater than can be mentioned here.

Lincolnshire has such a large area and so many little market towns that it is impossible for any visitor to see them all. The south of the county is certainly more beautiful than the north. Here we have the extensive bulb and potato farms, and some of the most beautiful churches

in the whole country. One village that no one should miss is Tattershall. Here is a fifteenth century brick castle that has been restored in the best manner during the last decade or so. Few, if any, finer examples of brickwork survive in this country.

Leicestershire is above all things a hunting county. Its villages are quietly charming—in fact, the whole district is characterized by gentle green slopes and pleasant streams. Loughborough is the second town in the county and is now a very busy little place. Charnwood Forest, with its granite hills and open moorland, is a beauty spot second only to the woods of Sherwood Forest. The geologist and the naturalist will find much to occupy their attention, and the pedestrian will find all he can wish for in the way of views.

Visitors who make Nottingham their headquarters will naturally have much more opportunity of seeing the villages which lie adjacent to their resting place. Edwinstowe and Ollerton are jumping-off places for the exploration of Sherwood Forest, and not far away is a village

which seems to have been forgotten by time. Laxton lies on the top of a hill, well off the beaten track. Here are the earthworks of a large castle, and here the primitive system of three-field agriculture still remains. The village common is unenclosed, and to see the wide, unhedged fields takes one back a couple of centuries.

On the banks of the Trent are many charming villages beloved of the riverman and fisherman—villages where life glides by as peacefully as the river. Quite near to Nottingham is Clifton, which keeps its old-world appearance and is the most popular picnic resort for the city. Near by is Gotham, a rather unattractive place, whose fame rests on its connexion with the famous fools. In the Vale of Belvoir are many delightful spots which are gradually being popularized by the motorist.

Taking these Midland counties altogether there is much to attract the visitor, though I am afraid many are content to pass through this district without pausing to discover the somewhat hidden beauties that lie off the highways.

NEW SURGICAL DEPARTMENT AT EDINBURGH UNIVERSITY.

On Friday, June 11th, as part of the celebrations of the bicentenary of the Medical Faculty in the University of Edinburgh, the Secretary for Scotland will open formally the reorganized surgical department. This department will in futuro comprise two parts—a department for teaching and a department of surgical research; these are housed in separate but contiguous buildings. The teaching department has been reconstructed by internal changes in the portion of the New University Buildings, which has for several generations of students been associated with the teaching of surgery. On the ground floor are three

GROUND FLOOR PLAN.

FIRST FLOOR PLAN.

FIG. 1.—Research Department: Plan showing the two floors and entrance to gangway leading to Teaching Department.

rooms intended for the preparation of museum specimens, and a frigidarium for the preservation of bodies used in the class of practical surgery; here also the various electrical, air pressure, suction, and freezing apparatus are installed. On this flat there is in addition a well equipped photographic dark-room in which are contained apparatus for making lantern slides by reduction, for copying illustrations in textbooks, and for microphotography, along with the usual requisites for development of photographs. An electric lift communicates with the theatre and adjoining rooms used for teaching. Three practical rooms, for the teaching of operative surgery to the class in small sections and for holding various demonstrations, have been constructed out of the lower part of the old surgical theatre, and a fine museum of surgical pathology, which is already well provided with specimens, is laid out with a lower floor and gallery, and is well lighted from the roof and by means of brilliant electric lights. A comfortably furnished students' common room is provided where students may read, and at their leisure inspect demonstration specimens laid out on a table running round the room. There is also a large retiring room for the professor and assistants where examinations will be conducted. A new theatre, capable of seating 240 students and well lit from the roof, has been provided by constructing a new floor over the practical rooms, so as to utilize the upper

half of the old theatre, familiar to many generations of former Edinburgh students. Part of the fitting of this theatre has been provided by the generosity of a relative of the late Professor Alexis Thomson, and on its wall is placed a memorial bas-relief in bronze of the late professor, designed and executed by Mr. H. S. Gamley, R.S.A.

A new building to the rear of the former university buildings houses a large suite of rooms for original research in practical surgery, surgical pathology, bacteriology, and biochemistry in its relation to surgical subjects. On the

ground floor are situated a common room and library for the use of the research workers, and a large and well equipped laboratory with places for twelve persons engaged in research. The benches provided for the research workers are furnished with various devices for electric lighting, heating, water, and taps by which air under pressure or suction can be obtained. By an ingenious arrangement, the working table, with its drawers provided for each worker, is readily removable, so that in the event of a worker being prevented for some time from utilizing his place the whole table can be wheeled away and a new table substituted in its place for another worker. Another in-

genious feature of the laboratory is a large incubator common to all the workers, but provided with separate drawers, each of which is allocated to a different worker, so that the chance of mixing or losing bacterial cultures is obviated. On this flat also are a reception room for specimens and a large bacteriological and section-cutting room, in which laboratory attendants make the various routine investigations required in connexion with the class and work of the department.

On the upper flat of the research department several rooms are provided for the individual research workers specially attached to the department. These include two operating theatres, which have been equipped with special elaboration. Underneath the operating table are terminals

for electric light and power, as well as taps for making connexion to apparatus requiring air under pressure or suction, and an apparatus for supplying intermittent

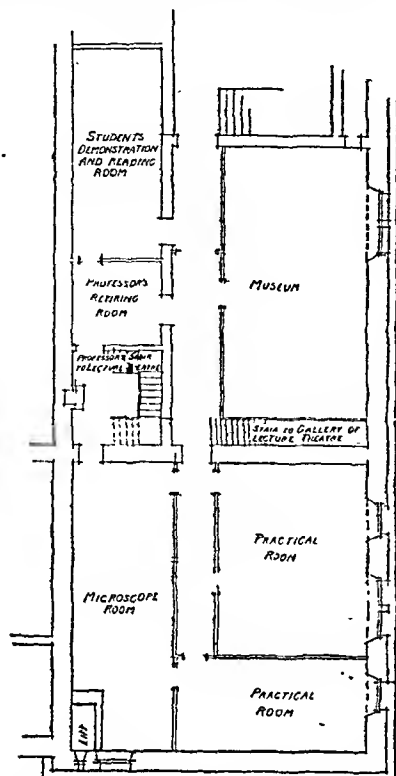

FIG. 2.—Teaching Department: Plan of intermediate floor below Surgical Lecture Theatre (see Fig. 3).

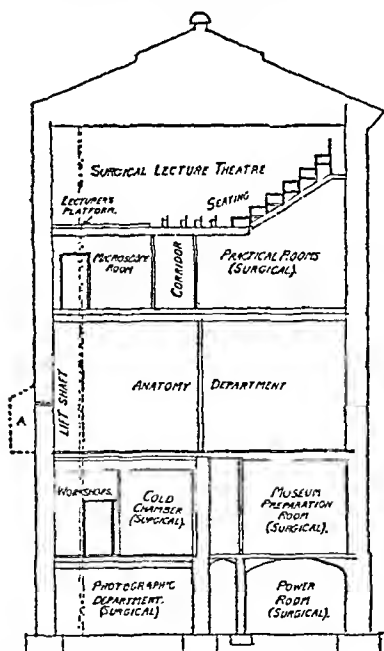

FIG. 3.—Teaching Department: Section showing the connexion between floors and with the Anatomy Department, and indicating, at A, entrance to gangway leading to Research Department.

suction. Taps also supply sterile water and saline solution from a large central sterilizing room. The floors are covered everywhere with india-rubber, and the roof lights, set on a gentle slope, are kept clean by a stream of water which washes away dust from their surface. Light is supplied through an outer glazed roof during the day

and after dusk by brilliant electric lights placed between the outer and inner roof. There are also anaesthetic rooms and recovery rooms, as well as a special room intended for post-mortem examinations. Adjoining the operating theatres is a large and well equipped x-ray room, and in one of the theatres terminals have been fitted, so that x-ray photographs can be taken in connexion with the operating table. A covered gangway connects the teaching and research departments, and a covered stairway leads from the latter to the building which shelters the animals used in connexion with this department and with that of physiology and pathology.

Already it has been found possible to accommodate a number of workers, although the equipment of the buildings has only just been completed. In one room research is proceeding into the nature of the cause of cancer, on the lines of recent work done in London; in another room work is being done on the growth and culture of animal tissues; and in yet another research is proceeding upon the effects produced by administration of various glandular extracts on the growth of young animals. Other workers are engaged in, or about to commence research upon, the lymph drainage of the abdomen, surgical conditions of the pituitary gland, the investigation of the renal circulation, routes of renal infection, the surgical pathology of intestinal obstruction, the conditions of nerve implantation in muscle, the surgery of valvular disease of the heart, the conditions of pleural infection, and the development of cholecystography.

The total cost of fitting up the new research department has been about £15,000, of which £10,000 has been borne by a grant from the general university funds, while £5,000 was provided by the Rockefeller Trustees.

Roba et Vetera.

EDWARD IV'S ARMY SURGEONS.

In 1475 King Edward led what Comines described as the largest, best disciplined, and most perfectly equipped army with which any English king had ever invaded France.

In the College of Arms—better known to Londoners as the Herald's College—there is a manuscript in which the badges and arms worn by the troops and their leaders are duly set forth, together with other interesting information.¹

The editor, F. Pierrepont Barnard, D.Litt., points out that the badges referred to were distinct from the personal arms of the nobility and gentry, and were intended to show to what unit the men belonged, and he suggests that this may have been the beginning of the uniform dress of soldiers. They must have served a similar purpose to the badges adopted by our army in the late war as indications of the divisions to which troops belonged. The daily rates of pay are recorded, and were as follows:

	s.	d.
A duke, one mark	13	4
A marquess	10	0
An earl, half a mark	6	8
A baron	4	0
A knight	2	0
An esquire or man-at-arms (not a knight)	1	0
An archer	0	6

It is of interest to compare the rates of pay of physicians and surgeons with the above. No physicians or surgeons are mentioned in the MS., but Dr. Barnard tells us that in the Tellers' Roll for the first quarter of 1475 it is recorded that a number of them were indentured for this expedition. The King's physician had the pay of a knight (two shillings) and two servants (sixpence each), and the physician and surgeon to the King's body one shilling and sixpence and one assistant surgeon sixpence a day. Seven other surgeons were paid one shilling a day, five more sixpence a day each. The King's secretary, Hatcliffe, and the Clerk of the Council had the same pay as the King's physician. Apparently Maister James (or Jakes) Fryse was the King's physician. He still held that post in 1482, and possibly continued to do so until the King's death in 1483.

Master William Hobbis or Hobbys was the physician and surgeon of the King's body. As such he had received in 1470 a grant of £40 a year. He was evidently well thought of by the Yorkist princes, for after Edward's death he became physician to Richard III at a salary of £64 a year. The names of twelve other surgeons who took part in this expedition are on record, of whom one, "Richard Felde, owre Surgeon," had held office since 1464, and in 1468 was given the no doubt lucrative office of Ranger of Forests in Hampshire. Although the physicians and surgeons had probably to find their own food, yet doubtless the pay was sufficient, seeing that a knight got only the same as the physician.

It may be interesting to compare these rates of pay with those in Cromwell's army nearly two centuries later, as stated by Professor Firth in his book with that title.² The purchasing power of money had much diminished, so that we find that in 1651 the pay of the regimental surgeon was six shillings a day. In Ireland under Cromwell it had been only four shillings, while the two surgeons' mates had half a crown a day. Financial tightness prevented the maintenance of the high rate of six shillings,

and by 1567 it had fallen to four shillings again. General Monck thought that this was too low, and raised it by a device which is characteristic of former times in the services. He put the surgeons on the roll as privates, so that they were enabled to draw nincence a day extra. In 1650, when Cromwell set out for Scotland, each regimental surgeon was allowed £15 to pay for his chest of instruments and dressings and £10 for a horse to carry it. Apparently they had to find their own board and lodging. Dr. Henry Glisson, a brother of the author of the treatise on rickets, was Physician-General to Manchester's army, and he and, later, the Physicians-General to Cromwell and Monck, received pay at the rate of ten shillings a day, while the Apothecary-General received six shillings and eightpence a day.

EXTENSIONS AT UNIVERSITY COLLEGE HOSPITAL, LONDON.

NEW OBSTETRIC HOSPITAL AND NURSES' HOME; NEW EAR HOSPITAL.

THE PRINCE OF WALES visited University College Hospital on May 28th for the purpose of opening the new Obstetric Hospital and the new nurses' home, and unveiling a memorial tablet at the new Royal Ear Hospital, a building which will shortly be ready for use. The Obstetric Hospital and the nurses' home, the foundation stones of which were laid by the King and Queen three years ago, are the gifts of the Rockefeller Foundation of New York, and the Royal Ear Hospital has been built by Lieut.-Commander Geoffrey Dureen in memory of his parents, to whom the tablet was dedicated. These buildings are all extensions of University College Hospital.

In 1920 University College Hospital was selected by the Rockefeller Foundation as offering the best opportunity in the British Isles for placing medical education on a modern basis. For this purpose a gift amounting to £1,205,000 was bestowed upon the medical school and University College, to be expended partly as an endowment fund for medical research and education, partly upon a building programme providing 180 additional beds, to include a new obstetric hospital containing 60 beds, and partly on building an institute of anatomy to improve the facilities for teaching preliminary medical science. The Rockefeller Fund provided for the whole cost of the new buildings, but it has been necessary to raise by voluntary subscription the sum of £180,000 as an endowment fund for the 60 beds in the Obstetric Hospital. Thirty of these beds are devoted to obstetrics and thirty to gynaecology. A senior member of the medical staff will be resident in the hospital, and will combine the work of undertaking complicated cases of labour with that of teaching students. The students on duty will also have the advantage of living in a students' house which is under the same roof as the hospital, and so they will be enabled to be on the spot when difficult cases occur. The whole of the obstetric work of the hospital will be under the care of a special director. The building, of which we publish a photograph, is a large and handsome structure designed by Mr. George Hornblower, architect, with Mr. Michael Waterhouse, of the building extension and reconstruction scheme. The new nurses'

home provides accommodation for about 250 of the staff. The Royal Ear Hospital, which was formerly situated in Soho, is now being rebuilt as part of the University College Hospital block. The acquisition of the new site and the construction and equipment of the hospital has cost £65,000, and the whole of this sum has been given by Lieut.-Commander Geoffrey Dureen. The hospital will contain 38 beds for in-patients and ample room for the treatment of out-patients. A feature of the hospital is to be a "silence room," with walls impenetrable by extraneous noises, that absolute accuracy and consistent results may be obtained in the examination of patients.

The Prince of Wales was received on arrival by Sir Ernest Hatch, treasurer and chairman of committee of University College Hospital, and by Princess Marie Louise. Sir Ernest Hatch read an address to His Royal Highness in which he detailed the circumstances of the Rockefeller benefaction just described, and the great and successful effort to raise the funds to endow the beds in the Obstetric Hospital. The Prince, before opening the buildings, said that the hospital was entitled to congratulate itself upon having been entrusted with the disposal of the vast sum represented by

New Obstetric Hospital and Residents' Quarters, University College Hospital.

the munificent gift of the Rockefeller Foundation. As a proof of the appreciation of the trust thereby imposed he mentioned the ready generosity with which the obligation on this country to endow the beds in the new hospital had been met. The large sum required for this purpose had been raised by subscriptions throughout the British Empire. Each of the Dominions, as well as Scotland, Wales, the English counties, and the main commercial interests and industries in the country, had done its share, and for this happy result thanks were due to the Ladies' Appeal Committee under the chairmanship of Princess Marie Louise, and to the chairman of University College Hospital, Sir Ernest Hatch, to whose untiring efforts the Prince paid a high tribute. He also expressed the hope that the appeal committee would not be disbanded, but would continue to watch over the interest and welfare of the respective wards and beds. Finally the Prince announced that a friend of the hospital wished

to mark that international occasion by making a donation of £10,000 towards the appeal which will shortly be launched for the general maintenance fund of the hospital.

Lord Burnham stated that each bed in the new Obstetric Hospital required a maintenance fund which, when capitalized, would represent about £3,000. The sum of £180,000, which was necessary for this purpose, had been collected, and the small cost involved in the collection had been offset by the interest on the earlier contributions.

At the request of Sir George Blacker, dean of the medical school and senior obstetric physician, the Prince then, after a fanfare of trumpets, declared open the Obstetric Hospital, and the fanfare was repeated when Princess Louise asked His Royal Highness to declare open the new nurses' home. In the course of a visit of inspection to the new hospital, when the members of the medical staff were presented, the Prince named one of the eight wards "The Prince of Wales Ward." Other wards are named after the King, the Queen, the Empire, and the City of London. In the "Friendship" Ward a bed has been endowed by the medical profession. The Prince chatted with some of the patients, and on behalf of the Queen presented a cot for each ward. He also inspected the nurses' home, and finally proceeded to the Royal Ear Hospital, where again he was received by the members of the medical staff, and in the entrance hall unveiled a memorial tablet bearing a Latin inscription to the father and mother of the donor of the new building.

The American ambassador was unavoidably prevented from being present at the ceremony. He was represented by Councillor F. A. Stirling.

Union of South Africa.

[FROM OUR CORRESPONDENT IN JOHANNESBURG.]

MEDICAL, DENTAL, AND PHARMACY BILL.

SINCE union in 1910 consolidating measures of various kinds have been introduced. Thus the Public Health Act, 1919, repealed no fewer than thirty-nine laws previously in force in the various provinces. By that Act the Department of Public Health of the Union was established, and its functions prescribed; the duties and powers of local authorities in regard to health matters were indicated; measures were introduced for the prevention and suppression of infectious diseases; for the control of public water supplies, meat, milk, and other articles of food; and for the prevention of nuisances in regard to dwellings and premises.

A want long felt is an Act to consolidate and amend the laws in force in the Union relating to medical practitioners, dentists, druggists, midwives, nurses, and masseurs. A bill of this nature has been before Parliament on several occasions, but it has had a troubled history. In 1923 the Medical, Dental, and Pharmacy Bill actually passed the second reading, and was then referred to a Select Committee, more particularly because of the one clause which has been the cause of much controversy. This clause deals with unqualified practitioners of medicine. In the Select Committee of 1923 one prominent member actually moved that faith-healers, hydropaths, naprapaths, neuropsychics, and other strange folk should be exempted from the penalties inflicted upon unlicensed practitioners who professed to diagnose and cure disease. This amendment, though seriously discussed, was rejected.

The bill at present before the House is, then, a consolidating measure, and is a logical outcome of the Act of Union. Sixteen laws will be repealed. As the Minister of Public Health, in moving the second reading, pointed out, it was the fruit of consultation with, and represented the agreed opinions of, all the professions and callings concerned. At the present moment there are seven different bodies exercising supervision over the medical profession. The bill will establish one South African Medical Council and one South African Pharmacy Board. All persons now registered will be automatically transferred to the new register; but those who cannot be registered now will not be registrable if the new bill becomes law. The most

troublesome clause in the bill has again proved to be the one dealing with unregistered persons. It reads:

"Any person not registered as a medical practitioner who (a) for gain, hire or reward, direct or indirect, or for the expectation thereof, practises as a medical practitioner or performs any act pertaining to the calling of a medical practitioner; or (b) professes to pursue, or by advertisement, representation or any means whatsoever holds himself out as pursuing the calling of a medical practitioner, or pretends to be or takes or uses the name of medical practitioner or any name, title, description or synonym, calculated to lead persons to infer, that he is a medical practitioner, or holds a degree, diploma or other qualification as a medical practitioner, or is a doctor of medicine, physician, surgeon or accoucheur, or that he is registered as a medical practitioner under this Act; shall be guilty of an offence and liable on conviction to a fine not exceeding one hundred pounds."

On each occasion that the bill has been before the House attempts have been made by persons practising the so-called cults to obtain rights which they did not possess before. The Minister was careful to point out that no one who possessed professional rights under existing legislation would be deprived by the bill of such rights. The position of persons practising certain cults would remain practically unaltered. They would not receive rights which they had not hitherto enjoyed, but neither would they lose any rights. The Minister (the Rev. Dr. Malan is a doctor of divinity, not of medicine) further pointed out that there was in principle no opposition between the methods of healing employed by the medical profession, on the one hand, and at least some of the cults. It was very often represented that the medical profession healed through medicine, and that those practising the cults healed without medicine—that they were drugless healers. That description was a false one. All the methods adopted by the drugless healers were well known to the medical profession, and were to a very large extent practised by the profession. But these were not the only methods of healing. When they were so deemed they very often became dangerous. Exponents of these cults would be allowed to practise, but if they did so for hire or gain it would have to be under proper medical supervision. The law held that no person not properly trained, qualified, and certificated was permitted to handle delicate electrical machinery, because it was something that might mean life or death. The human body was much more complicated and delicate machinery, and it was only right that people who handled it should be properly trained and qualified.

In the subsequent discussion the interesting feature was the criticism of the bill by the Labourite Minister of Labour (Mr. Boydell). He stated that for a good many years he had urged that the door should be left open, for the practice of their profession, to drugless healers. He himself could testify to the benefits he had derived from drugless healing. He would be guilty of mean ingratitude did he not plead on its behalf. It would be unfair to deprive sick people of a chance of recovering their health in any way they could when other means had failed. Sir Thomas Smartt, an Opposition member, was quick to turn to advantage the difference of opinion between two members of the Pact Cabinet. He then asked the Minister of Labour if he would agree to a man who had not been through any apprenticeship suddenly blossoming out as a skilled artisan. On the whole it appears unlikely that the bill will become law this year, which is very greatly to be regretted.

VELD RODENTS, PLAGUE, AND "TIGER RIVER" DISEASE.

The South African Institute for Medical Research has for some time been conducting investigations into the matter of plague in South Africa, both in the laboratory and in the field. These investigations are under the charge of Dr. J. H. Harvey Pirie, resident bacteriologist, and Dr. Ingram, medical entomologist. Plague has for many years been enzootic amongst certain of our veld rodents. At what stage these animals first became infected is uncertain. But the disease has spread amongst the gerbilles until at the present time some fifty thousand square miles of veld are affected. Presumably rats at some time escaped from an infected ship at the coast and conveyed the disease to our wild rodents.

Ridding so large an area of sparsely populated country of rodents is a wellnigh impossible proposition. Very

elaborate precautions are everywhere being taken to prevent the domestic rats of the towns becoming infected. Recently the discovery of a new disease of rats—the so-called "Tiger River" disease—has encouraged the belief that a valuable weapon in the anti-rodent warfare had become available.

Tiger River disease, the gross pathological lesions of which in the liver and spleen are similar to those of plague, is caused by a Gram-positive, motile bacillus which has apparently not been previously described. Cultures sent to the Lister Institute could not be placed in any of the existing groups. It was first isolated from a dead gerbille sent in for plague examination. Its pathogenicity for most animals is low. Guinea-pigs and rabbits are infected with difficulty, and then only when injected with the infective material. It has not been found possible to infect larger mammals such as cats, dogs, or monkeys. But the smaller veld rodents are easily infected experimentally either by feeding or injection. The germ is capable of producing severe mortality in these small veld rodents among whom plague is enzootic. It is hoped, therefore, that it may prove of great value in the attempts to exterminate these animals in certain regions. An experiment in this direction was made in Kroonstad. A section of the veld was enclosed with closely meshed wire netting, and infection with the Tiger River disease was introduced into the enclosure. The disease spread rapidly, and after a while examination showed that the rodent population of the area had been almost completely wiped out. A disease which is harmless to the larger mammals and is deadly to small rodents will be of obvious value. But unfortunately it is apparently only the veld rodents which are highly susceptible. The ordinary house rats seem to be immune. Inquiries have already been made at the South African Institute for Medical Research by enthusiastic overseas medical officers of health, who hoped that this might prove to be a means for dealing with domestic rodents; but they have had to be disappointed.

Some days ago doubt was expressed as to whether the disease enzootic amongst our veld gerbilles was in reality plague, and questions were asked about the matter in the House of Parliament. The plague authorities have, however, never been in any doubt concerning the subject. The only two diseases which might possibly be mistaken for plague, and which affect both man and wild rodents as this disease has been doing, are the diseases known as melioidosis and tularaemia. Neither of these diseases has ever been reported in South Africa. Melioidosis is confined to the Malay peninsula, and tularaemia apparently does not exist outside the United States of America. In both diseases there are fundamental and striking differences between the bacillus responsible for them and that responsible for plague. The publicity which has been given to the speculations of uninformed persons is particularly unfortunate and dangerous. The danger lies in the possible relaxation by the general public of the usual antiplague precautions.

THE STAFF OF THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH.

The staff of the Routine Laboratories of the South African Institute for Medical Research is being considerably strengthened by the appointment of four additional officers. These appointments are to a large extent the outcome of an arrangement recently entered into between the Institute and the University of the Witwatersrand, under which the Institute became officially responsible for the staffing of the departments of pathology, bacteriology, and parasitology in the medical school of the University. Sir Spencer Lister, research bacteriologist at the Institute, recently visited Great Britain with a view to selecting additional officers. As the result of that visit, the following gentlemen have been appointed, and are now on their way to South Africa:

George Buchanan, M.D., Ch.B., D.P.H. Edin., late lecturer in bacteriology, University of Edinburgh, and Special Commissioner and adviser to the Scottish Board of Health on spirochaetal jaundice, has been appointed superintendent of the Routine Laboratories of the Institute.

F. W. Simson, M.B., Ch.B. Edin., late lecturer in pathology, University of Sheffield, has been appointed a senior grade pathologist in the Routine Laboratories.

W. K. Duncombe, M.B., R.S. Durh., D.T.M. and Hy. Eng., late demonstrator and research student in the department of tropical pathology at the London School of Hygiene and Tropical Medicine, has been appointed a junior pathologist in the Routine Laboratories.

Lancelot W. Barlow, B.A., D.P.H. Camb., M.R.C.S., L.R.C.P., late assistant medical officer of health, Bloemfontein, has been appointed from among local applicants a junior pathologist.

The following officers at present on the Institute staff have been delegated to carry on the duties of lecturers in the medical school of the University of the Witwatersrand:

Dr. A. Sutherland Strachan, lecturer in pathology.

Dr. J. Becker, lecturer in bacteriology.

Dr. Annie Porter, lecturer in parasitology.

Ireland.

MEDICAL REGISTER (IRISH FREE STATE).

SIR JOHN WILLIAM MOORE, M.D., who presided last week at the annual general meeting of Drumcondra Hospital, Dublin, made an announcement with regard to medical registration in the Free State. He stated that an agreement had been reached and would be embodied in a bill which will be brought before the Dail. He began by referring to the proposed amalgamation of hospitals in Dublin, and said that a very considerable sum of money was virtually promised to carry it into effect, amounting to something over a million sterling. It is withheld, he stated, owing to the uncertainty with regard to medical registration in the future in the Free State. He was glad to say that an agreement had been reached which he hoped would be effective. The bill in which it was to be embodied would be brought before the Dail, and would then have to be adopted on the other side of the water. He thought that it would be satisfactory, because it would not meddle materially with the present system by which a young medical practitioner was able to seek his livelihood, not only in the Free State, but throughout the far-flung British Empire. Were that taken away nothing would compensate for it. The *Dail political correspondent* of the *Irish Times* stated in a recent issue of that paper that the final draft of the permanent bill is now in process of completion, and, so far as he could gather, the proposals which it embodied were substantially the same as those submitted on behalf of the profession. The next step was consultation with the General Medical Council. Should that body express its disapproval of the scheme there would presumably be an end to it. It was not anticipated, however, that the General Medical Council would withhold its consent. The doctors' representatives, he understood, would shortly go to London to submit the proposals in their final form to the General Medical Council, which, in its turn, might be expected to make the necessary arrangements for their recognition. It was not believed that corresponding, or, in fact, any legislation would require to be introduced in the British Parliament. It was the intention of President Cosgrave's Government to have the proposed new bill introduced in the Dail before the recess, that a full statement on the subject should be made by the President before the adjournment, but that the bill should not be proceeded with until the autumn. The feeling in official circles would, he added, seem to be that, having waited so long, the new scheme of registration would lose nothing by its non-adoption for at least another six months. The basic suggestion of the permanent legislation would be that the present system of registration on the Register of the General Medical Council would be allowed to stand, but that, in order to give effect to the wishes of the Free State Government in regard to the control of registration and the discipline of medical practitioners a separate Medical Register, with a supervising medical council, would be established in the Free State. Thus a student qualifying at any recognized Free State university or school would be compelled to enter his name on the Free State Medical Register if he wished to practise in the Free State. He need not do so if he intended to

practise outside the Free State; in the latter case he would enter his name on the general *Medical Register*. It would be almost essential for him, however, to have his name inserted on both registers, since before he could obtain a post or practise either in England or the Dominions he would need to have some practical experience in hospitals or as an assistant to an established medical practitioner.

Scotland.

ST. ANDREWS POST-GRADUATE COURSE.

The staff attached to the James Mackenzie Institute for Clinical Research at St. Andrews have arranged to hold a post-graduate course which is to commence on Monday, June 14th, and is to last for a fortnight. The meetings will be held in the Clinical Research Institute at St. Andrews, with the exception of a few afternoon meetings at the Royal Infirmary in Dundee. An introductory lecture will be given by Dr. A. Maitland Ramsay, honorary director of the Institute, on June 14th, at 4 p.m. Thereafter five lectures, each lasting one hour, will be delivered daily until June 29th. Members of the course who wish to carry out practical work in the laboratories may do so at hours to be arranged with the teachers.

ROYAL INFIRMARY, EDINBURGH.

At a meeting of the managers of the Edinburgh Royal Infirmary held on May 3rd the question of a proposed shelter for friends of patients waiting on visiting days for admission to see their friends who happen to be patients in the institution was considered. There appears to be a difficulty between the managers of the infirmary and the City Corporation as to whether the proposed shelter should be erected inside or outside the walls of the institution. The managers are anxious that the corporation should erect a shelter immediately outside the wall to the east of the institution, but there would appear to be no room to do this. On the other hand, the proposal to erect a verandah glass covering inside the institution wall would block a roadway and darken wards in the immediate vicinity. The number of cases waiting admission to the institution on May 1st was 2,360.

GLASGOW DENTAL HOSPITAL.

The report presented to the forty-first annual meeting of the Incorporated Glasgow Dental Hospital held on May 26th showed that 50,297 operations had been performed during the year at the hospital. There had been a profit of £135 on the conservation and extractions departments, and a profit of £607 on the prosthetic department, but the public contributions to the hospital had amounted only to £354. The chairman, Mr. M. Robin, in moving the adoption of the report, stated that the governors were looking out for a new site for the hospital, and funds were needed to start rebuilding operations. Dr. J. Forbes Webster, dean of the hospital, stated that its services were in great demand, but the existing building was quite inadequate when compared with the population and wealth of the city. He said that people in general did not realize the importance of taking proper care of the teeth. It had been said that Britons possessed the worst teeth on earth, and also that Glasgow citizens had the worst teeth in Britain. It was notorious that the teeth of the poorer classes were very bad, and that to maintain the general health of the community much needed to be done for their improvement.

DISABILITY OF DEAFNESS.

The annual meeting of the Mission to the Deaf and Dumb for Glasgow and the West of Scotland was held on May 27th. Sir Steven Bilsland, Bt., presided. The report showed that the expenditure had been £2,139, as against £1,835 for the preceding year, with a debit balance for the year of £171. Sir John MacLeod, Bt., gave a short address, in which he stated that it was not generally realized what a serious disability deafness really was. It was estimated that there were about 1,000 deaf and dumb persons over school age in Glasgow and the surrounding district. Though the active life of blind people was spent

in darkness, their ears permitted them to enjoy the full advantages of speech and music, and they could and did attain public positions, in Parliament for instance, to which deafness was a complete bar. Deafness, on the other hand, cut at the root of every activity except the purely physical. Even when education had done its most and best, the intellectual, social, industrial, and religious life was heavily handicapped. The deaf man could not be expected, even although he was as intelligent as his hearing fellows, to measure himself unaided against them in the struggle of life. It was, therefore, the work and privilege of this institution to afford the deaf all the assistance it could.

England and Wales.

THE COLLEGE OF NURSING.

The new headquarters building of the College of Nursing in Henrietta Street, Cavendish Square, was opened on May 31st by the Queen. Sir Arthur Stanley, chairman of the council, related the history of the College since, in 1916, it began in two rooms lent by the late Sir James Boyton; shortly afterwards it was transferred to No. 7, Henrietta Street. In 1917 the sympathy and practical assistance of the British Women's Hospital Committee were obtained, and in particular that of Lady Cowdray, treasurer of the committee, who gave very active help. The Nation's Fund for Nurses was started to provide an endowment fund for the College and the nucleus of a fund, now known as the Tribute Fund, for nurses in ill health or distress. The Tribute Fund, he said, now amounted to over £100,000, and was carrying on very valuable work in relieving the anxieties and sufferings of sick and aged nurses. The College endowment had now reached about £68,000, but £100,000 was required. (It will be remembered that last week an appeal appeared in our columns—p. 921—for the support of the medical profession in this most necessary undertaking, for which donations are being received at the College by Mr. Comyns Berkeley, the honorary treasurer.) Sir Arthur Stanley went on to explain how Lady Cowdray, realizing the great need of a club for nurses, had bought and furnished No. 20, Cavendish Square, for the use of nurses and other professional women. She had next asked Sir Edwin Cooper to design a building for the College of Nursing to be erected on the site of the gardens and stables of the Cowdray Club. Lord and Lady Cowdray met the entire cost of the club for nurses and the College, including their fitting and equipment; there were three ways of communication between the two buildings, and a roof garden had also been constructed. The State registration of nurses had come about largely as a result of the influence of the College, which was also taking an important place as an educational centre. This side of the work would develop very rapidly with the ampler room and better facilities for teaching now available. The College had also striven to secure better conditions for nurses in hospitals and nursing homes, and a scheme of pensions on superannuation had been drawn up by the College in conjunction with King Edward's Fund and other organizations; it was at present being considered by hospital authorities. Sir Arthur Stanley announced that he had received a letter from Dame Sidney Browne, matron-in-chief of the Territorial Nursing Service during the war, and the first president of the College, enclosing a cheque for £300 to be used for research in respect of the nursing of tropical diseases. Lady Cowdray then asked the Queen to accept the deeds of the building, which Her Majesty handed over to Dame Sarah Swift, president of the College. The Minister of Health in his address spoke of the fine example of practical generosity set by Lord and Lady Cowdray. The improved conditions of the College would enable the profession of nursing to realize still higher ideals and to make more rapid progress in the future. After Sir Edwin Cooper had presented to the Queen a memorial book of the building she declared the building open, and the Archbishop of Canterbury pronounced a benediction. Her Majesty subsequently inspected the building closely, spending a considerable time in the

record room, where the records and present addresses of nearly all the 25,000 members of the College are filed. Other rooms visited included the invalid cooking room, the research departments, and the special rooms for post-graduate courses. The British Medical Association was represented at the ceremony by the Deputy Medical Secretary, Dr. G. C. Anderson.

MANCHESTER ROYAL INFIRMARY.

The annual report of the Manchester Royal Infirmary for 1925 states that there is a need for considerable extension. The present accommodation only provides for the reception of the average number of surgical patients presented each week as cases of accident or emergency; all other patients must be placed on a waiting list, to be admitted in their turn as opportunity offers. At the beginning of 1925, 1,152 persons were awaiting admission, and at the end of the year the number had increased to 1,682. The situation is becoming more acute each year with the increase in the area and population served by the Infirmary. Before any scheme of extension is practicable the accommodation for the nursing staff must be enlarged. The addition of 81 nurses and 28 maid-servants will be necessary if accommodation for 180 more patients is to be provided. At a special meeting of the trustees in June, 1925, it was resolved to appeal for £150,000. It is also necessary to diminish the present working hours of the nurses (day staff 63; night staff 73) to 56 hours a week, and to provide for nurses, massenses, and students of the school of massage, who are at present lodged in premises outside the Infirmary. The existing accommodation for dining and service must be doubled, and rooms for study, lectures, and recreation be obtained. It has long been desired to establish a preliminary training school for fifteen probationers undergoing two months' preparatory work as an introduction to their training in the wards, in order to reduce the serious wastage during this period in consequence of physical unfitness. Future requirements will be anticipated by planning the nurses' home in such a way as to permit of the addition of more stories as required. The fitting and equipment of premises for treatment by artificial sunlight is in progress, part of the existing buildings being utilized. They will form a section of the x-ray, massage, and electrical department. During 1925 a research laboratory for clinical investigation was opened at the Infirmary in conjunction with the University. It is hoped that an increased number of valuable contributions to medical science may result, especially in the case of cancer, of which no fewer than 890 cases received treatment during 1924. The number of new casualty cases treated in the accident room at the Royal Infirmary, and at the central branch, has increased from 19,491 in 1922 to 26,347 in 1925, and the daily average number of such cases is now seventy-five, as compared with fifty in 1920. During the last four years an average of over 950 persons annually required admission as in-patients as the direct result of accidents.

BIRMINGHAM HOSPITAL FOR WOMEN.

At the annual meeting last month of the governors of the Birmingham and Midland Hospital for Women it was announced that the new wards which had been opened in February, 1925, had accommodated 187 patients by the end of the year. The treatment of these additional patients had necessitated extensive alterations to the operating theatres, which had been completed by the autumn, and, as the result of the various additions and improvements, 300 to 400 additional patients could be dealt with each year in the future. During the year under review 2,280 in-patients had been treated, all of them suffering from grave diseases. From the time the hospital was opened in 1871 up to the present no fewer than 44,525 in-patients had been received. The admission of out-patients had increased slightly, and had reached 4,054. The work of the maternity hospital continued to grow steadily, and 991 in-patients had been treated during the year; it had, however, been impossible to utilize the whole of the hospital owing to difficulties which had been encountered in completing and adapting the building. The out-patients had considerably increased, and the total for the year was 6,336; increasing use was being made of the convalescent home.

India.

[FROM OUR OWN CORRESPONDENT.]

BENGAL KALA-AZAR CONFERENCE.

The second Bengal Kala-azar Conference was attended by about 600 delegates, including the chairmen of several municipalities and representatives and medical officers of some 200 rural antimalarial societies. Lord Lytton, the Governor of Bengal, in opening the conference, said that the Government had made a survey to ascertain the prevalence of the disease and the areas of infection; research work had thrown light on the symptoms, the nature of the disease, and the best lines of treatment. District public health officers had been appointed with a view to placing the treatment of the disease on a sound administrative basis, and facilities were now provided for the special training of medical officers. Local organizations had been very active also in this work. The Central Co-operative Antimalarial Society had in 1924 sixty-seven centres for the voluntary treatment of villagers, and the Bengal Health Association had twenty-four kala-azar centres; both bodies had received grants from the Government, and it was possible that the grants would be increased in the coming year. The papers read at the conference dealt with the incidence of the disease in various districts, the incubation period, schemes for eradication, and treatment by antimony salts. It was decided to form a kala-azar information bureau for collating reports about the disease in the province, and to continue and complete the kala-azar survey.

KASHMIR HOSPITALS.

The work of the Kashmir Medical Mission of the Church Missionary Society increased considerably during 1925; the out-patients at the hospital at Srinagar numbered 21,175, and 1,829 in-patients were received, of whom 1,358 were admitted on the surgical side. There were 312 operations for entropion and trichiasis, and 799 other minor eye operations. Cataract is relatively uncommon, and only 83 patients required operative treatment. Bone disease is prevalent, and 83 sequestrotomies were necessary in the lower extremity alone. Surgical tuberculosis has increased, and kangri-burn cancer is of frequent occurrence. The total number of surgical operations was 6,433. The superintendent, Dr. E. F. Neve, who began work at the hospital in 1886, will hand over the charge in the coming autumn to Dr. H. T. Holland. Dr. Neve's length of service exceeds by three years that of his brother, Mr. A. Neve, who was connected with the hospital from 1882 to 1919. Dr. E. F. Neve is also honorary superintendent of the Kashmir State Leper Hospital, and in his report for 1925 he announces that the new buildings for the healthy children of lepers were completed last summer and are now occupied. We referred to this addition to the hospital on April 25th, 1925 (p. 802), and it is now clear that the extensive accommodation for these children and for the lady superintendent of nursing has been provided at a comparatively low cost. Active treatment of leper patients with ethyl esters, gynocardate tablets, or chaulmoogra emulsion has been continued with very encouraging results, in spite of the fact that some of the patients dislike the length of the course of treatment necessary. During the year 90 new patients were admitted and 135 surgical operations were performed.

MOBILE DISPENSARIES IN THE CENTRAL PROVINCES.

The annual public health report of the Central Provinces and Berar for 1924 contains an account of the thirty mobile dispensaries which are at work in the various districts. During the year under review 4,511 villages were visited and over 60,000 patients treated, an increase of nearly 14,000 patients over the previous year. The chief conditions treated were malaria, digestive and respiratory disorders, and diseases of the skin and eye; 7,731 antiplague inoculations and 1,673 anticholera inoculations were also given. In addition to treatment the staff of the dispensaries inspected over 50,000 children in village schools, checked the vaccination and vital statistics in the villages,

and reported on the water-supply and sanitation. Educational propaganda is carried on, including the organization of lectures at village fairs. Instruction is given on the prevention of plague, cholera, small-pox, and malaria, the dangers due to flies, and the principles of child welfare. These dispensaries are available for concentration on the outbreak of an epidemic at any centre in the province. It is hoped to increase their number, and to reduce the size of the area over which each at present travels.

Correspondence.

FUNCTIONAL ALBUMINURIA IN ATHLETES.

SIR,—If Dr. Abrahams will consult my paper on functional albuminuria in athletes, published in the Medical Society's *Transactions*, vol. xxx, he will find that I answer one or two of the points raised in his letter of May 1st. My observations were based on the examination of 167 specimens of urine, taken from half an hour to an hour after rowing, and of this number 100 showed a very definite quantity of albumin. My observations seemed to prove that the quantity of albumin depended entirely on the degree of exertion. In more than one instance in which I was able to get specimens immediately after a severe race, the urine of every member of the crew contained albumin, and in some cases very large quantities. In some instances I was only able to get specimens from men who had rowed short spurts during training, and in these cases albumin was often absent.

Dr. Abrahams says in his letter, "I have investigated the effects of track athletics upon a fairly extensive scale . . . yet subsequent albuminuria has been conspicuously absent," and then he adds, "From my own experience I have always been of opinion that the albuminuria described by Dr. Collier and others as occurring in oarsmen is not due to the exercise *qua* exercise, but depends upon mechanical factors which are easily invoked in the ease of rowing and obviously absent in running." Now my results with regard to this point are entirely opposed to his. I examined the urines of twelve men in training for the Inter-University Sports after severe exercise, and in every single case I found albumin, and generally in considerable quantities. I next asked the medical officers of Sherborne, Repton, and Cheltenham Schools to examine the urines of some of their boys, taken from half an hour to an hour and a half after racing, and of 38 specimens examined 37 contained albumin.

My observations led me to realize that in a very few hours after exertion the urine would be quite free from albumin. The conclusion I came to was that the albumin was probably due to acute passive congestion of the kidneys as the result of temporary overdistension of the right side of the heart. Some years later this theory was strengthened by the fact that in 1912 I had an opportunity of examining the urines of a large number of men who were taking part in a twenty-four hours walking contest promoted by the Blackheath Club. The urines were taken after they had completed twenty-two hours' walking, and in every instance I believe had covered more than a hundred miles; in not a single specimen did I find a trace of albumin, nor did any of the competitors show any sign of overdistension of the right side of the heart.—I am, etc.,

Oxford, May 27th.

WILLIAM COLLIER.

SIR,—There is no doubt that strenuous exercise of any sort can and often does produce transient albuminuria in young adolescents. In track racing it is quite common amongst boys, and (within limits) the shorter and quicker the race the more likely there is some albumin to be found in the urine. For example, the quarter and half mile races are run at a much higher rate of speed than the mile, and albumin is found much more constantly and in larger quantities in the shorter ones. I have frequently examined the urine of competitors directly after these races: sometimes a deposit of as much as one-sixth of albumin has been found after the quarter-mile in perfectly healthy boys, without any trace next day. In the mile or steeple-

chase there is generally only a slight cloud. My experience, therefore, is at variance with that of Dr. Abrahams (May 8th and 15th, p. 845).—I am, etc.,

May 24th. L. R. LEMPRIERE,
Medical Officer, Haileybury College.

DEATHS IN THE BATH.

SIR,—From time to time we read of persons found dead in the bath. That these tragedies are not more frequent, in view of the millions of baths taken daily, shows that the danger is comparatively remote; still, as there is a danger, and as there appears to be a good deal of misconception of the nature of the danger, I am venturing to write this letter.

Apart altogether from the question of death from the products of combustion in geyser-heated baths, there is the risk inherent in the bath itself. Whenever the body is immersed in water much above or much below the skin temperature, certain changes of blood pressure take place, and while the wonderful compensatory apparatus of the body makes these changes quite innocuous in the healthy state, in certain unhealthy states the circulatory system may be unable to accommodate itself with sufficient rapidity, and death may ensue.

As it is in hot baths that such fatalities are more often recorded, let us take them first.

On entering a very hot bath there is first of all a constriction of the vessels of the skin in the part immersed, and, with this, a reflex contraction of the correlated deep vessels. The result of this is a higher blood pressure and an increased blood flow to the non-immersed part—the head. This condition is soon succeeded by cutaneous hyperaemia and a lowered blood pressure. There are therefore two dangers—*apoplexy* on first entering a bath, and faintness and *heart failure* on prolonged immersion; and persons with high blood pressure and brittle arteries, and those with enfeebled heart, should be warned of their own special dangers and shown the measures necessary to minimize the risks.

(a) *Apoplexy*. Before getting right into the bath, apply a sponge of very hot water two or three times to the carotids and to the nape of the neck. This diminishes the cerebral arterial supply. Then get into the bath and immerse rather gradually.

(b) *Heart failure*. Don't take the bath too hot, and don't stop in too long.

In cold baths the only risk worth considering is that of apoplexy. Here repeat the process advised, using a cold sponge to the carotids and nape of the neck.

There are, of course, numerous other factors which play their part in an ordinary bath, but they are minor points, mention of which would be out of place in a short note such as this.—I am, etc.,

Kensington, W., May 30th.

ARTHUR S. HERBERT.

DYSENTERY IN MESOPOTAMIA.

SIR,—Will you allow me to make a somewhat belated contribution to a correspondence which took place in your columns in February, March, and April of this year under the above heading?

The correspondence arose from an observation by your reviewer in analysing the *Report of the Health of the Army for the Year 1923*. This report has only now come into my hands. The figures adduced for the incidence of amoebic and bacillary dysentery as determined by the laboratory were as follows:

		Total.	Amoebic.	Bacillary.
Iraq	...	207	181	?
Turkey	...	112	1	61
Egypt	...	64	35	29

In face of these figures your reviewer made the statement: "This bears out much of what has previously been recorded in connexion with the geographical distribution of amoebic and bacillary dysentery."

Dr. Boney and Dr. Mitchell very rightly challenged this statement by referring to their laboratory experience in Mesopotamia during the war. Mesopotamian dysentery,

as I have fully analysed elsewhere,¹ was amoebic only to the extent of 20 to 25 per cent. of cases. *Epidemic dysentery* in Iraq, as elsewhere, was bacillary. Consequently, if the figures in the army report are to be regarded as sound, things must have greatly changed. But have the conditions really changed? I note in the army report that in Iraq the admission rate for dysentery rose from 10.2 to 104.3 per 1,000, "owing to an outbreak of dysentery and diarrhoea affecting a column of troops operating in Northern Kurdistan in April, when some 200 cases occurred." Is it conceivable that these cases were in the main amoebic? I think not, and until we have further information with regard to the figures cited, both from the clinical and bacteriological sides, I prefer to conclude that Iraq dysentery has not changed.—I am, etc.,

J. C. G. LEDINGHAM,
Late Consulting Bacteriologist,
Mesopotamia Force.

London, S.W.1, May 26th.

THE TUBERCULIN DISPENSARY.

SIR,—I have returned to London with the specific intention of reviving the tuberculin dispensary system of dealing with tuberculosis and consumption (chronic phthisis) among the wage-earners in large cities, and the work will begin at 32, Fitzroy Street, Fitzroy Square, W.1, on June 15th at 9 a.m. I invite all those who have been associated with me in the past to be present, and I trust that medical men, including panel doctors, may send their patients for treatment as they send them to the out-patient department of a hospital. I wish not only to treat patients, but to offer by means of object lessons direct proof to doctors of the value of the system to patients who cannot afford to give up their daily work. A year's experience will teach medical men that the system is safe and sound in practice. Moreover, the general practitioner will be able to watch for himself the slow and laborious process by which patients can be restored to comparative health.

The system in vogue under which the treatment of chronic phthisis and other forms of tuberculosis is relegated to medical officers of health is in the interest neither of the patient nor of the general practitioner. I wish to help both the general practitioner and the patient.

The evaluation of rival methods of treating chronic phthisis is not the simple matter many doctors think it is, unless certain conditions are strictly enforced.

1. *All the cases treated must be recorded.* If failures are not recorded and if favourable cases are specially selected, we cannot assess the true value of any method of treatment. The reputation of sanatorium treatment has been largely formed from the results obtained in selected cases.

2. *The method on trial should be the exclusive method.* Otherwise faulty logic may lead us to doubtful or even wrong assumptions and conclusions.

3. *The diagnosis must be beyond doubt or cavil.* If tubercle bacilli have been demonstrated in the discharges, the diagnosis is beyond any doubt. If no bacilli can be found, the tuberculin test must be used, but the interpretation of a tuberculin reaction needs experience and knowledge. Accordingly in the process of evaluating the virtues of rival systems, it is necessary to exclude cases in which no tubercle bacilli have been found. But even so, one must compare like with like, and, while we record all cases, we must group these cases roughly according to the stage of the disease; Turban's classification is the best known and the simplest, though far from perfect. Further, since Stage 3 (Turban) is almost beyond the influence of all methods in 80 per cent. of the cases, it is best to place cases in this stage in a class by themselves. I have seen extraordinary results, even in this third stage, when tuberculin, ultimately in large doses, has been given. Some such patients whom I treated in 1908-11, even though severe ulceration of the larynx existed, are still alive and enjoy life, and have led the lives of ordinary people and not of invalids. The patients merely with definite physical signs and more than suggestive symptoms, who react to tuberculin locally, generally, and even focally, form the most interesting class of all, and may or may not need immediate treatment. We should remember that the most advanced forms of consumption were at one time in this early stage, and it is our duty to do all we can to prevent the disease passing into the later stages. My long experience justifies me in saying that systematic treatment in this early stage prevents the disease passing into the later stages in 95 to 100 per cent. of the cases, at any rate for many years. Briefly, then, to test the value of tuberculin or any other method, all cases in the first and second stages which manifest open lesions with tubercle bacilli in the expectoration should be recorded.

4. All the cases of this character (Stages 1 and 2) should be

¹ Journ. Roy. Army Med. Corps, 1920.

treated by the method of choice and by no other method, and all of them should be controlled by after-examinations at least once a year for five years after the beginning of the treatment.

Observing these conditions as closely as possible, I published my first series of cases in my Weber-Parkes Prize Essay (1910), amplified in my book *Tuberculin in the Diagnosis and Treatment of Tuberculosis* (1912). Those who run may read. In 1923 I wrote a vindication of the tuberculin dispensary for the poor, and my records of all the cases in the first and second stages of open chronic phthisis, treated at the tuberculin dispensary without any serious sacrifice of work or wage, gave this result: 68 per cent. were alive eight years after treatment and most of them were still at work. The London County Council results were: 28 per cent. were alive four years after treatment. Nothing is said of their capacity for work. Lastly, I have just prepared a general survey of the principles that should guide us in the use of tuberculin in diagnosis, prognosis, and treatment. This book, *The Principles of Immunity in Tuberculosis*, which Messrs. Nisbet have ready for publication, is designed to be a handbook for those who study and work at the tuberculin dispensary.

I can claim to be about the only Englishman who has used tuberculin continuously on every possible occasion since the year of its discovery (1891); and each succeeding year of observation and experience has increased my conviction that tuberculin, used in doses of proper strength, properly timed, properly administered, and carefully controlled by constant clinical observations, is far the best remedy known to science, benefiting, as it does, 75 per cent. of those suffering from consumption and tertiary manifestations affecting other organs than the lungs.

Tuberculin treatment is the only alternative to sanatorium treatment in the widest sense. Artificial pneumothorax is no alternative, because tuberculin prevents most of the serious conditions that justify such a serious and prolonged procedure, which has serious risks of its own. But, for economic and sociological reasons, sanatoriums under existing conditions cannot benefit 20 per cent. of the cases of consumption occurring in the wage-earners of London and other large cities. I hope to prove to medical men by object lessons that the tuberculin dispensary is the institution *par excellence* for the neglected 80 per cent. of sufferers who can never enter sanatoriums. At the tuberculin dispensary we expect to succeed in fully 75 per cent. of all cases, because we shall make full use of tuberculin as a means of diagnosis, and thereby discover the disease in the secondary stage, before the tubercle bacilli have reached the blood vessels—in fact, in the earliest stage, when tuberculin can do wonders.

Let medical men gain the experience I have gained at the tuberculin dispensary, and they will learn, as I have learnt, that both for the treatment and prevention of the tertiary manifestations of tuberculosis among the poorer classes the key to success lies in imitating Nature's own ways. At least our methods are not secret, and I would implore the profession and the public to try a plan that is deduced from a careful study of the complicated nature of consumption in human beings.—I am, etc.,

W. CAMAC WILKINSON, M.D. Lond., F.R.C.P.

London, May 31st.

THE DEFINITION OF BLINDNESS.

SIR,—I am a bit disappointed with the substance of Mr. Bishop Harman's paper on the definition of blindness (May 29th, p. 907). The title appealed to me, and I turned to the article with high hopes of help. But it seemed to me that his only point was to criticize a useful step in the right direction.

Circular No. 681 may not be the last word on the subject of blindness, but it surely is better than the haphazard way in which the selection of blind persons for various benefits and training has been carried out. Does Mr. Harman realize that there is no system at all in existence for the examination and certification of persons who apply for old age pensions at an earlier age than 70 on account of blindness, and that certification for the purpose of other schemes such as necessitous grants, and blind training centres, may vary in value from the report of an ophthalmic surgeon

through the certificate of a general practitioner to the more statement of a lay visitor or a relieving officer?

That I am not making a random statement may be apparent from the following instances which have come under my notice this year.

(1) I was asked to certify a man for a necessitous grant who was already drawing the old age pension (as a blind person) and found that although he had incipient cataract he had at least 6/12 vision in his better eye.

(2) As honorary surgeon to an eye hospital, I had a request from a relieving officer to certify that a woman had not sufficient vision to carry on her occupation as tailoress, and when I pointed out to him that this was not sufficient to qualify her for the blind old age pension, he assured me that he had been able to get the pension for several other cases on a similarly worded certificate and so remove them from his Poor Law relief list.

(3) On appointment as honorary ophthalmic surgeon to our local blind institute, my first duty was to weed out several cases which were not really blind, and could not be satisfactorily trained.

Mr. Harman's remarks about the relativity of blindness are surely commonplace to anyone who has thought about the subject at all. It seems to me, therefore, that instead of damning Circular 681 because it does not embody the full report of the special committee of the Royal Society of Medicine, we should welcome it as a sign of awakening, and, from the point of view of dealing with the certification of the blind, a step in the right direction. I would suggest that the next step should be for the Ministry of Health to make a definition of the quality of the certificates, and—what follows from that—the quality of the remuneration they propose to offer for adequate certification.—I am, etc.,

Plymouth, May 30th.

CECIL B. F. TIVY.

ALLEGED INTESTINAL ANTISEPTICS.

Sir,—In your issue of May 29th is an advertisement in which the following words appear:

"Doubt having been expressed by a medical practitioner in a recent issue of the *B.M.J.* as to the efficiency of Dimol when taken in the form of pulverettes, we desire once more to call attention to the fact that, where there is a deficiency of pancreatic enzyme, all keratin-coated tablets or pulverettes are liable to pass undissolved throughout the intestinal tract. For this reason, and at the suggestion of various correspondents, sugar-coated B Dimol pulverettes (yellow) have been prepared and are found to give most gratifying results."

It is not unreasonable to assume that the reference made here is to my article on the action of certain alleged intestinal antiseptics, which you published on February 27th last. I shall be glad, therefore, if you will allow me to correct an altogether misleading impression which this advertisement may otherwise produce. In my experiments with dimol, the tablets of this preparation used were *not* keratin-coated, but the "sugar-coated dimol pulverettes (yellow)" mentioned in the last sentence I have quoted from this advertisement. This should have been perfectly evident from my article, in which it is stated (p. 368) that a tablet of dimol "weighs, after removing its sugar coating, about 4 grains."—I am, etc.,

London, W.2, May 31st.

LAWRENCE P. GARROD.

MENTAL INEFFICIENCY.

Sir,—I have read the British Medical Association Lecturo on "Mental inefficiency: treatment or punishment" by Dr. W. A. Potts, reported in the *Journal* of May 22nd (p. 857), with great interest.

Dr. Potts, I notice, places the determining age of a criminal between the ages of 9 and 10 years. He later points out that only a limited number of persons charged can be fully examined, and gives a rough and ready guide for magistrates and court officials to enable them to select the right cases.

May I be permitted to suggest that it would be better if the reports of the school medical officers were fully scrutinized? In these days, when the country is provided with such an excellent scheme for examining all children (as a routine at least three times during their life at the elementary schools, and as special cases *re* mental deficiency if considered necessary by teacher or doctor), the information obtained should be at the disposal of court officials.

Apparently Dr. Potts has not recognized the help of the school medical service at all.—I am, etc.,

MANION BONYCORNE, M.B., Ch.B., D.P.H.,

Bristol, May 24th.

Late Deputy and Assistant M.O.H.,
Swindon, Wilts.

THE LATE SIR JOHN WILLIAMS.

Sir,—In your interesting obituary notice of Sir John Williams I notice (p. 923) the name of "Sir Hugh Owen" in connexion with the National Library of Wales. Who was "Sir Hugh Owen"?

I knew Dr. Henry Owen of Poyston, Haverfordwest, D.C.L. of Corpus Christi College, Oxford, and a great friend of Sir John Williams and of mine. He collected a library of Welsh books, which I understood were to be incorporated in the National Library, and built a library for them at Poyston, which I have seen. Is not "Sir Hugh" a misreading of "Dr. Henry" in the MS.? I notice lower down in the same page what looks like a similar uncorrected error—"request" for bequest—which strengthens my surmise.

In connexion with the collection of books for the National Library an amusing incident occurred. One of them told me (I think it was Owen) that each of them, unknown to the other, had ordered his agent to bid for a small book, of the value of a few pence, at a forthcoming sale. The sale took place, and the book was knocked down to one of them for £5. They afterwards found that their agents had been bidding against each other, unwittingly, as each of them had expressed a desire to get it to complete his collection. For years afterwards they kept receiving at intervals catalogues with a special note: "At the ——— sale in (date) this book fetched £5."

—I am, etc.,

Nutley, May 30th.

FRANCIS CHAMPNEYS.

* Sir Hugh Owen, who was born at Carnarvon in 1804, was first a clerk at the Poor Law Commission and afterwards chief clerk of the Local Government Board. The *Dictionary of National Biography* says of him:

"The great work of the later half of Owen's life was the organization of higher education in Wales, and it is to him, above all others, that the University College of Wales at Aberystwyth owes its existence. . . . Owen was the chief instrument in bringing about a reform in the *Eisteddfod*, thereby renewing its usefulness and reviving the national interest in it."

He died in 1881. There is a statue of him at Carnarvon.

"Request" is probably, as Sir Francis Champneys suggests, a misprint for "bequest," but the report of the Historical Manuscripts Commission is not at hand.

THE PRESERVATION OF APPLES.

Sir,—The letter from Dr. Jones on the use of carbonic acid in the preservation of food, published recently in the *BRITISH MEDICAL JOURNAL*, leads me to record the fact that for years past I have experimented in a mild way in the preservation of apples (home grown) for domestic use, and at last, thanks to a tip given by a lecturer from the School of Horticulture, Cambridge, I have succeeded to my entire satisfaction.

The method is as follows: The apples, when freshly gathered, are placed in earthenware crocks, and sealed down with pasted paper, in exactly the same manner as the cook covers her jam-pots. The crocks should be kept in as oven a temperature as is possible. Apples stand a low temperature much better than potatoes.

The scientific idea (theory) is that they secrete CO₂. When taken out for use they should be allowed to stand in the air for at least twenty-four hours, "to come to life again," otherwise they taste "clung" or musty.

Personally, I could not afford these crocks, or horse troughs, so I got New Zealand butter-boxes from my grocer, and pasted them inside and out with several layers of glazed paper, such as is used by the shilling weeklies.

I enclosed a sample of six apples for the Editor to express his opinion. They were put down in October, 1925, and the box opened this week.

There must be many practitioners with orchards who find that there is a glut of apples in September and October, when one cannot give them away, while at the present time they are worth at least 1s. a lb. I hope they may find this tip useful.—I am, etc.,

Diss, Norfolk, May 22nd.

H. M. SPEIRS, M.D.

* In the opinion of the editorial staff the apples forwarded by Dr. Speirs are wonderfully fresh, crisp, and juicy; they are ripe, and look as though they were only a few weeks off the tree.

Obituary.

ERNEST SEPTIMUS REYNOLDS, M.D., F.R.C.P.,

Consulting Physician, Manchester Royal Infirmary, and
Emeritus Professor of Clinical Medicine in the
University of Manchester.

ERNEST SEPTIMUS REYNOLDS, whose death on May 22nd from acute influenzal pneumonia was briefly announced in our issue of last week, was born in Manchester on April 7th, 1861.

As a boy he was educated at the Manchester Commercial Schools, which no longer exist, and gained many prizes there. He matriculated at the University of London in 1878, and entered the Owens College and the Manchester Royal Infirmary in the same year as a medical student. His prize-taking career continued; he won the Platt Physiological Exhibition in 1880, and was fourth in honours in physiology in the Intermediato London M.B. He qualified as L.S.A. and M.R.C.S. in 1883, and took the London M.B. in 1884, in which he was third in honours in forensic medicine; he graduated M.D. in 1885.

As soon as he was qualified he was appointed junior assistant medical officer to the Macclesfield County Asylum, but after three months removed to the Cheadle Royal Asylum of the Manchester Royal Infirmary. There he worked for three years, and was then appointed pathologist and assistant medical officer to the West Riding Asylum, Wakefield, where he was engaged for nine months in original investigations. He left Wakefield in 1887 to become resident medical officer at the Manchester Royal Infirmary; he held this post for the long period of four years, during which time he amassed a great store of clinical experience. In 1891 he was appointed honorary physician to the Ancoats Hospital and physician to the Manchester Workhouse Infirmary. In the latter post he had 1,200 beds under his supervision. In 1892 he was appointed lecturer in hygiene to the Lancashire County Council, and during the final illness of Dr. James Ross he acted as lecturer in medicine at the Owens College, delivering a course on nervous diseases.

In 1899 he was elected to the honorary staff of the Manchester Royal Infirmary, and remained in active work on it until he was appointed honorary consulting physician in 1921.

In 1884 he published a *Primer of Hygiene* for the use of higher grade school children and for those who attended elementary lectures on hygiene, as given in evening continuation classes, mechanics' institutions, university extension and county council courses. It met with much success, having been reissued twelve times after revision, and is still in demand. Two years later he published a small work on *Hygiene for Beginners*, which was an enlargement of the *Primer* with some anatomy and physiology introductory to the hygiene. This has been reprinted with necessary additions seven times.

Reynolds was the most talked of physician in the kingdom, and probably in Europe, for a time in 1900 when he discovered the presence of arsenic in beer, which was

poisoning people in unknown numbers. For twelve months he had noticed in his wards and out-patient department a considerable number of cases of unusual skin eruptions of a more or less indefinite character, such as erythema, keratosis, pigmentation—the last being especially common among the poorer patients. Some of the pigmentation cases were diagnosed as Addison's disease by his assistants, but he was not satisfied with this diagnosis. Then in one week six cases came before him with erythromelalgia of hands and feet and a series of cases of herpes zoster appeared. About the same time an extraordinary number of cases of so-called "alcoholic paralysis," principally women, many of whom had taken very little beer, were admitted to the workhouse hospital. Other observers noted the increased prevalence of "alcoholic paralysis" and attributed it to increased drinking. He had doubted for many years whether ethylic alcohol *per se* caused peripheral neuritis, and this doubt was supported by the epidemic

being amongst beer drinkers and not spirit drinkers. Then when it was seen that the skin lesions were occurring in the cases of paralysis, and herpes zoster in "beautiful" form, he bethought him that arsenic was the only known drug that produced herpes, and, as one of the sisters in charge of his wards tells us, he said, "I've got it." Improbable though this hypothesis of arsenic poisoning at first seemed to him, it was valid and not known to be untrue. He therefore obtained some of the beer most commonly taken by the sufferers, and on November 15th, 1900, by Reinsch's test, he easily obtained a deposit on the copper foil and arsenious oxide in a combustion tube. He communicated his discovery to Professor Dixon Mann, who examined another sample of beer with positive result. Dr. Dixon Mann informed Professor Delépine, who, unknown to Dr. Reynolds, was also investigating the epidemic of paralysis, etc., at the request of the medical officer of health for Salford, and he, on November 22nd, traced the arsenic to certain sugars used in brewing. From the sugars the arsenic was traced to sulphuric acid used in their preparation. One firm of brewers only used the contaminated sugars, but

it supplied over two hundred breweries in the Northern and Midland countries. The beer contained arsenic in amounts varying from 0.01 to 1 grain per gallon, the average being about 0.2 grain, or the equivalent of 14 or 15 min. of liquor arsenicalis per gallon.

The discovery created a great sensation in the town and neighbourhood, which continued for some time as confirmatory results came from other observers. An account of the epidemic appeared in this JOURNAL in a series of articles (1900-3), and a paper on the subject was read before the Royal Medical and Chirurgical Society on January 8th, 1901. The sequence of the symptoms in the arsenic cases was: (1) digestive symptoms; (2) laryngeal catarrh, bronchitis, and acute skin symptoms; (3) disturbances of sensibility; (4) motor paralysis with the skin lesions. These observations agreed with those of Brouardel in 1839 in a series of fifteen cases of homicidal arsenic poisoning. An addendum to this series of papers was one published in the *Medical Chronicle* in 1901 on "Some old records of epidemic arsenical poisoning." The amount of beer taken

Ernest S. Reynolds

[N. S. Kay, Manchester.

daily by some of the patients had not been enough to produce neuritis from alcohol according to the views then held, and had only contained about as much arsenic as there is in 3 or 4 minims of liquor arsenicalis.

Reynolds learned a good deal about peripheral neuritis from James Ross and Julius Dreschfeld, who were working at it when he was resident medical officer in the infirmary. In the eighties and nineties of last century peripheral neuritis of supposed alcoholic origin was very common in Manchester and especially in Ross's wards, so much so that the clerks were pleased to get away from it. One day, as they walked their student rounds, they knew that there was a patient with diabetes mellitus in the ward—a youth with a wolf-hunger but still emaciated—and they thought they would have a change of subject with him. But when Ross was told what the case was he immediately pulled up the bedclothes and demonstrated the diabetic form of peripheral neuritis. "Alcoholic" neuritis is very uncommon now in Manchester, and the old group of symptoms is rarely seen—flabby anaemic face; complaints of morning sickness and distaste for food; cramps at night and the necessity of getting out of bed to stand on the cold hearthstones to relieve them; wrist-drop and ankle-drop; and the agonized look of muscular hyperaesthesia brought on by squeezing the calf. There must have been some arsenic in the beer for years before Reynolds found it, and it can be truthfully said of him, "He made beer purer." The rarity of the above type of neuritis nowadays, when whisky and beer are still consumed in very considerable quantities, strongly supports his opinion that ethyl alcohol alone does not cause peripheral neuritis.

He had a very large consulting practice, and was much sought after for an opinion on mental cases. His experience in asylums eminently fitted him for this work, and as he was very definite in any opinion given his advice about certifying patients was very helpful to practitioners. His advice on the treatment of nervous cases on lines which he had found valuable after years of experience was excellent. The cult of the modern psychotherapy did not appeal to him; the only new thing in it, he said, was Freudism, about which he was scornful. Some of his comments on it were reminiscent of Mercier at his best.

Reynolds took a prominent part in the opposition of the profession to the National Insurance Act when it was going through Parliament, and was one of the platform speakers in a mass meeting of the profession in Manchester. He could see no good whatever in the bill, nor could the meeting. He rarely appeared at public meetings or wrote to the lay press, holding strongly the view that professional reticence is most seemly for a Fellow of the Royal College of Physicians; but when a fitting occasion arose he lent the weight of his authority in support of some matter of moment, such as a defence of asylums when they were charged a few years ago with improper treatment of the patients in them.

In 1912 Reynolds was president of the Manchester Medical Society, and in his address took the opportunity of stating his views of the practice of medicine as a fine art; the main theme was the value of careful bedside observation and the importance of making a diagnosis whenever possible without the aid of laboratory methods. "A short time ago I asked a student how he would diagnose a pleuritic effusion. He promptly answered 'By x rays.' I then said: And supposing you were practising in the Isle of Skye, how would you diagnose it?" He said, 'I don't know.'" He was out and out a clinician, and never did any laboratory work. He used its methods as aids to diagnosis in suitable cases, but he often broke a lance, with a habit he had at times of over-sharpening its point, against the tendency to use them before a full clinical examination had been made. He did not approve of the present Mayo Clinic system of accumulative departmental diagnosis.

In October, 1888, he was admitted a Member of the Royal College of Physicians, on which occasion he was congratulated by Sir Andrew Clark, P.R.C.P., for the distinguished manner in which he passed the examination, and received a "special resolution" from the Censors' Board to the same effect. This was a rare and great honour, the Registrar informed him, only conferred about once in three

or four years. As a consequence, he was elected to the Fellowship in 1896—a very short period of probation after passing the M.R.C.P. for a provincial physician. He was appointed Bradshaw lecturer in the Royal College of Physicians in 1917, and chose as his subject the "Causes of disease," to which his thoughts had been directed by trying to find the cause of the "very distressing and prevalent affection, disseminated sclerosis." It was very thoughtful and covered a wide range; but he had nothing new to offer in regard to the causation of disseminated sclerosis, which in his experience is "the commonest organic disease of the nervous system in which morbid changes can be found."

For some years Reynolds was professor of clinical medicine in the University of Manchester, and gave the students a weekly lecture at the Royal Infirmary, bringing to his aid the very practical experience of an acute clinical observer and his power of interesting exposition. His lectures were very attractive, for the students recognized a master in his work and a dominant personality in the profession. He was a very clear thinker, precise speaker, and a good witness in law courts. He frequently took part in trials under the Workmen's Compensation Act, and barristers did not like the task of cross-examining him. He also gave evidence from time to time in mental cases. He had a fund of interesting experiences, and was a very entertaining companion when he related them.

Dr. Reynolds was secretary of the Section of Psychological Medicine when the British Medical Association held its Annual Meeting in Manchester in 1902, and vice-president of the Section of Neurology and Psychological Medicine at Liverpool in 1912; he was one of the representatives of the Lancashire and Cheshire Branch on the Central Council in 1912-13.

We are indebted to Dr. ARCHIBALD DONALD for the following appreciation:

As one who knew Dr. Reynolds intimately for many years, I should like to pay a tribute to his memory. It is for others to deal with his career, with the work he accomplished, and with his standing as a physician; but perhaps I may be allowed to refer to some of his personal characteristics.

He belonged to what some may regard as the old-fashioned clinical school, and was very outspoken in condemning some of the more modern methods in medicine. He believed that the present-day student was being taught to rely too much on artificial aids, such as the use of x rays and other laboratory methods, to the exclusion or restriction of careful clinical training. He thought that the trained physician should be able to arrive at a sound diagnosis by the unaided use of the senses of sight and touch, supplemented by the reasoning faculty. He himself cultivated the habit of most careful observation and examination, and was often guided by some small symptom or circumstance which might very reasonably have been overlooked. He had, in consequence, the reputation of a sort of Sherlock Holmes in medicine. It is true that now and again, like all others who have had a large consulting practice, he made mistakes: we are all liable at times to have a bias in certain directions, and Dr. Reynolds was no exception in this respect. But in spite of the occasional failure of a "lightning" diagnosis, he was, in my opinion, unrivalled in the disentangling of a difficult nervous or mental case, and it is in this sphere that he will be very much missed.

His tastes were all in the direction of a quiet life. He had his consulting rooms in town, but unlike most of his colleagues he never joined a club. But he was by no means unsocial and enjoyed the society and conversation of a limited number of friends. He was by nature a student, and was interested in many subjects outside his profession. It was his habit, after he had dealt with his correspondence, to read at night until the early morning hours. Fiction had little attraction for him, and his taste lay in the direction of serious literature. At one time, as a means of improving his methods of clinical investigation, he took up the study of logic, and was a keen disciple of John Stuart Mill. Later he delighted in the writings of Mercier, Maudsley, and similar authors, the sort of reading

that most of us are too intellectually lazy to attempt as a recreation. Not very long ago, when he was urged to take more rest, he replied that the years were passing and that he had a lot still to learn.

He never employed a secretary, although his professional correspondence was very large. He had acquired the art of shorthand writing in early life and employed it very freely. All his notes were taken in shorthand, and he wrote all his letters himself.

He was by nature of a shy and reticent disposition and was always content to let his work speak for itself. He owed nothing to social influence, and it was not in his nature to push himself. The one great professional disappointment in his life was when the chair of medicine became vacant on the death of Professor Dreschfeld, and he was passed over by the Senate of the University, many of whom must have been ignorant of his strong claims to the appointment. Under a somewhat quiet and even cold exterior he had great sympathy and kindness. He was a very staunch friend in times of trouble. He was as interested in the poor and less fortunate as in the well-to-do. He will be greatly missed by a large number of former patients, by many men in general practice who valued very highly his advice, but most of all by the few who were privileged to know him intimately.

SIR JAMES CANTLIE, K.B.E., LL.D., F.R.C.S.,

Consulting Surgeon, Seamen's Hospital Society; formerly Lecturer, London School of Tropical Medicine; and Surgeon to Charing Cross Hospital.

By the death of Sir James Cantlie, in his 75th year, there has passed away a remarkable man and, until he retired owing to ill health, an outstanding figure in the medical profession. A man of strong individuality tempered with a full measure of Scottish humour, a ready writer and speaker, and a born teacher, he was wont to use these gifts unsparingly and courageously in any good cause which in his view might be of service to the advancement of medical science or to the welfare of the general public.

Born in Dufftown, Banffshire, in 1851, and educated locally, he afterwards proceeded to the University of Aberdeen, where he obtained his degree in arts and medicine with honours. He then came to London to finish his medical education, studying at Charing Cross Hospital. In a short time he became demonstrator of anatomy in the school, a post he held from 1872 to 1887. He was appointed assistant surgeon to the hospital in 1877 (the year in which he obtained the F.R.C.S. Eng. diploma) and surgeon in 1887. In 1883 he was one of twelve young medical men sent to Egypt to assist in dealing with the outbreak of cholera, the infection of which had been brought into that country by pilgrims returning from Mecca. Probably it was this visit to the mysterious and fascinating East that influenced Cantlie's decision in 1887 to give up his post of surgeon at Charing Cross Hospital and accept Patrick Manson's invitation to settle in Hong-Kong. Perhaps the decision to go to China was also strengthened by the ridicule that had been showered on him by his disquisition on the "Degeneration of Londoners," which was published in 1885. It needed twenty years to pass and a great war to realize that there was some foundation for the warning of the young surgeon of Charing Cross Hospital. Cantlie was not long in Hong-Kong before he became dean of the College of Medicine for Chinese, an institution which owed its inception to the far-sightedness of Patrick Manson. It was in Hong-Kong that Cantlie acquired an extensive experience in tropical diseases in addition to his surgical practice, and it was there that he encountered, in 1894, the first serious epidemic of plague in that colony, which owed its origin to an earlier epidemic in Canton that cost that ancient city a loss in deaths of 80,000 of its inhabitants. During his nine years in China he formed a lasting friendship with Sun Yat Sen, who was his pupil at the Hong-Kong College of Medicine.

On his return to London in 1897 there were three questions he was constantly asking: Why should there not be a tropical medical school in London to train civilian medical officers and others going to the tropics? Why not

a section for tropical medicine at the annual meetings of the British Medical Association? And why not a tropical medical journal published in London? He met with others from the tropics who were asking the same questions and willing to join with him in obtaining all three. Among these was his old friend Sir Patrick Manson. It was accordingly arranged that Cantlie should read a paper at the Imperial Institute on the desirability of the establishment of a tropical school for the education of medical men going to the tropics. After a discussion on the subject a resolution was unanimously passed in its favour, and a committee was formed to meet at Sir Patrick Manson's house to work out details. Sir Patrick at that time was medical adviser to the Colonial Office, and interested Mr. Joseph Chamberlain in the scheme, with the result that Mr. Chamberlain presided at a dinner to obtain funds for the founding of a school of tropical medicine and hygiene in London, with the result that £16,000 was collected at the dinner. It occupied a considerable time before the laboratories were ready for the students, but in 1899 the London School of Tropical Medicine was opened, and at its first session there were seven students, one of whom is now Admiral Sir Percy Bassett-Smith, K.C.B., the distinguished naval surgeon, and a past-president of the Royal Society of Tropical Medicine and Hygiene.

The Council of the British Medical Association agreed to add to its sections one specially devoted to tropical medicine. At the first meeting of the section in Edinburgh in 1898 Sir Patrick Manson (in the chair) read out the famous telegram from Ross of his discovery of the life-history of the malarial parasite in the mosquito. Cantlie also acted as secretary of the section, of which in later years he was vice-president and president. At the same time the first number of the *Journal of Tropical Medicine and Hygiene* was issued, the editors being Cantlie and Professor W. J. Simpson (now Sir William Simpson) who, on leaving India, had relinquished the editorship of the *Indian Medical Gazette*. Later, the Society of Tropical Medicine and Hygiene was founded, Sir Patrick Manson becoming the first president. It is now the Royal Society of Tropical Medicine and Hygiene, and Sir James Cantlie, during his presidency, presented the society with the gold chain and insignia to be worn by the president. He was created K.B.E. in 1918, and received the LL.D. degree from his old university, Aberdeen, in the following year.

Cantlie did not confine his activities to tropical medicine or surgery. His untiring energy and love of work would not allow him. In the days of volunteering he was an enthusiastic Volunteer, and when the Territorial armies were formed he became Honorary Colonel R.A.M.C.T., 1st London Division. For many years he lectured regularly at the Polytechnic on first aid to the wounded. Later he founded the College of Ambulance, and by his teaching there the large number of men and women he trained for service during the war deserves our heartfelt gratitude. In this connexion we must not forget his devoted wife, Lady Cantlie, and the large share she took in his work. She trained during the war an enormous number of V.A.D.s and was a real helpmeet to her husband. Lady Cantlie's death some time after the war was a great shock to Cantlie, who was never the same light-hearted man as before. He leaves four sons.

At the Newcastle Annual Meeting of the British Medical Association in 1921 he was President of the Section of Ambulance and Red Cross. He had represented the Hong-Kong Branch on the Council of the Association on two occasions, and was a member of the Dominions Committee from 1919 to 1922.

We are indebted to Dr. J. MITCHELL BRUCE, consulting physician to Charing Cross Hospital, for the following appreciation of his old friend and former colleague:

No one knew Sir James Cantlie better than I from his boyhood to his last days. As a lad, come of fine old Scots stock, sturdy in build, of keen, "open," confident countenance, and hearty, kindly, straightforward manner, he was the only student of his time at Aberdeen who attended arts classes in the kilt. Honours both in arts and in surgery proved the high order of his intelligence, but from

the first he had a restless disposition, and he interrupted his medical course at Aberdeen to follow me to Charing Cross Hospital. Here, he used to say, I taught him anatomy and taught him how to teach anatomy. In due course he was demonstrator, extraordinarily successful in the results of his students at examinations for qualifications and for the public services. Indeed, as a teacher of practical subjects he was unsurpassed in his time— incisive, epigrammatic, and always humorous, yet with complete control of his pupils. It was through anatomy and at this early stage of his career that Cantlie's attention was unexpectedly attracted to ambulance by circumstances best known to me; and in justice to Cantlie's reputation it is right that these circumstances should be related—in which he took the first step in a partial digression from the recognized professional career of a hospital surgeon and teacher which led him to intimate association, first with the St. John Ambulance Association and later with the Red Cross.

My friend Surgeon Major Peter Shepherd, A.M.S., unexpectedly ordered on active service in Zululand, begged me to correct the proofs of a manual on *First Aid to the Injured*, which he was drawing up for the St. John Ambulance Association. I consented, and introduced him to Cantlie, and we two saw the first edition of the manual through the press. Shepherd fell at Isandlwana, sacrificing himself for the life of a comrade. The memory of his gallantry is preserved in the Shepherd medal in surgery at Aberdeen. Such was Cantlie's introduction to ambulance. But it may well be asked what influenced a young, rising surgeon, on the active teaching staff of a metropolitan hospital and school, to continue to sacrifice time and opportunities of strictly professional advancement for occupation of this character. Naturally a close observer and keen critic of men and things, Cantlie developed by training in science a strong disposition to accept nothing as being all that can be known and the best possible. In the world of his interests he was ever discovering some need of improvement, some public want which had not occurred to others. He was essentially an inventor, certainly a pioneer in things great and small. But so intent was he on the end he had in view that he would be indifferent to the cost of reaching it. He was fearless to a fault. Not to speak of precious time, nor of money (of which he was altogether careless), he was in spirit too determined and independent to hesitate to sacrifice professional practice and position to what he considered his duty to the country. He acted accordingly.

This critical way of looking at the world about him was illustrated in many incidents in Cantlie's life—many notions, projects, or dreams only—other than those three great movements which give his career a course and character of its own: training hundreds of the V.A.D. for war service, "raising" the V.M.S.C., and founding the School of Medicine for the Chinese—the beginning of a university. In the public ambulance service he was the first to organize a portable x-ray installation to carry the benefits of radiography to the remote poor. He projected a system of first-aid instruction for youths proceeding to foreign parts of the Empire far from surgical help. In routine clinical examination he took not only the weight of the patient but the weight of the patient's clothes, which he considered should bear some definite relation to each other. He waged war against the Eton jacket because it exposes the renal regions. He carried on a keen campaign against the "baby's comforter." He arranged a novel system of physical exercises for old men to improve the remnants of their vigour before it was too late. Men of his own generation will recall his "Degeneration of Londoners," in which he maintained that no family in London survives beyond the third generation; and his project to bring sea air in pipes from Brighton into London. In anatomy he observed that congestion of the ileo-caecal veins, one of the remote roots of the portal system—"piles of the appendix" as he called it—may well account for some cases of appendicitis.

In private life Cantlie had no equal in the power of amusing persons of all ages from infancy to advanced life. Always bright, he was the friend to turn to; to spend an hour with, when one wanted cheering with story or song.

mostly in his own native Doric, both rendered with fitting gesture, for he was a born actor. He was in great request for his after-dinner speeches and songs as "guest of the evening" at gatherings of his fellow countrymen, particularly his fellow graduates, through the length and breadth of England. Then, as in the lecture room, and on a platform whatever the occasion, an ever-ready, confident speaker, he thoroughly enjoyed himself. More than once he preached the sermon on Hospital Sunday in St. Martin's Church; indeed, he once addressed a Jewish audience on the hygiene of Moses. His pupils who survive him will not have forgotten how he founded the Students' Dinner at a place of refreshment in the Strand, hardly to be described as a restaurant and certainly not a café.

When I look back upon the days of our long and intimate friendship I comprehend again what I marked in each of its chief events—the consistency of his high qualities, how he was ever original in his conceptions, inventive in his ideas, impulsive in his projects, unhesitating in his activities, indifferent to criticism, no doubt ambitious, but always working for a worthy end—the public good. The King and country recognized their debt to him, but the true public monument to Cantlie is the R.A.M.C. T.A., "raised" as the V.M.S.C. on that day in 1883 when he called for volunteers from his pupils at Charing Cross to have their first practical lesson in ambulance as a provision for service in war.

Dr. J. G. BLACKMAN (Portsmouth) writes:

May I be permitted the privilege of paying a small tribute to the fragrant memory of my old friend and teacher, Sir James Cantlie? At the time I entered the Charing Cross Hospital Medical School, in 1872, Cantlie, who was completing his curriculum there, held the post of assistant demonstrator of anatomy. In those days the primary F.R.C.S. examination was the first fence, and we looked upon "Jimmie"—as he was affectionately known to us—as our big brother, ever ready and anxious to assist us over; and he never failed us. In season and out of season he was ever at hand to help us to our goal; and if anyone had a difficulty in his work or otherwise he could always count on him for advice or help. Cantlie had the great gift of a happy and cheery disposition, and his demonstrations were often enlivened by amusing anecdotes, in broad Scotch, of his late teacher, Professor Struthers of Aberdeen. James Cantlie was an outstanding character apart from his profession, and his ingenuousness sometimes led him to "back a loser," but that fact neither daunted his supreme faith in humanity nor abated his magnanimity and generosity in dealing with his fellows. It is these happy memories which rise when one hears that his work is finished.

HUGH BRAUND KENT, M.S.LOND., F.R.C.S. ENG.,
Tongshan, North China.

THE untimely death of Hugh B. Kent, at the age of 43 years, has already been reported, but it is only meet that some account should be recorded of the invaluable work he did for several years in North China, the particulars of which have been but recently received.

H. B. Kent was the fourth son of Horace Kent, barrister-at-law, of Chelsey Hill, near Wallingford, Berks. Educated at Oxford High School under the headmastership of A. W. Cave, he entered Guy's in 1904. Kent was very popular among his contemporaries as a student at Guy's, where he also had a distinguished career, obtaining the Arthur Durham prize in 1905 and 1906, the Michael Harris prize in anatomy in 1906, and also the junior proficiency prize and a certificate for the Wooldridge prize in physiology in the same year. In October, 1908, he obtained the degrees M.B., M.S.Lond. He was appointed clinical assistant to Sir Cooper Perry and Dr. Shaw in 1909, and he would without doubt have been appointed house-surgeon or the like had not circumstances compelled him to start in practice without delay. Kent therefore accepted a post in the Colonial Service in West Africa in 1909, and at the end of that year he was offered, and accepted, an appointment at Tongshan, North China, as principal medical officer of the Kailan Mining Administration and the Chinese

Peking-Mukden Railway. At the time when he took over this work, in July, 1910, there was a hospital for foreign residents and for the Chinese at Tongshan, not, however, fully equipped to supply the requirements of modern medicine and surgery, whereas at the time of his death on November 24th, 1925, the hospital had been greatly extended and thoroughly fitted out in almost every direction. These results could not have been achieved without the sympathetic co-operation and material support of the chiefs of the Kailan Administration and of the Peking-Mukden Railway, and for their help Kent invariably expressed his unflinching gratitude. On the other hand, it must not be forgotten that it was Kent's initiative, perseverance, and recognized capacity which enabled him to secure these concessions, redounding as they did to the credit of the companies concerned, and resulting in improvements in the hospitals and in their administration which have left them in the creditable and efficient condition they occupy to-day. The way in which the x-ray apparatus was obtained is a striking example of the confidence engendered in all with whom Kent came into close contact. The Chinese are, as a people, averse to surgical treatment. Yet as a result of Kent's success as a surgeon he largely overcame their dislike, and he secured the support of the Chinese to such an extent that, with the exception of a small contribution by the Kailan Directorate, the x-ray apparatus was subscribed, mostly in small sums, by the Chinese themselves. Fifteen years is a short time in which to establish such a first-class reputation as a surgeon, and yet that was what Kent did, in spite of grave disability at times from ill health. From the year 1912 until his death he suffered recurrences of illness sufficient to render many men permanent invalids; and yet his ill health seemed but to brace him to renewed activity, for in 1919 he obtained leave to come home and work for the M.S. degree, and again in 1923 for the F.R.C.S.

The value of a man's life is measured, not in length of days, but in what he accomplishes in the short space allotted to him, and in that sense Kent kept the measure filled to the brim; nevertheless his friends here and in China cannot cease to deplore the fact that he died so young and withal so full of promise for the future. Happily he ripened early, and he lived long enough to reap some of his sowing, although the full harvest was never garnered. Kent was a student all his days; thoroughness, enthusiasm, common sense, with a keen sense of humour, were the characters which made him the man he was. He had the true surgical instinct, the keen eye and sure hand, and the confidence based on knowledge: he possessed the mind and will to overcome difficulties, the inability to recognize defeat. In fact, he was the very type of Englishman eminently fitted for the pioneer work he undertook in a foreign country, which work not only redounded to his own credit, and incidentally to that of his parent medical school of which he was so fond, but at the same time was of incalculable benefit to his fellow creatures in that great and far continent of China to which he devoted the best years of his short life.

JOHN FAWCETT.

Dr. JAMES MACDONALD, who died in his 70th year, on May 10th, received his medical education at Edinburgh, where he graduated M.B., C.M. in 1881, proceeding M.D. in 1895, with commendation for a thesis on diphtheria. After holding assistantships in Newcastle and Manchester he went to Carlisle, in 1884, as assistant to the late Dr. MacLaren, and was for a short period medical officer to Carlisle Dispensary. In 1886 he started an independent practice in Carlisle, which speedily became very large. For some years he was medical officer to the Stanwix district of the Carlisle Union, and later held a similar appointment in the Caldewgate area. He was medical officer of the Carlisle Fever Hospital for forty years, and medical officer of health to the Carlisle District Council since 1895. After the introduction of the Insurance Act Dr. Macdonald was a prominent member of the Cumberland Insurance Committee, and, since 1917, was chairman of the Panel Committee. Dr. Macdonald took an active interest in the progress of the British Medical Association;

he was president of the Border Counties Branch in 1908 and chairman of the English Division of the Branch in 1922-24. He was keenly interested in various forms of athletics, and was one of the founders of the Carlisle and Silloth Golf Club. He was twice married, and is survived by a widow and two sons, one of whom succeeds him in the practice. A colleague writes: His influence with all members of the Cumberland Insurance Committee and the reliance which they placed in his judgement on the contentious matters which have cropped up are largely responsible for the smooth working of the Act in this area.

Dr. REGINALD WILLIAM WILSON, who died on May 6th at his residence in Croydon, was born in 1857, and was educated at Merchant Taylors' School. In 1876 he was apprenticed to his cousin, the late Dr. Danford Thomas, and entered St. Mary's Hospital, obtaining the diplomas M.R.C.S. Eng. in 1882 and the L.R.C.P. Ed. in 1884. For a short time he held the post of assistant medical officer at St. Olave's Infirmary, Rotherhithe, and was subsequently assistant medical officer at Chelsea Infirmary for three years. In 1885 he was appointed medical superintendent of the Croydon Infirmary, retaining the post until 1922. He was widely known and highly esteemed in the Croydon district, particularly for his unflinching kindness and sympathy. He leaves a widow and two sons, one of whom is in the medical profession. He was a member of the British Medical Association up to his retirement in 1922.

Dr. JAMES R. C. MACKINTOSH died at Anstruther, Fife, on April 13th, at the early age of 35 years, from cycle injuries sustained while on his round of calls the same day. A native of Glasgow, he was educated at Inverness Royal Academy, and graduated M.B., Ch.B. Glasg. in 1913. At the university he was awarded the senior Arnott prize for physiological physics, also the university bronze medal for physics. At the outbreak of the war he was holding a house appointment at Whips Cross Infirmary, London; he obtained a commission in the R.A.M.C. and served there until after the armistice. After demobilization he continued in hospital work, and later became a medical missionary in Nagercoil, India. He returned last year and had settled in general practice at Anstruther. Dr. Mackintosh is survived by a widow and two young sons. He was a member of the British Medical Association.

HENRY BROUGHAM GUPPY, M.B., F.R.S., late surgeon Royal Navy, died at Martinique, on the voyage home from Tahiti, on April 23rd, aged 71. He was born in December, 1854, the youngest son of T. S. Guppy, M.D., of Falmouth, and educated at Sherborne, Queen's College, Birmingham, St. Bartholomew's Hospital, and Edinburgh University, graduating at the last named as M.B. and C.M. in 1876. For nine years—1876 to 1885—he served as surgeon in the navy, being medical officer of H.M.S. *Hornet* in the China and Japan seas, and of H.M.S. *Lark*, a survey ship, in the Western Pacific. He investigated the formation of coral reefs in the Keeling Islands, and carried out extensive geological and botanical researches in Java, Hawaii, Fiji, the western coast of South America, the West Indies, and the Azores. He received the gold medal of the Linnean Society in 1917, and was elected F.R.S. in 1918. He published several works in which he embodied the results of his researches: *The Solomon Islands and their Natives*, 1887; *Geology of the Solomon Islands*, 1887; *Observations of a Naturalist in the Pacific*—vol. i, *Geology of Vanna Loru, Fiji*, 1903, vol. ii, *Plant Dispersal*, 1906; *Studies in Seeds and Fruits*, 1912; *Homes of Family Names*, 1890; and *Plants, Seeds, and Currents in the West Indies and the Azores*, 1917. He married twice: first, Annie, daughter of J. Jordan, in 1887; and secondly, in 1900, Letitia, daughter of A. J. Warde, of Yalding, Kent.

Professor GIUSEPPE GRADENIGO, a leading Italian otologist and founder of the *Archivii Italiani di otologia e laringologia*, has recently died at the age of 65.

Universities and Colleges.

UNIVERSITY OF LONDON.

Annual Report.

THE annual report of Sir Cooper Perry, Principal Officer, on the work of the university year 1925-26 states that the total admissions by all channels numbered 7,577, as compared with 7,603 in the previous year, and 3,852 in the last year before the war. The great majority (5,485) of the entrants came in through the matriculation examination. There were 3,819 candidates for degrees, as compared with 3,420 in 1924. The number who obtained degrees and diplomas was 2,508, as compared with 2,642 in 1924.

The new scheme, approved provisionally for one year, for the conduct of the second examination for medical degrees allows the practical examinations to be held at the schools. Similar arrangements have been applied to the examinations in botany, chemistry, physics, and zoology for the final examinations in arts and science. A scheme for the conduct of the final B.Sc. (special) and B.Sc. (engineering) examinations for internal students at the Imperial College has been approved. As the result of an arrangement with the London County Council the Senate has adopted the principle that, save in exceptional cases, the minimum salary of a university professor shall be £1,000 a year, and of a university reader £500; this will apply retrospectively for three years to the salaries of professors and readers paid or mainly paid out of the Council's grant. The visitation of schools of the University is being continued, and during the year reports of inspectors were received with regard to the London School of Tropical Medicine, the Lister Institute of Preventive Medicine, the Royal Dental Hospital and the London School of Dental Surgery, and the Royal Naval Medical College. In touching on the financial side Sir Cooper Perry said that the Treasury, acting upon the recommendation of the University Grants Committee, had increased the total annual grant to the University, its colleges and schools, from £377,000 to £462,000; in addition, non-recurring grants, amounting in all to £26,000, had been made towards meeting pressing needs. By the decision of Buckinghamshire to make a grant the tale of Home Counties which contribute to the cost of students' education in London is about to be completed.

In concluding his report Sir Cooper Perry made reference to three matters which, he said, were of great importance to the life of the University as a community. The first was that the Senate had purchased a sports ground at Motspur Park and was negotiating for a host-house at Chiswick. The second was the existing position with regard to the Bloomsbury site, which had been offered back to the Duke of Bedford's trustees, who had accepted the offer. The third matter was the report of the Departmental Committee on the University; the President of the Board of Education had announced that the Government was in general agreement with the recommendations of the Committee and proposed to introduce legislation for the purpose of setting up a statutory commission for the University accordingly.

University College Hospital Medical School.

Three scholarships will be awarded during this month: (1) The Bucknill Entrance Scholarship, entitling the holder to the course of intermediate medical studies at University College, and the final course at University College Hospital and Medical School. The examination will be held on Tuesday, June 29th. (2) Two Goldsmith Entrance Exhibitions, entitling the holder to the final course, are open to students preparing for the degrees of the University of London, or other British universities, or for the diplomas of the Royal Colleges of Physicians and Society of Apothecaries. Full Secretary, University College Hospital, Gower Street, London, W.C.1.

UNIVERSITY OF LIVERPOOL.

At a meeting of the Council held on May 26th it was agreed to confer the title of Associate Professor on Dr. W. J. Dilling, lecturer in pharmacology and general therapeutics.

UNIVERSITY OF EDINBURGH.

IN consequence of the recent announcement by Professor B. P. Watson of his intention to resign the chair of midwifery and diseases of women as from September 30th next, the Curators of Patronage of the University are prepared to consider applications for the chair. Intending candidates may obtain particulars from the Secretary to the Curators, 4, Albany Place, Edinburgh.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

SURGERY.—R. V. Cookes, C. F. L. Hazard, S. E. Hymans de Tiel (Section ID), L. O. Jagassar, K. G. B. McMahon.
MEDICINE.—R. V. Cookes, M. Escovar, J. E. Howard, R. F. Middleton, J. Pattis, A. Purvis, H. A. Sack, M. Stinesbeck, F. Widdlake.
FORENSIC MEDICINE.—R. P. Charles, M. Escovar, H. J. Fordham, E. J. Jones, E. Kessel, P. H. L. Moore, A. Purvis, R. I. Richards, H. A. Sack.
MIDWIFERY.—A. K. A. Carter, L. O. Jagassar, K. G. B. McMahon, R. F. Middleton, E. Kessel, I. Rivlin, A. D. Shubsachs.

The diploma of the Society has been granted to Messrs. M. Escovar, C. F. L. Hazard, S. E. Hymans de Tiel, E. J. Jones, E. Kessel, P. H. L. Moore, I. Rivlin, H. A. Sack, F. Widdlake.

LONDON INTERCOLLEGIATE SCHOLARSHIPS BOARD.

Medical Scholarships.

Six medical entrance scholarships and exhibitions of an aggregate total value of £512, tenable in the Faculty of Medical Sciences of University College and in the medical schools of University College Hospital, the London Hospital, and the London (Royal Free Hospital) School of Medicine for Women, will be offered. The examination will commence on June 29th. Full particulars and entry forms may be obtained from the Secretary of the Board, S. C. Ranner, M.A., the Medical School, King's College Hospital, Denmark Hill, S.E.5.

The Services.

DEATHS IN THE SERVICES.

Inspector-General Standish Thomas O'Grady, R.N. (ret.), died at Folkestone on May 10th. He was the son of the late Captain Robert Dring O'Grady, of the 30th Foot, and was educated in Dublin, where he took the L.R.C.S.I. in 1875, and the L.K.Q.C.P. in 1876. He became Deputy Inspector-General on February 18th, 1901, and retired on January 26th, 1910, with a step in rank to Inspector-General. When fleet surgeon in charge of Yarmouth Hospital, he received the thanks of the Admiralty for his efficient administration of that institution.

Surgeon-General James O'Brien Williams, R.N. (ret.), died at Othly St. Mary on May 8th, aged 74. He took the L.R.C.S.I. in 1875, and graduated as M.D. and M.S. of the Queen's University, Ireland, in 1877. Entering the navy soon after, he attained the rank of deputy surgeon-general on January 25th, 1906, and was granted the rank of Surgeon-General on his retirement on November 25th, 1911. When surgeon of H.M.S. *Albacore*, at Suakin, in 1887-88, he voluntarily placed his services at the disposal of the senior medical officer of the Egyptian army, and for so doing, and for his help in the treatment of the wounded after the action of Mareh 4th, 1888, he received the thanks of the Egyptian Government. Surgeon-General O'Brien Williams had been a member of the British Medical Association for forty-three years. He is survived by his widow and two sons.

Colonel Charles Cooper Reilly, C.B., Army Medical Service (ret.), died at Countess Wear, near Exeter, on May 3rd, aged 65. He was born at Kildare on July 18th, 1862, and was educated at St. Thomas's Hospital, taking the M.R.C.S. and L.R.C.P. (London) in 1884. He entered the army as surgeon on January 31st, 1885, became colonel on April 23rd, 1914, and retired on July 18th, 1919. He served in the Sudan, 1885-86, receiving the Egyptian medal and star; in South Africa in 1900-01, when he received the D.S.O. for his actions in the Orange Free State, in the Boer War; in the actions at Johannesburg, Pretoria, and Cape Colony, including the action at Wittebergen, receiving the Queen's Medal with four clasps; and in the war of 1914-18, at first as A.D.M.S., and from 1915 as D.D.M.S., being mentioned in dispatches in the *London Gazette* of July 13th, 1916, and being decorated with the C.B. in 1917.

Medical News.

A PAMPHLET issued by the Department of Scientific and Industrial Research (which will supply copies on receipt of a request addressed to the Secretary at 15, Old Queen Street, S.W.1) gives an indication of the wide range of the investigations on the proper utilization of natural and artificial light which the department is conducting under the supervision of its Illumination Research Committee, whose two medical members are Sir J. Herbert Parsons and Dr. H. Hartridge. Such matters as the relation between illumination and speed and accuracy of work in the printing and other trades; the design of reflectors; the access of daylight in picture galleries; and the effect of colour, distribution of light, and "flicker" on ease of work are being considered. In view of the millions of pounds expended annually in this country on lighting, the need for experiments in order to ascertain the best methods of using light and to encourage true methods of economy is evident. Good lighting is a subject of interest to the whole community, and there is no one who is not to some extent dependent upon it in his daily work.

THE French Government has decided to establish a laboratory for the control of antisyphilitic drugs issued to public dispensaries or placed on sale. At the request of the Government the Académie de Médecine has appointed a commission to advise as to the details of the organization of this laboratory and as to its cost.

THE annual oration will be delivered to the London Dermatological Society by Sir Humphry Rolleston, Bt., on Wednesday, June 16th, at 4.30 p.m., at St. John's Hospital, Leicester Square. The subject is the relations of dermatology and general medicine. The annual dinner of the society will be held at the Trocadero Restaurant at 6.45, when Sir Humphry Rolleston will be the guest of the society.

THE Joint War Committee of the British Red Cross Society and the Order of St. John give notice that, owing to the heavy cost of housing, they intend six months hence to destroy all the correspondence, vouchers, and receipts in their possession. If, therefore, any member of the late personnel requires a reference application should be made before June 30th next to the Secretary of the Joint War Committee, 19, Berkeley Street, W.1.

THE Fellowship of Medicine and Post-Graduate Medical Association announces that Mr. V. Zachary Copo will give a demonstration in surgery at St. Mary's Hospital, Paddington, on June 9th, at 3.30 p.m., and Mr. Whiting a demonstration in ophthalmology at the Royal London Ophthalmic Hospital, City Road, on June 10th, at 12.45 p.m. These demonstrations, organized by the Fellowship, are open to all members of the medical profession without fee. The Chelsea Hospital for Women provides a two weeks' course from Wednesday, June 9th. A four weeks' course in genito-urinary diseases will be held from June 7th to July 3rd at All Saints' Hospital. From June 14th to 26th the City of London Hospital for Diseases of the Heart and Lungs will give a special course. There will be a course, primarily for general practitioners, at the London Temperance Hospital from June 14th to 25th from 4.30 to 6 p.m. The following courses will be held during July: cardiology at the National Hospital for Diseases of the Heart, dermatology at the Blackfriars Skin Hospital, neurology at the West End Hospital for Nervous Diseases, ophthalmology at the Royal Eye Hospital, and an intensive course in medicine, surgery, and the specialties at the North-East London Post-Graduate College (Prince of Wales's General Hospital), Tottenham, N. Syllabuses and the general course programme may be had from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1, who will also supply copies of the *Post-Graduate Medical Journal*.

A COURSE of post-graduate lectures at the Cancer Hospital, Fulham Road, S.W.3, in June and July, will commence on Wednesday, June 9th, at 4.30 p.m., when Mr. W. E. Miles will speak on carcinoma of the rectum. On Friday, June 11th, Mr. Cecil Rowntree will lecture on cancer of the breast. The further lectures of the series will be given on subsequent Wednesdays and Fridays at the same hour, terminating on July 16th, when Dr. Stanley Wyard will deal with carcinoma of the stomach.

THE annual general meeting of the London and Counties Medical Protection Society will be held at Victory House, Leicester Square, W.C.2, on Wednesday, June 9th, at 4 p.m.

THE annual general meeting of the Röntgen Society will be held at the British Institute of Radiology, 32, Welbeck Street, London, W.1, on Tuesday next at 8.15 p.m., when papers will be read on radiography of the accessory sinuses and on a method of dosage for use in actinotherapy.

ALL medical graduates of the University of Brussels are invited to a meeting, at 4 p.m. on June 9th, at 147, Harley Street, when they will be received by the President, Dr. Fielden Briggs, and an address will be given by Dr. Arthur Haydon, Honorary Secretary of the Brussels Medical Graduates' Association.

AN exhibition of Tardenoisian and pigmy types of stone implements will be opened at the Royal Anthropological Institute, 52, Upper Bedford Place, W.C.1, on Tuesday, June 8th, at 2.30 p.m. It will continue open till Tuesday, June 22nd. On that day at 8.30 p.m. a paper will be read by Mr. V. Gerdon Childe, on the first colonisation of Central Europe. It will be illustrated by lantern slides.

DR. E. A. OWEN, head of the radiology division at the National Physical Laboratory and secretary of the Röntgen Society, has been appointed to the professorial chair of physics in the University College of North Wales, Bangor.

ARRANGEMENTS have been made at Queen Charlotte's Maternity Hospital, Marylebone Road, for the accommodation of an increased number of medical students and practitioners, who can now be received for courses of practical midwifery at short notice.

THE International Committee of the Red Cross will hold a competition in Geneva in the autumn to adjudge the best type of the following for use in war: (a) stretcher; (b) arrangement for carrying a stretcher in a railway carriage, aeroplane, carriage, ambulance, sleigh, or boat; (c) labels for wounded in the field; (d) first-aid outfit to be carried on the person; (e) identity discs. The competition will be judged by a special international committee of experts, and prizes will be awarded. All exhibits must reach Geneva by August 1st at latest, and packages should be addressed to Lo Comité International de la Croix-Rouge, 1, Promenade du Pin, Geneva, Switzerland, and marked "Specimens for the institution of the international study of ambulance material." This is necessary in order to avoid Swiss customs duty.

THE KING has appointed Dr. Cecil M. Relston (Chief Medical Officer) to be an official member of the Executive Council of the Presidency of Dominica and has given directions for his appointment to be an official member of the Legislative Council of that presidency.

THE Prince of Wales will open the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W., on July 15th.

THE dinner of the Society of Apothecaries, which was postponed on account of the general strike, will be held on Tuesday, June 15th, at 7.30 o'clock, at Apothecaries' Hall, Blackfriars. The Lord Mayor and Sheriffs will attend.

DR. NORMAN TATTERSALL, who has been for fourteen years thieriosis physician to the Welsh National Memorial Association, was presented by the medical practitioners of Mid-Glamorgan, on May 22nd, with an address and a bureau, on the occasion of his departure to Leeds, where he is taking up a similar appointment under the Leeds Corporation.

THE Sudan Government has decided to utilize the Lee Stock indemnity fund: first, to build a new medical research laboratory of the same type as that of the Kitchener School of Medicine; secondly, to provide for a travelling railway laboratory; thirdly, to finance an intensive campaign against bilharzia and ankylostomiasis; fourthly, to combat ophthalmia, principally in the Northern Sudan; and, lastly, to carry out improvements of the Omdurman leper settlement. The *Times* correspondent in Cairo, from whose dispatch we take this information, states that this allotment will exhaust about half the fund and that the use of the remainder is still under consideration.

THE fiftieth session of the French Association for the Advancement of Sciences will be held at Lyons from July 26th to 31st. At the Section of Medicine and Surgery, which will be under the presidency of Professor J. Teissier, the following questions will be discussed: (1) Asystoles of reflex origin, introduced by Dr. Dumas; (2) evolution of chlorides in the organism, introduced by Dr. Florence.

THE eighteenth International Congress on Alcoholism will be held at Derpat from July 22nd to 28th, when papers will be read on the psycho-physiological action of alcohol, alcohol and the death rate, alcohol as the cause of accidents and poverty, hypnotism in the treatment of alcoholism, local opium, and prohibition. Further information can be obtained from the International Office for Combating Alcoholism, Avenue du Grammont, Lausanne.

THE French National League for Combating Venereal Disease has offered a prize of 5,000 francs for the best work on heredo-syphilitic psychopathies in the child and adolescent and their role in juvenile criminality; a prize of 5,000 francs for the best work on the association of syphilis and tuberculosis in osteo-articular affections; and a prize of 20,000 francs for the most important discovery in venereology in 1926 and 1927. The essays for the first two prizes must be written entirely in French and be sent in triplicate to the *Ligue française contre le péril vénérien* before October 1st, 1928.

AT the invitation of Dr. Plantier a party of London medical men made a short trip to Biarritz and the surrounding country during the Whitsun holidays. The members of the party were hospitably entertained by Dr. and Mme Plantier at Héliant, one of the most modern therapeutic institutions in France. Excursions were made to other health resorts along the Côte des Basques, and as the weather was kind they were thoroughly enjoyed.

WE have received the first part (A-D) of the sale catalogue published by *L'Art Ancien*, Lugano, of early books on medicine, natural sciences, and alchemy. Each entry is accompanied by a brief explanatory or historical note in English, and the text is freely interspersed with contemporary woodcuts.

THE International Federation of Eugenics will hold its next meeting in Paris on July 2nd and 3rd, when the chief subjects for discussion will be the medical certificate before marriage, consanguineous marriages, and immigration.

THE Société de Pathologie Comparée has offered two prizes of 500 francs each for the best unpublished essays on pernicious anaemia, and cancer in man or its relations with cancer in animals and plants. The essays should be sent to the general secretary before October 1st.

DURING the period December 6th, 1925, to January 2nd, 1926, 1,295 fatal cases of plague occurred in Java.

THE number of new cases of syphilis admitted to the Hôpital Saint-Louis, Paris, was 1,955 in 1924 and 2,445 in 1925—an increase of 20 per cent. in a year. A similar recent increase in syphilis has also been noted in the provinces.

DR. ETIENNE BURNET, subdirector of the Pasteur Institute of Tunis, has been awarded the Tunis medical prize of 5,000 francs for his work on Mediterranean fever. He has also been nominated assistant director of the institute.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, **British Medical Association House, Tavistock Square, W.C.1**, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

REFERRED PAIN.

"Y. T." writes: Can any of your readers refer me to a book or paper in which "referred" or "reflected" pain is fully considered?

ALTERATIONS TO A HOUSE.

"X. Y. Z."—On the information furnished, assuming that the house is above working-class standard, the Housing Acts as to habitability will not apply. Assuming that one or two rooms only are affected, it is thought unlikely that a local authority, if called in after the re-erection of the glass house, would hold that a nuisance, requiring action under the Public Health Act, existed. The question is primarily one of right as between landlord and leaseholder, depending on all the facts. It would be best to take legal advice.

INCOME TAX.

Motor Car Depreciation, etc.

"J. L." sold in 1923 for £95 a car which cost him £400 and bought a second hand car for £200, and in 1924 sold for £16 a cycle which had cost him £58, buying in 1925 a second-hand cycle for £22 8s.

"* (1) Obsolescence allowance, to be treated as a professional expense reducing the year's profits, for 1923, £200—£95=£105, in respect of the car transaction, and for 1925, £22—£16=£6, in respect of the cycle transaction. (2) Depreciation allowance for 1925-26 at, say, 20 per cent. of the value of the car and cycle, as written down from the original cost at the same rate of depreciation over the period from the dates of the original sales to the last date at which "J. L.'s" accounts were made up prior to April 5th, 1925.

"P." states that the car expenses, including depreciation, of his wife and himself in performing the duties of their public appointments exceeded the amount of their allowances. Can they claim relief in respect of the difference?

"* There is no legal bar, but the expenses must be proved to have been incurred wholly, exclusively, and necessarily in the performance of the duties of their offices. It is usually difficult to prove that the allowance made by public bodies is insufficient on that rather stringent basis. It makes no difference to the total tax payable whether joint or several returns are made, but in either case the wife's earnings should be shown separately.

LETTERS, NOTES, ETC.

TREATMENT OF GOUT.

DR. VAUGHAN PENDREB (East Sheen) writes: I have recently had under my care a very instructive case of gout—a short, plump man, aged 50, who has had gouty attacks since he was 31. The disease has been inherited from his grandfather and father, as, in my experience, is invariably the case. There is no albuminuria. Two years ago a friend advised him to take atophan, the drug so widely used at present. After he had taken a hundred pellets there developed an attack of diarrhoea and melaena; his friend was affected in the same way; in neither case was the gout improved. In January, 1926, he was given aquinol, the sales equivalent of atophan (allyl phenicinchonester). The gout was uninfluenced, and when I was called in at the beginning

of March he was gravely ill with severe gout in his feet, and protracted anaemia that was only cured after a fortnight's stay in Ramsgate and much arsenic. I feel sure that the quinine in the aquinol had acted as a very potent haemolyser. After many years' experience I am convinced that the Hippocratic dictum—that the *Colchicum autumnale* is the remedy for gout—is true. Full doses must be given. Five drops are useless; fifteen or more every four hours is the only cure of the disorder known to-day. The much discussed depression caused by the drug is a myth.

BROW PRESENTATION.

THE recent cases of brow presentation recorded in the **BRITISH MEDICAL JOURNAL** have induced Dr. HARRY FREEMAN (Dalston) to send the following record of a case which was successfully delivered: A multipara, aged 34, had been in labour for twelve hours before I was called. On examination the membranes were ruptured, the cervix nearly fully dilated, and a brow (right mento-anterior) was presenting. The patient had had two very easy previous confinements, and has a very roomy pelvis; the foetal heart sounds were easily audible, so under anaesthesia I converted to an occipito-posterior, and rotated. This proved much easier than I anticipated, and after flexing the head and pushing it well down into the pelvis, forceps were applied and the child delivered alive, though badly bruised. Before intervention I had, however, waited an hour, but there was no progress whatever and it seemed that the head would get impacted. The mother made an uneventful recovery, and the child, now 2 months of age, is perfectly well in every respect.

IODINE INJECTION IN RHEUMATOID ARTHRITIS.

In a letter with reference to an article on intramuscular injection of guaiacol-iodine-camphor oil by Dr. S. Watson Smith (October 10th, 1925, p. 648) and a subsequent letter (March 6th, p. 449), Dr. R. KERRY (Montreal) writes: The hypodermic injection of iodine has been used here for a number of years with consistently good and often striking results. It does not appear that the addition of camphor or guaiacol to iodine is beneficial, and it certainly renders the injection more irritating. A 1 in 40 solution of iodine in sesame oil, if about six months old, is unirritating at the time of use and is followed by no reaction; this is probably true if other bland oils are used. The pain caused by a freshly made solution is negligible. Trial has been made of a 1 in 50 colloid, but it is less active than the oily solution, though more pleasant to use. Intramuscular injection is not necessary, but the oil must be carried well through the skin, as induration, lasting some months, results if it be not placed deeply enough. The injection, he says, is followed by prompt relief from pain, owing to disappearance of inflammatory pressure, and, in acute cases, by a rise of one or two degrees in temperature, which seems to be beneficial rather than otherwise. When gross lesions are present, as in extensive pulmonary tuberculosis, toxæmia, resulting from the use of iodine, may overwhelm the patient, and fatal cases have so occurred. One-quarter of a grain of iodine (the ordinary weekly dose) in the body of an adult can have but small value as a germicide, and its undoubted potency must be due to its action, directly or indirectly, as an antitoxin.

ADVERTISEMENTS BY POST.

DR. GEORGE JONES (London, S.E.) writes: During the recent strike there was a sudden and most blessed disappearance of advertisements sent by post. Now the enterprising firms have begun again and are making up for lost time. Could not this waste of time, money, and printer's ink be stopped? I do look at the advertisements in the **BRITISH MEDICAL JOURNAL** and other journals. I try to look through some of the regular advertisements of a few well known firms, but life would not be long enough to read the lot. Can no means be discovered of saving the time and eyesight of the profession? Many "ads." are quite well written and some are interesting, but the volume of printed matter consigned to the waste-paper basket is a grief to me.

DEATH FROM PNEUMONIA AFTER NITROUS OXIDE ANAESTHESIA.

Correction.

AN accident seems to have overtaken page 896 of last week's **JOURNAL**, in which the line at the foot of col. 1 was mutilated and that at the foot of col. 2 disappeared altogether. The reference in the footnote in the first column is "*Zeit. f. Hyg. u. Infektionskrankh.*, 1918, 85, 1"; the missing line in the second column consisted of the word "acidosis," which ended the paragraph. We desire to express our regret to Professor Ernest Glynn, author of the article affected.

MEDICAL INSURANCE AGENCY.

WE are asked to say that a member re- has received particulars not given his name and address. The inquiry refers to a 1920 Belsize car.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 62, 63, 66, 67, and 68 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 64 and 65.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 207.

A Lecture

ON

PREVENTIVE MEDICINE AS APPLIED
TO OBSTETRICS.*

BY

J. M. MUNRO KERR, M.D.,

PROFESSOR OF OBSTETRICS AND GYNAECOLOGY, GLASGOW UNIVERSITY.

In the "Resolutions of the General Medical Council with regard to Professional Education" which came into force in January, 1923, you will find the recommendation: "That throughout the whole period of study the attention of the student should be directed by his teachers to the importance of the preventive aspects of medicine." You are commencing the study of obstetrics and gynaecology. What, therefore, could be more appropriate on this the opening day of the session than an address on preventive medicine as applied to obstetrics?

The science and art of obstetrics are concerned with: A, Pregnancy; B, Parturition; C, Puerperium. Each of these events has disturbances peculiar to it. Some of them are preventable; others with our present knowledge are beyond our control. In this introductory lecture I propose to deal only with the more common complications which are preventable.

A. PREGNANCY.

In many of the early civilizations the pregnant woman received special attention and consideration. Crude tests for pregnancy and remedies for the incidental discomforts were employed. The instability of the nervous system was recognized, and great importance was attached to the effect of external influences. But the scientific management of pregnancy, or, as it is more popularly expressed, "the care of the expectant mother," is of recent date, and has gradually evolved as we have come to understand in some slight degree the complicated changes in the normal physiological processes which produce the disturbances peculiar to pregnancy. Only in the last decade has this important branch of preventive medicine received official recognition. In 1915 a very far-reaching Act was placed on the Statute Book—namely, the Notification of Births (Extension) Act, 1915—which relegated to the public health authorities the responsibility of the proper care not only of the parturient and her offspring up to school age, but also of the mother during pregnancy. As a result, an ever-increasing number of ante-natal clinics have been established. Unfortunately, full advantage is not taken of them. To remedy this failure of pregnant women to seek medical advice it has been suggested to make the payment of maternity benefit, which all insured women enjoy under the Insurance Act, conditional on the pregnant woman engaging a medical practitioner or midwife some months before the expected confinement. The recommendation by the Committee on Puerperal Morbidity and Mortality that this should be done at least twelve weeks beforehand is futile; for the most common disturbances of pregnancy commence very much earlier than is generally supposed. Besides, many pregnant women suffering from chronic disease, such as syphilis, albuminuria, glycosuria, tuberculosis, etc., must be treated at the very commencement of pregnancy.

Now, you very naturally ask why this physiological process of pregnancy should produce such serious disturbances. As you are all aware from your physiological studies, the process of pregnancy should be a "symbiosis harmonique homogène" (Bar), in which the mother takes her food better, utilizes the food which she takes, and improves in general health. Unfortunately, however, in many instances it is of a very different nature: the ovum in its growth and maintenance not only draws on the mother's capital, but also on her tissues. The mother's tissues begin to be consumed by reason of the very early in pre-natal development.

as many writers indicate. Its incidence dates back to the time of embedding, when the tissues of the endometrium are digested and destroyed by the trophoblast of the ovum, and the end-products are directly thrown into the maternal circulation. In no other way can one explain a case which was under my care many years ago and profoundly impressed me at the time. This was a patient who began to have nausea and vomiting ten days after marriage. The last menstruation ended two days before her marriage. Thus the early disturbances incidental to pregnancy were experienced about the seventh or eighth day after fertilization, and anything from the first to the sixth day from the commencement of embedding.

There occurs in pregnancy, therefore, a battle between natural resistance and enemy forces, the imperfectly controlled activities of the ferments produced by the developing ovum. When the latter gain mastery a "negative phase" of metabolism is produced and the various complications of pregnancy develop, which are referred to as the toxæmias of pregnancy.

The care of the expectant mother is chiefly concerned with assisting her to combat this tendency towards a negative phase, by careful dieting, improving elimination, avoiding fatigue, and administering particular and more specialized remedies according to her requirements. To accomplish this satisfactorily the patient must be seen and overhauled at short intervals (three to four weeks). At the present time this medical examination is still incomplete, for we know comparatively little regarding these ferments, and we have still only very crude methods for testing their presence and the early dyscrasias they induce. But if pregnant women are supervised and suitably treated the graver toxæmias seldom develop. A striking instance of this is eclampsia or convulsions, for among pregnant women supervised by obstetric specialists and careful general practitioners it very rarely occurs. The death rate from eclampsia in Scotland and Glasgow during the years 1918-23 was as follows:

Death Rate from Eclampsia.

Year.	Glasgow.	Scotland.	No. of Births.	
			Glasgow.	Scotland.
1918	20=0.85 per 1,000	100=1.01 per 1,000	23,524	93,554
1919	29=1.12 " "	103=1.02 " "	25,835	106,263
1920	22=0.67 " "	134=0.93 " "	32,526	136,546
1921	25=0.87 " "	125=1.00 " "	29,712	123,201
1922	22=0.73 " "	122=1.06 " "	28,298	115,085
1923	35=1.31 " "	126=1.13 " "	25,702	111,902

Another most interesting group of disturbances are the complications which arise as a result of disorder in the ductless glands, for all these glands are affected by pregnancy. Take, for example, the increased diastatic content in the urine, associated in many instances with disturbances in the internal secretion of the pancreas; or the albuminuria which in some instances is associated with an imperfect thyroid secretion.

These disturbances, which the pregnant woman contracts as a result of this negative phase of metabolism, not only endanger her life during pregnancy—they increase the dangers of parturition. Nor is this the whole toll: in a number of instances, where they are not completely recovered from, they produce permanent chronic disease. For example, I know of several women who are at present suffering from chronic albuminuria which had its incidence in an albuminuria of pregnancy; some who have asthma when their general health is lowered, or their digestive process disturbed; and others whose general health, digestion, and feeling of well-being have never quite returned to the normal. Lastly, the injurious influence which these poisons exercise on the child must be taken into account. Some 30 to 40 per cent. of stillbirths are due

* Introductory to the systematic class of obstetrics and gynaecology, Session 1925-26.

* Recently my attention has been directed to another case in which the morning sickness occurred on the eighth day after marriage and eleven days after the last day of the period.

to this cause. The chief difficulty at present is the treatment of these complications while they are still incipient. Among the well-to-do and comfortably off this does not arise—the patient can be transferred to a nursing home, or trained nurses brought in to take charge; but among those in less comfortable circumstances this is impossible in the patient's home, and institutional treatment is totally inadequate. A more satisfactory condition can only be reached when adequate hospital accommodation has been provided for all cases requiring institutional treatment.

In addition to this medical care of the expectant mother there is the more definite investigation and examination late in pregnancy with the object of recognizing or preventing the complications of parturition. The more common of these may be summarized under three heads: (a) malpositions of the child, (b) deformities of the pelvis, (c) tumours obstructing the canal.

(a) *Malpositions of the Child*.—An enormous number of women are allowed to drift into labour without a sufficient examination, and without any attempt being made to diagnose and correct malpresentations prior to labour. Transverse presentation can always be corrected, even in the later days of pregnancy. A similar procedure should also be followed in breech presentation, a complication not very serious in a multipara, but attended with great difficulty and resulting often in serious injury to the mother and child if the parturient is a primipara. Now, practically all these cases of breech presentation can be recognized in the later weeks of pregnancy, the child turned, and a vertex presentation established. In recent years a further advance has been made—namely, the conversion of occipito-posterior positions of the vertex (where the back of the child is towards the back of the mother—a very common and troublesome condition) into dorso-anterior positions. Personally I have not been very successful with this manoeuvre. There are probably some peculiar factors still not understood which determine occipito-posterior positions; and so, while I believe a certain number may be corrected, it is not possible to do this in all cases. Fortunately, however, in most instances timely intervention during labour can bring about a correction of this very common and troublesome complication of parturition, but this will be referred to later.

(b) *Deformities of the Pelvis*.—This is a common cause of difficulty, especially in Glasgow where rickets is so prevalent; by pelvimetry, manual examination, and radiography it is possible to determine the degree of pelvic deformity and to estimate accurately the relative size of head and pelvis. Having done this, one is in a position to select beforehand the most suitable treatment, with the result that the foetal and maternal death rate from this serious complication can be reduced to a very low figure indeed. I remember one year in the Maternity Hospital I and my assistants had no maternal death and only one foetal death in our department among the cases which we saw in the late weeks of pregnancy or early in labour.

(c) *Tumours Obstructing the Canal*.—These are not difficult to recognize or treat, if diagnosed before labour commences.

B. PARTURITION.

The problems of pregnancy are simple compared with those of parturition. Already morbidity and mortality incident to pregnancy are progressively lessening, but this cannot be said of parturition.

I. THE INCIDENCE AND CAUSES OF MATERNAL MORTALITY IN CHILDREN.

(a) Infection.

The death rate from puerperal infection in Scotland and Glasgow for the years 1921-23 was as follows:

Deaths from Puerperal Infection.
(Per 1,000 births.)

Year.	Scotland.	Glasgow.
1921	2.42	2.45
1922	2.53	3.28
1923	2.2	2.7

Although parturition is a natural process, unfortunately in a large proportion of cases it does not run a natural

course any more than does a pregnancy; further, where it terminates spontaneously its management must be carried out with all aseptic precautions. Puerperal infection is a wound infection. Infection of a wound can only be prevented by special preparation of patient, surgeon, and nurses; so in obstetric practice puerperal fever can only be prevented by employing similar procedures. This is done in all maternity hospitals. Puerperal infection in such institutions only occurs (in uninterfered-with cases) where the individual has accidentally acquired infection prior to her admission to hospital. This is termed "autogenous infection." Could all parturient women be treated in well appointed maternity hospitals or nursing homes puerperal infection could be reduced to a minimum. This is not practicable. But the providing of institutional treatment for all primiparae, in addition to all multiparae whose labour is obviously or likely to be a complicated one, is feasible, and would be of tremendous advantage; for the primipara is much more prone to infection than the multipara, because her labour is generally longer and more difficult.*

As regards domestic midwifery practice, a number of women can be safely treated in their own homes, provided the accouchement is carried out on approved lines. But a much greater number cannot be attended as satisfactorily, and still more should not have their confinements at home, for, apart altogether from the danger, every sense of decency is violated by confinements taking place in such houses.

The reasons why infection is more prone to occur in domestic midwifery practice are:

(1) The preparation of the patient beforehand cannot be carried out thoroughly in a private house. To appreciate this it is only necessary to contrast the preparations made by a surgeon prior to operation and those generally employed by the obstetrician, or by any medical attendant in domestic practice. You are familiar with the extreme care taken by the surgeon in the cleansing of his hands, in the wearing of rubber gloves, in the sterilization of his instruments, in the preparation of the field of operation, in ensuring that only absolutely sterilized swabs and dressings are employed, and that sterilized towels, sheets, etc., are placed below the patient and immediately around the field of operation. How different the case of the parturient confined in her own bed, attended by an accoucheur whose hands are often imperfectly cleansed and who seldom wears rubber gloves, sponged before and after delivery by nurses, who perform all kinds of duties—toilet of the bowels, tidying of the rooms, cooking—and who rarely if ever wear rubber gloves. Take, again, the swabs and dressings—very often removed from a packet of gamgee or cotton-wool bought from the nearest chemist and never sterilized. Fortunately, however, not all practitioners trust to such unsterilized swabs and dressings. Many obtain sterilized gauze from such firms as Bell and Croyden, or a local nursing home, while at present I am glad to report that a number of health authorities are prepared to supply such dressings for a small sum, or free of charge in necessitous cases. But probably the greatest source of danger is from the field of operation. The surgeon who is about to perform an operation shaves the field, cleanses it most carefully with soap and water and antiseptics, and surrounds it with towels before he proceeds to the operation. The field of operation in the case of the parturient, except in maternity hospitals and in the hands of obstetric specialists and a few general practitioners, receives but perfunctory attention, and yet it is a most septic area. The hair of the pubis and folds of the vulva teem with pyogenic organisms, constantly added to from the bowel, which is in the immediate vicinity. Until the same procedure is carried out in all parturitions as is followed in surgical operations maternal mortality and morbidity will not appreciably diminish, for from this area organisms extend and are carried up by the examining fingers, especially if the obstetrician has to carry out any obstetric operation such as forceps delivery or version. It has been urged that women would object to such preparations. This I am sure is not so. I am perfectly certain that if it were impressed on all parturient women that this detail is necessary, few would object. As a matter of fact they make no objection when this is done in a nursing.

* Vide Table I, p. 75, 1923 Report, Medical Officer of Health.

home, or in their own homes prior to an operation. There is no use pretending that parturition is a simple physiological process, and that the management of it is equally simple: in 20 to 30 per cent. of cases there are major or minor abnormalities, and in all there is the risk of infection.

(2) Where operative intervention is necessary there is not the same assistance available as in a hospital or nursing home, where one or more assistants can be summoned. This is a matter of very great importance.

(3) Because a confinement upsets the rest of the work of a busy general practitioner, and he is inclined to hasten the delivery. I shall refer to this more fully in a moment.

(b) Haemorrhage.

The next most important cause of maternal death is haemorrhage, the incidence of which is about 0.8 to 0.85 per 1,000. The haemorrhages of the later weeks of pregnancy and parturition are accidental occurrences which, as far as we are at present aware, cannot be prevented. We can, however, lower the mortality, which is very considerable in this complication, by improvement in treatment, and especially if a greater number of such cases are transferred early to hospital.

(c) Injuries.

These are very difficult to estimate, because in many cases where injury to the patient results from the delivery death takes place not as a result of shock or injury, but owing to the fact that the bruised tissues become infected; death is usually due to septicaemia. Most of the grave injuries result from hastening unduly the delivery. As a matter of fact the two generally go together. To extract the head situated at the outlet is comparatively simple and safe, and at worst will only result in a slight tearing of the perineum which can be easily repaired; but to apply forceps while the head is high in the pelvis, especially if it is still within the neck of the uterus, is a different matter. No one can ever pull down the head with forceps as well as Nature can drive it down. Infinite patience is necessary in many cases. The busy general practitioner says he has not time to wait, and after some years he persuades himself that not only is it more convenient to himself to deliver with forceps as soon as possible, but that it is actually in the interests of his patients that they should not be allowed to remain in labour longer than necessary. Further, and this is a very important matter, many individuals, particularly of the artisan class, appraise the value of the accoucheur by the promptitude with which he delivers them and relieves them of their suffering. This hurrying of a delivery with forceps cannot be too strongly condemned. Yet, knowing this, and with witnesses who represented how serious and how frequent were the injuries which resulted from too early application of forceps, the Scottish Departmental Committee* has nothing further to suggest than discussion in medical societies and journals, as if this had not already been done of nauseum, and without having the slightest effect in bringing about a more careful attitude towards the employment of forceps.

II. THE INCIDENCE AND CAUSES OF INFANT MORTALITY (STILLBIRTH) THE RESULT OF LABOUR.

There are four common causes of death during delivery: injury; certain forms of haemorrhage during the later weeks of pregnancy and labour; prolapse or falling down of the umbilical cord; and prematurity.

(a) Injury to the child is naturally proportional to the difficulty of the delivery. The prevention of this has already been considered in connexion with maternal mortality and morbidity.

(b) Haemorrhage (Maternal).—As regards haemorrhage, we find that this takes a very great toll of both mothers and children. In one particular condition where the after-birth comes first (placenta praevia) the maternal death rate of the Glasgow Maternity Hospital in 489 cases for the years 1920-24 inclusive was 13 per cent. and the foetal death rate 71 per cent.—not a very satisfactory state of matters, and one which could be greatly improved were

the cases of this complication recognized early and transmitted to hospital immediately. The results of the Edinburgh Maternity Hospital are practically the same.³

(c) Prolapse of Cord.—As regards the falling down of the cord, we find that it is associated with a very high infant death rate, but a negligible maternal mortality.

(d) Prematurity as a cause of foetal death is well known to you.

III. REMEDIAL MEASURES NECESSARY TO LOWER MATERNAL AND INFANT MORTALITY IN CHILD-BED.

There is at present a general conviction that improvements are necessary; the difficulty lies in determining the direction in which these should be initiated. As a contribution to the subject I would put forward the following policies.

1. Modifications and Improvements in Present-day Domestic Midwifery.

A number of the suggestions which I am about to make will be accepted and are easily carried out; others are more controversial and more difficult to secure.

(a) It is essential that hospital accommodation should be increased. Practically all grave surgical and medical diseases receive institutional treatment. Until a similar course is followed in obstetric practice maternal and foetal mortality and morbidity cannot be greatly reduced among the artisan class.

(b) All nursing homes and private houses in which women are received for their confinements should satisfy the health authorities. I am sure everyone will agree with the recommendation of the Scottish Departmental Committee (paragraph 101) "That legislation be considered to make the conduct of maternity homes illegal unless they are registered by the local authority and conducted to their satisfaction." In some nursing homes the appliances for sterilizing instruments, towels, bed-linen, etc., are inadequate; the conveniences for any operation defective; and the nursing inefficient and insufficient. Even more dangerous are private rooms or houses in which women are received for their confinements.

(c) Power should be secured by the local health authorities to remove a patient from her dwelling house to hospital if the house is deemed unsuitable for a confinement.

(d) As far as possible, primiparae should have their confinements in a hospital or nursing home. I have already pointed out the relatively large mortality and morbidity in primiparae.

(e) It is of the very greatest importance that the training of maternity nurses should be extended, and that every two or three years they should have a revision course in an institution.[†]

(f) Rubber gloves for midwives and nurses. All midwives should be compelled to wear sterilized rubber gloves when sponging the patient during and after her delivery. It is a very simple detail and would cost very little. This is necessary as they are called upon to do all manner of household duties—bathing the child, cooking food, tidying the house, keeping the patient's room in order, stoking the fire, etc.—and as their hands in consequence are frequently contaminated.

(g) The supply of a sterilized outfit for the confinement. This question has already been considered.

(h) Better training of students in clinical midwifery. It is little short of a disgrace that at the present day the student on graduation is unfitted for the practice of midwifery. His clinical training is inadequate, yet the day after he qualifies he may be called upon as assistant or locum tenens to perform serious obstetric operations which he has never done himself, or even seen performed. He would never attempt to deal with medical or surgical problems of the same magnitude. In this connexion the reports of the English and Scottish Curriculum Sub-committees are of particular interest, for both committees recommended a period of continuous and uninterrupted

* The Midwives and Maternity Homes Bill recently introduced applies only to England.

† This has been recommended by the Ministry of Health, Whitehall, Circular 517, p. 3, June, 1924.

* Paragraph 72, Scottish Departmental Report.

training in obstetrics and gynaecology as the best arrangement to secure satisfactory instruction in these departments. The English committee advocated six months, "no extraneous subjects to be studied at the same time."⁴ (St. Thomas's Hospital School has recently adopted this recommendation.) The Scottish committee was of opinion that one term—namely, three months—might be sufficient, and suggested that during this term instruction in vaccination and medical diseases of sick children should be included.⁵ It is only by having students for a continuous period that it is possible to give them adequate instruction. Obstetrics is on a different footing from that of medicine and surgery, because the exigencies of hospital obstetric practice are such that regular hours for teaching, demonstrations, etc., are not always possible and cannot always be arranged beforehand. The great success attained by the Rotunda and Coombe Hospitals in Dublin is largely due to the fact that students resident in these hospitals give up their whole time to the study of obstetrics and gynaecology. Personally I think that three months' clinical training would be sufficient, provided the students were given a preliminary course of thirty to forty lectures. This course should be given in the fourth year, and the three months' concentrated clinical teaching during one term of the fifth year. Further, I think it would be of great advantage to the final year student if for the other two terms of the fifth year he did either medicine or surgery. Thus he would do obstetrics, gynaecology, and pediatrics one term; medicine, ophthalmology, and fevers in another term; and surgery and throat, ear, and nose in the third term. Taking our school of Glasgow with a final year of roughly 150 students, that would mean that 50 were allocated to each of these divisions, and these 50 distributed over the different clinics. This would result in only three or four senior students being attached to each clinic. Under such an arrangement the student would gain a much more thorough clinical experience in obstetrics, medicine, and surgery, than is possible under existing conditions.

(i) *Special revision courses for general practitioners.* If general practitioners are to continue to undertake obstetric practice it would be almost necessary for them to undergo revision courses in hospital every two or three years. In times past they gained experience in a haphazard fashion from the numerous cases they attended. But obstetric practice is passing largely into the hands of midwives, with the result that general practitioners are gradually losing in experience and dexterity. The tendency therefore must be: (1) a number, and probably the best general practitioners, will refuse to undertake the responsibility of difficult obstetric practice—namely, emergency calls by midwives—except *ad misericordiam* appeals; (2) less capable practitioners will volunteer; (3) young graduates of little experience anxious to increase their practice will undertake the work.

2. An Obstetric or Maternity Service.

Although domestic midwifery practice might be improved along the lines suggested, the improvement would not be very decided. Sooner or later I believe it will be necessary to establish an obstetric or maternity service. I have long held this view, and in recent years have questioned a large number of my medical friends in general practice regarding such a service. The majority of them have expressed the opinion that they would be very pleased indeed to be rid of obstetric cases, especially among the artisan class, as they interfere with the ordinary work of a practice. A number, however, are opposed to the suggestion, but this opposition I reckon would be short-lived.

The future of domestic medical practice must be in the direction of pure medicine. Undoubtedly, a generally knowledge and experience of all the specialties is necessary, but medicine has become such a vast field that it is impossible for any single individual to follow new developments in all its branches. If preventive medicine is to be advanced, it is in the field of general practice that most can be accomplished. Specialists rarely see disease at an early stage: it is the general practitioner who has this great opportunity. Rather than be worried with the weary drudgery

of midwifery practice, with its irregular hours and constant anxieties, surely it would be preferable to have more time to devote to pure medicine. Many of my friends in general practice are most despondent over ordinary general practice and its future. Personally, I do not share their pessimism. There is a tremendous future for general practice if the general practitioner, instead of trying to qualify in every specialty, devotes his time and energies to becoming an expert physician.

This special obstetric service to which I have referred should be relegated to obstetric specialists who would give up their whole time to the particular service (this would include ante-natal and post-natal maternal and infant welfare). It would be inadvisable and unfair to other local practitioners to appoint one individual practitioner for part-time service, except in outlying country districts, where obviously it is impossible to have such specialists. In large cities and towns the difficulty of establishing an obstetric service would not be very great, nor would it be costly, for the skeleton of the scheme is present in the existing hospitals and health centres. The difficulty would be with the outlying parts of Argyllshire, the Western Isles, and the extreme North of Scotland. But even in these outlying districts much could be done, and few disasters would result if all patients were examined during pregnancy and before labour, if in the event of there being a suspicion of the probability of any difficulty they were transferred to the nearest maternity centre, and if all primiparae were transferred to these centres.

Further, the natural body to direct such an obstetric service is the Ministry of Health* and the different boards of health. For, as you are aware, by the Notification of Births (Extension) Act, 1915, on them has been placed the responsibility of seeing that not only the expectant mother and the mother and child after delivery, but the mother during her delivery, shall receive proper care. It would be desirable that at the Ministry of Health for Scotland some individual who has had extensive practical experience of obstetrics and maternal and child welfare should act as director of the service, and that in addition assistant directors should be located (for Scotland two, or at most three, would be sufficient), say in the North, East, and West of Scotland. This, I think, would be necessary, as so very few of those engaged in public health work have had any practical experience of obstetrics.

Arguments may very readily be advanced that this is giving the Ministry of Health and the health authorities too much power, is interfering with the liberty of the subject in removing from her the choice of doctor,† and involves the expenditure of large sums of money. At every step, as more responsibilities have been placed on the health authorities, the same objections have been raised against interference with the liberty of the subject and the vested interests of the profession.

(a) *Institutional Department of Obstetric Service.*—In Glasgow there are three institutions which receive maternity cases—the Royal Maternity Hospital, the Parochial Hospitals, and the Cottage Nurses' Training Home in Govan. In 1922 the Maternity Hospital treated 3,641 indoor cases, the Parochial Hospitals (Duke Street, Oakbank, and Stobhill) 254 cases, and Govan Hospital 159 cases. Now the Maternity Hospital is very much overcrowded, and I estimate that institutional accommodation there would require to be doubled.‡ But what really is most urgently required is an additional maternity hospital in the busiest centre of the south side of the city. Obstetric specialists are in charge of these institutions. They and their assistants would continue in charge, and act as consultants to those engaged in the ordinary outdoor maternity service. Their position in the obstetric service could be determined later, but they should ultimately be the senior officers of this service, and as their positions are vacated by retirement or death the more junior members of the staff would be promoted. This in turn would mean promotion of those engaged in the domestic

* A similar proposal was made by Professor A. Louise McIlroy in this Journal, October 4th, 1924 (p. 642).

† The obstetric service indeed would not preclude any individual electing to be attended by a general practitioner or obstetric specialist. ‡ It has been decided recently to increase the accommodation in the Royal Maternity Hospital by forty to fifty beds.

part of the service. Whether the services of the senior or hospital staff should be whole- or part-time would require to be considered. Personally, I think they should be permitted to undertake consultative obstetric practice.

(b) *The Outdoor or Domestic Part of the Service.*—Now, on the basis of the outdoor department of the Glasgow Maternity Hospital and the figures of births in Glasgow in 1922, Mr. Jones, secretary to the Public Health Department, has very kindly supplied me with an approximate estimate of the number of obstetric specialists Glasgow would require for a maternity or obstetric service such as I suggest.

"City of Glasgow (1922):"

"Total births"	29,493
Of which medically attended—	
By doctors at home	8,288
By doctors in institutions	3,025
	11,313
Leaving births non-medically attended	18,180
Of which attended by—	
Maternity Hospital outdoor nurses	3,678
Other institutional nurses	661
Certified midwives	13,682
Others	159

The proportion of births medically attended is equal to 38.4 per cent., and non-medically attended 61.6 per cent.

"Assuming that the services of a medical man will be called in, as at present, the problem is to ascertain what proportion of the 18,180 births non-medically attended will require medical assistance.

"The Maternity Hospital report shows that for the year 1922, out of a total of 3,757 births attended by the outdoor nursing staff, 454, or 12 per cent., were classified as 'abnormal.' These abnormal cases were attended by a doctor, two of whom were able to overtake the whole work.

"Assuming further that the proportion of abnormal cases exhibited among the Maternity Hospital outdoor cases will apply to the total of 18,180 non-medically attended births, then the relative number would work out at 2,179.

"If, therefore, two whole-time doctors are able to overtake 454 cases, five doctors should be able to overtake the total work. It is understood the outdoor medical assistants attached to the Maternity Hospital work alternate turns of twenty-four hours each. It is unlikely that a permanent staff would be prepared to do this, and in order to make provision for day and night duty, holidays, sickness, etc., it would probably be necessary almost to double the estimated number. Of course, whatever total number is determined upon would be inclusive of the two at present engaged by the Maternity Hospital.

"As shown above, 13,682 births were attended during the year 1922 by certified midwives. During the year these midwives issued 3,120 emergency calls for medical assistance. This is equal to 23 per cent., compared with the Maternity Hospital 12 per cent. Midwives, however, are required by the rules to call for doctors in a variety of circumstances which, under the Maternity Hospital classification, are probably not regarded as abnormal.

"Midwives would continue to make these calls, and probably it should be provided that this work should be undertaken by the proposed permanent staff. This makes it necessary to provide adequate numbers, but the ten suggested above might be regarded as a sufficient provision to undertake the whole work.

"Medical fees on midwives' emergency calls during the year 1922 amounted to £2,040, and this sum would be available towards meeting staff salaries."

I am inclined to think that Mr. Jones's estimate of ten obstetric specialists is possibly too generous, but if some of the industrial centres in the immediate vicinity of Glasgow were included it would probably be very near the mark. These obstetric specialists would naturally be responsible for ante-natal and post-natal work in connexion with the various centres to which they would be allocated. Each of them should have a specially trained midwife to act as an assistant. To my mind one of the strongest arguments in favour of this service is that the obstetric specialists would be constantly supervising and instructing the midwives.

As already stated, the rural problem is more difficult, but a very large proportion of the rural population could be served by obstetric specialists attached to the health departments of particular centres. There would remain, however, in the outlying parts of the country a number of individuals who could only be treated with extreme difficulty by an obstetric specialist from the nearest centre. But if all primiparæ and any multiparæ in whom there is the slightest suspicion of a difficult delivery were taken

into the nearest district hospital, this particular objection to an obstetric service because of unsatisfactory rural conditions would be largely overcome. Surely, if a very large proportion of women would be benefited by a maternity service, and only comparatively few could not avail themselves of it, it is advisable to do what is best for the greater number.

Nor would the cost be very great. In fact, on balance a saving would probably be effected, for about 50 per cent. of gynaecological affections are the result of infection, injuries, etc., during parturition. The cost of such cases to general and special hospitals is considerable, and would naturally be very greatly lessened by the establishment of an efficient obstetric service.

C. PUERPERIUM.

Time permits of only a word or two regarding the complications of the puerperium. These are for the most part the result of infection and injury during parturition, and are therefore preventable, as already detailed. There are, however, two special disturbances which, although of a minor character and never fatal, are responsible for a very considerable percentage of the gynaecological ailments encountered in general practice. They are subinvolution, or defective involution of the puerperal uterus, and backward displacement of the uterus. Subinvolution is a sequel of infection and retention of membranes, while backward displacement can be prevented by the wearing of a well fitted vaginal support for a month or two.

You see, therefore, how much preventive medicine can accomplish in the field of obstetrics if the care of the expectant mother is undertaken early in pregnancy, if the prospective complications of parturition are recognized and corrected as far as possible, if institutional treatment is made adequate, and if parturients in their own homes are looked after by efficient midwives whose work is supervised by obstetric specialists available at all times in case of necessity.

DIVERTICULA OF THE OESOPHAGUS.*

BY

JOHN MORLEY, CH.M., F.R.C.S.,

HONORARY ASSISTANT SURGEON, MANCHESTER ROYAL INFIRMARY;
HONORARY CONSULTING SURGEON, ANCOATS HOSPITAL;
LECTURER IN APPLIED ANATOMY,
MANCHESTER UNIVERSITY.

DIVERTICULA of the oesophagus are a somewhat uncommon cause of dysphagia, but the more general use of radiological examination in all lesions of the oesophagus has shown us that they are not as rare as was formerly supposed. They provide us with difficult problems as regards their etiology and surgical treatment, while they present a clinical picture distinctive enough to be well worthy of study.

It will be convenient first to describe briefly three illustrative cases, and then to deal in general terms with the problems that arise.

CASE I.

A man, aged 58, a textile machine worker, was admitted to the Manchester Royal Infirmary under my care on August 1st, 1924. He first noticed something wrong with his throat seven years before, when he was troubled with a choking sensation associated with difficulty in swallowing. The trouble was at first intermittent, but had grown much worse of late, and he had lost 14 lb. in the last five months. Soon after swallowing his food he would choke and bring part, but not all of it, back. Occasionally he would bring up, unaltered, some articles, such as peas, which he had swallowed twenty-four hours before. Long after a meal he was troubled by a constant inclination to swallow, and frequently he noticed a gurgling noise in his throat.

On admission the patient was considerably emaciated, but in

* Part of a post-graduate lecture delivered at the Manchester Royal Infirmary.

fairly good health otherwise. Examination of the neck revealed a fullness on either side in the lower part, but more pronounced on the left side. On palpating the neck a gurgling sensation could be felt and some food regurgitated into the mouth. X-ray examination showed a well marked pouch at the junction of the pharynx and the oesophagus, on the posterior wall (Figs. 1 and 2), projecting down between the spine behind and the oesophagus in front, and causing considerable pressure on the oesophagus. The pouch was rinsed out frequently with boric lotion for some days before operation.

Operation.

On August 6th, under chloroform and ether anaesthesia, an incision was made on the left side of the neck along the anterior border of the sterno-mastoid, extending from the upper border of the thyroid cartilage to the sterno-clavicular joint. The sterno-mastoid and the carotid sheath were retracted laterally, and the thyroid gland and trachea drawn medially after division of the middle thyroid vein. The pouch was now easily separated from the lax connective tissue around it, and drawn up into the wound. The neck of the pouch was fairly wide, though narrower than its fundus. The wall of the sac was thick and fleshy, and felt not unlike a normal stomach on palpation. A large oesophageal bougie was passed in order to help in defining the neck of the sac. Some resistance was noticed as this bougie entered the upper end of the oesophagus immediately below the neck of the sac.

With the bougie *in situ*, two pairs of Schoemaker's colectomy forceps were applied to the neck of the sac transversely and the pouch removed by cutting between them with a knife. The divided mucosa on the stump was sterilized with pure carbolic, and a continuous Cushing suture of fine catgut inserted over the forceps with a curved needle. On removal of the forceps the suture was drawn tight, inverting the edges. The same suture was then brought back as a second layer covering in the first, after the manner of a continuous Lembert suture. Yet another row of invaginating catgut suture was superimposed, and the wound closed with a tube-drain to the site of the excision.

For the first twenty-four hours rectal saline was given, with no fluid by the mouth. For the next three days sterile water and brandy were allowed by the mouth, and then a fluid diet until the end of the tenth day. The tube was removed on the third day. There was only a trifling serous discharge from it, and by the seventh day the wound was completely dry and remained so. The patient has had no further difficulty in swallowing; he has put on weight, and remains in good health. Fig. 3 shows a radiogram taken after the operation.

CASE II.

A man, aged 63, was admitted to hospital on October 16th, 1924. He had been troubled with intermittent difficulty in swallowing solid food for two years, but for the past five weeks the trouble had been much more severe. During this latter period he had been able to swallow fluids only with the greatest difficulty, and could not manage any solid food at all. Nearly everything that he swallowed would regurgitate in about five minutes. He had lost 1½ stone during the past five weeks, and had only passed three small constipated motions during that period, while the amount of urine had been scanty.

History and Condition on Admission.

The patient had typhoid fever twenty years ago, and syphilis two years ago for which he was treated by his private doctor. The dysphagia commenced before he contracted syphilis.

The patient when admitted was in a very weak and emaciated condition. There was no swelling or gurgling to be detected in the neck, but x-ray examination showed a typical oesophageal pouch (see Fig. 4) in the usual position. The Wassermann reaction was positive. The sac was prepared for operation as in the previous case by washing out with boric lotion.

Operation.

On October 20th intratracheal ether was given by Dr. Pinson. Primary excision of the sac was carried out through a vertical incision on the left side of the neck, as in Case I, but on account of the patient's poor condition a Senn's gastrostomy was performed in addition.

The patient was fed entirely through the gastrostomy tube for the first ten days. The drainage tube was removed from the neck on the sixth day, and, except for a trifling serous discharge from the tube track for three days after this, the wound healed by first intention. The gastrostomy tube was removed on the tenth day and the gastric fistula closed almost immediately. He began to take solid food on the fourteenth day, and has swallowed without difficulty since, and regained his normal weight.

CASE III.

A man, aged 52, gave the following account of the history of his trouble.

"About five or six years ago I began to notice that particles of food swallowed the day before returned to my mouth. There was no heaving or straining; they simply seemed to appear from nowhere. This went on for a year or two, and as it caused me no pain and little inconvenience I took little notice of it. In 1922

it became much worse. Bigger quantities of food began to return, and I became subject to a very unpleasant choking cough. This attacked me more particularly when in bed, and lasted sometimes half an hour, sometimes with short intervals throughout the night. I found that I was unable to dispose of food such as beefsteak, no matter how long I chewed it. Thinking that imperfect mastication might be the cause, I had all my teeth extracted, and artificial teeth put in. There was no improvement, and as my general health was suffering, I consulted by doctor, who suggested that I might have a pouch in my gullet. A temporary improvement in the symptoms led to some further delay, but finally the trouble became worse and worse. I might get almost to the end of a meal, and then a sip of water or tea or any other fluid upset everything, and I had to rush from the room and choke and cough until I had evacuated a good portion of the food which I had swallowed. I simply had no control. The position had now become intolerable, and at my doctor's suggestion an x-ray photograph was taken, which confirmed his suspicion."

The patient's previous health had been good in all other respects. He was in fairly good condition and had not lost weight appreciably. Whenever he coughed a diffuse bulge could be seen on the left side of the neck from the clavicle to the level of the hyoid bone. No gurgling was elicited on palpating the neck. X-ray examination (Figs. 5 and 6) showed a large pouch at the upper end of the oesophagus extending down into the superior mediastinum.

Operation.

On December 12th, 1924, intratracheal ether was given by Dr. K. B. Pinson. Primary excision of the sac was carried out from the left side of the neck as in the other two cases. The wall of the sac consisted of thick mucous membrane covered by a thin outer fibrous covering. The neck of the pouch was closed as in the other cases and the wound sutured, with a small tube leading to the line of suture.

The patient made an uneventful recovery. Rectal saline was given for the first forty-eight hours, and nothing by the mouth. For the second forty-eight hours, as the salines were not well retained, sterile water was given by the mouth, and after this dilute Benger's food. The tube was removed on the fifth day. The discharge from it had been negligible, and the wound was soundly healed before the tenth day, when soft solid food was allowed. The operation has resulted in complete relief from his symptoms.

ETIOLOGY.

The malady of which these three cases are typical examples occurs usually in elderly men. The point at which the pouch originates is constant. It is on the posterior wall of the pharynx, at a relatively weak spot between the transverse and oblique fibres of the cricopharyngeus muscle. The pouch is therefore, strictly speaking, pharyngeal, but I have followed the usual custom in calling it oesophageal. The initial cause of the herniation of mucosa remains something of a mystery. There is no evidence of congenital origin, and we can only assume that for some unknown reason the circular muscle fibres at the upper end of the oesophagus fail to relax in the process of deglutition. Increase of intrapharyngeal tension inevitably results, and the mucosa bulges at the spot where it has least muscular support. When once the pouch has reached a certain size a vicious circle results. To the spasm of the upper oesophageal sphincter is added the mechanical pressure of the distended pouch, which, held forward by the unyielding vertebral bodies behind it, presses upon and occludes the oesophagus in front. It is an interesting point that, according to Dürr,¹ half the cases of oesophageal pouch are associated with goitre. Von Hofmeister,² in a series of 9 cases, removed a retrosternal goitre in 5 at the same time as he extirpated the pouch. The frequent association with this type of goitre, which is notoriously liable to cause pressure on the oesophagus, suggests that sometimes a goitre is the cause of the increased intrapharyngeal pressure which leads to the herniation of mucosa. In one of my cases the difficulty in passing an oesophageal bougie during the operation pointed definitely to a spasmodic stricture of the upper circular fibre. Rare cases of pouch formation have also been recorded. I conclude that a pouch can form there must be a pharynx, due either to spasm of the upper oesophageal sphincter, to retrosternal goitre, or occasionally to organic stricture.

DIAGNOSIS.

The occurrence of dysphagia in an elderly man naturally arouses a suspicion of that common and disastrous lesion

FIG. 1.—Case I. Antero-posterior view of pouch.

FIG. 2.—Case I. Lateral view of pouch.

FIG. 3.—Case I. After operation.

FIG. 4.—Case II. Antero-posterior view of pouch.

FIG. 5.—Case III. Antero-posterior view of pouch.

FIG. 6.—Case III. Lateral view of pouch.

epithelioma of the oesophagus. The dysphagia caused by a pouch differs from that met with in malignant stricture in the intermissions in its early stage, the regurgitation of food in bulk some long time after a meal, and the attacks of characteristic choking and coughing with which this regurgitation is often associated. In the later stages a fullness of the neck, with gurgling and ejection of food on pressure over the sac, may make the diagnosis clear. The only certain diagnostic method, however, consists in an x-ray photograph after a bismuth meal, and it is surely unnecessary to stress the point that this should be a routine procedure in every case of dysphagia.

TREATMENT.

Whatever its origin, the oesophageal pouch when well established offers a grave mechanical obstruction to deglutition. It cannot be denied that only surgery can restore these patients to normal health, and except in the rare cases in which there is a certain tolerance of the pouch, and a trick of successful swallowing is acquired, operation should be advised. On that all surgeons are agreed. Differences of opinion have arisen, however, as to what is the best and safest surgical procedure to adopt. The most obvious method of primary resection of the sac and suture of its neck has acquired a somewhat sinister reputation in certain quarters on account of the risk of leakage, with consequent surrounding sepsis in the cellular planes of the neck, and even suppurative mediastinitis. It was on account of these dangers that Goldmann³ introduced a two-stage operation, isolating the sac at the first stage and ligating the neck with silk, so as to cause necrosis of the sac. Ten days later the mummified sac is extirpated with the thermo-cautery, and though a temporary fistula often results there appears to be little danger of fatal cellulitis. Wilkie and Hartley,⁴ while admitting that the one-stage operation is ideal, recommend, on account of its danger in feeble and elderly patients, a modification of Goldmann's two-stage operation. At the second stage they perform a subincisional resection of the sac, leaving the outer fibrous coat, or tunica propria, *in situ*. They consider that a temporary fistula is to be expected in about 50 per cent. of the cases. W. Hill⁵ and Fritz König,⁶ in order to avoid altogether the risks associated with the removal of the sac, advise its isolation and suspension in an upward direction by suturing it either to the hyoid bone or to the upper part of the omohyoid muscle. The method of inversion of the sac, or invagination into the pharynx, has also been suggested, but it is by no means free from risk of causing asphyxia, and by the best opinions it stands condemned.

What, then, may we consider to be the operation of choice? While a small sac in an enfeebled patient may be dealt with satisfactorily by suspension to the region of the hyoid bone, I believe that the operation of choice is primary excision and suture. There are, however, certain precautions necessary if grave danger is to be avoided. The sac must be rendered as sterile as possible by frequently washing out with a mild antiseptic, and it must be emptied before operation. When the sac is isolated a large bougie should be passed into the oesophagus, and kept there until suture is complete. The suture of the neck of the sac must be carried out with the most extreme accuracy and care, after the technique usually adopted in closing the duodenal stump in a Polya gastrectomy. In this last detail lies the crux of the operation, and I believe it should only be attempted by those who have served a long apprenticeship to the technique of gastro-intestinal surgery. The anæsthetic should be either local infiltration with novocain or intratracheal ether. The wound should always be drained for the first few days. The after-care demands rest from deglutition for some days, and in emaciated patients, who need something more than rectal saline, a gastrostomy performed at the same time as the excision affords the readiest means of securing it, and is a very real safeguard against the danger of leakage.

RADIATION TREATMENT IN EXOPHTHALMIC GOITRE.*

BY

J. H. DOUGLAS WEBSTER, M.D., M.R.C.P.Ed.,

PHYSICIAN IN CHARGE OF DEPARTMENT OF RADIOLOGY,
MIDDLESEX HOSPITAL.

It is very difficult to assess the value of any form of treatment for diseases such as exophthalmic goitre in which there is much variation in severity and tendency to natural cure or relapse, and in which some cases pursue an even or mildly fluctuating course for years, while others are so acute that their course may be measured in days or even hours.

Different views as to suitable treatment must depend largely on the average type of case seen. Generally speaking surgeons and radiologists see worse cases than physicians or general practitioners. To take extremes, how different must be the opinion regarding the general severity of the disease held by Sir William Hale-White, who found on an analysis of a large series of cases that 50 per cent. were cured by rest and medical measures (with only a slight tendency to relapse), compared with the opinion of Crotti as to its severity; for Crotti has performed thyroidectomy, and often thymectomy in addition, "in every case that has come his way."

The radiological view as to treatment, now based on thousands of treated cases, may be put thus: Of those patients who are not cured by medical measures only a small percentage cannot be relieved by radiation, while a large percentage are cured.

My own experience with x-ray treatment has been 163 cases, from which, unfortunately, 37 must be excluded owing to insufficient "follow-up." (It would be very useful if our hospitals would establish "follow-up departments" like those established recently in a few American hospitals.) Twenty-four cases are also excluded, as they are now under treatment, all improving. Of the 107 remaining, 88 showed marked improvement, a percentage (82) similar to some of the results reported by other radiologists. The number of males was 11. There were four acute cases, and all these did very well, reacting promptly; one was back to work in a month. Of those who had only begun treatment, or who did not respond promptly, six were operated on, and of these six two died of the operation. Slight improvement was noted in seven cases. In six only of those who had six or more treatments, and were followed up, was there no sign of improvement; several of these had pronounced nervous symptoms and their home conditions were unsatisfactory.

The x-ray techniques advised are very various. On the one hand, there is a small repeated dose method. Thus Fischer gives ten small doses within three weeks, then a three weeks' pause; then ten small doses as before, and three weeks' pause; then ten again, and a three months' pause; then ten again if necessary—thirty to fifty radiations in all. On the other hand, Nordentoft and Blum have given single large doses, repeated only once to thrice if necessary. In many of their 100 cases reported a single treatment sufficed for cure. The first of these extremes—many small doses—is very troublesome to the patient; the second appears to me to be risky, as an undesirable or even dangerous reaction might be produced. A single massive radium dose has been followed by acute exacerbation, with a fatal result; and with a non-malignant condition no risk is justifiable that can be avoided.

I have not employed any of these extreme dosage systems, but have used various techniques: first, a small weekly dose method, increasing the interval gradually, then a larger suberythematous dose repeated three- or four-weekly; and lately I have used a method of attempting to half-"saturate" the thyroid with cumulative doses in the first month or two, then, as progress is established, the intervals have been gradually increased to months. In this way a number of patients recently have been restored

*A contribution to the discussion of the combined Sections of Medicine, Surgery, Therapeutics, and Electro-Therapeutics, Royal Society of Medicine, March 9th, 1926. See BRITISH MEDICAL JOURNAL, March 27th, p. 572.

to health with only about $2\frac{1}{2}$ H. doses to each side of the thyroid, if large, or to the whole gland from one or other side, if small, repeated in five to eight treatments in all, taking two to four months for great relief or for cure. For very small thyroids I use 1 mm. aluminium filter, for moderately enlarged ones 3 to 4 mm. filter, and for large hard glands 0.5 mm. zinc filtration, in each instance giving a dose about one-half to two-thirds of the dose which will produce an erythema on the sensitive skin of the exophthalmic patient, whose erythema dose is about 60 to 70 per cent. that of the small erythema dose for an average skin.

I have not used radium, as the Middlesex Hospital radium is so much booked up for cases of malignant disease. But Abbe, Aikens, Dawson Turner, Burrows, and others have reported good results. The radium techniques recommended differ very much, quantities from 10 mg. to 500 mg. element being used, either close to the surface, or at 5 to 6 cm. distance, or buried in the gland.

As to whether radiation treatment causes adhesions and hinders a possible later operation, I have an open mind; there is rather a conflict of facts and opinions in the literature. Von Eiselsberg was one of the first to raise the objection, but Holzknacht has said rightly that adhesions, if due to radiation, should be anterior rather than posterior, as the back of the thyroid, with the usual near medium voltage technique, has a considerably less dose than the front. To avoid the possibility, in cases where operation is in the balance, a two or three months' trial of radiation may be made without much risk of causing adhesions, with the usual mild technique. If distance doses and high voltage treatments are given for medium or small thyroids the risk would be greater. In large gland cases a choice should, if possible, be made between operation or radiation, and one or another method adhered to for whatever result there may be.

It is well known that x-ray private cases on the whole do better than hospital out-patients, because the home conditions are more suitable, and as a rule they can obtain rest and quietness while the treatment is in progress and the disease is active.

The only anxiety in undertaking any new cases is in the first weeks, when a suitable dose and dose method is being chosen for the particular patient. I have seen stimulation effects, due to insufficient dosage, in patients referred to me who had begun treatment elsewhere. Towards the end of the treatment it is sometimes very difficult to know when to stop; when in doubt a few months' rest should be given. I have seen slight myxoedematous changes appear towards the end of a course of treatment; in every such case, however, the pendulum has swung back, when treatment was stopped, to an approximately normal thyroid balance. I think the best results are attained when there is a gain in weight to slightly above the patient's previously normal weight.

The nervous symptoms are usually the first to improve: sometimes after one treatment benefit is noticed; sometimes the pulse rate comes down very quickly, in others it takes some months to reduce though the patient feels well. The exophthalmos and thyroid enlargement remain to some degree in most of the long-standing cases. In more acute cases not supervening on an old goitre the eye symptoms and thyroid enlargement may become normal.

As to local results, I have had no case of burning. Slight telangiectases have been seen in three or four cases where the method of employing doses just suberythematous has been kept on too long, or where insufficient pauses have been made, as improvement began to be evident.

Interesting points for discussion arise as to the response to radiation of predominantly vagal or sympathetic types of case, and as to the part played by the thymus. Many radiate the thymus as a routine, together with the thyroid. I have only given thymus radiation when there is not the expected response with thyroid treatment, or when marked myasthenia, coarse tremor, lymphocytosis with leucopenia, and amenorrhoea, added to a predominantly vagotonic type, suggest the presence of a considerable thymic element in the case. Of the patients who die at operation so many succumb from "thymic death" that thymic radiation might well be given where possible as a routine before

thyroidectomy. X-ray examination may be helpful in the diagnosis of thymus enlargement or substernal thyroid.

Surgery had a thirty years' start of radiology in the treatment of exophthalmic goitre, but thyroid surgery has been fortunate in remaining almost entirely in the province of experts, whereas anyone, medical or lay, who has access to an apparatus can give x-ray treatment. Moreover, x-ray dose measurements only passed the elementary stage in the last fifteen or twenty years. Hence many x-ray failures. It is regrettable however, that books, even such as Crile's, should be still disfigured with pictures of x-ray burns on the neck; such photographs are as meaningless now as old operation statistics would be. From the radiological point of view it is deplorable that Crotti, in his book, should devote 606 pages to a consideration of the thyroid, and dismiss radiation with a table of old statistics and a third of a page of print, ending up with the entirely erroneous verdict that "even in the most competent hands complications, such as burns, may occur." A statement like this should really not have appeared in a book dated 1922.

In conclusion, it may be said that radiation is one of the few therapeutic measures which have stood the test of time. It stands well in the forefront among the 239 different drugs and other remedies for the disease which were collected by Marine.

TREATMENT OF THROAT AND EAR CASES IN CHILDREN.*

A RETROSPECT OF FIVE YEARS' WORK IN THE ELEMENTARY
SCHOOLS.

BY

HENRY SMURTHWAITE, M.D., B.S.,
SURGEON, THROAT AND EAR DEPARTMENT, GLOUCESTER
ROYAL INFIRMARY.

DURING the last five years I have been doing work more or less in connexion with the Gloucestershire scheme for the extension of medical services, and I desire here to explain the class of work being done under it. The children in the elementary schools are systematically examined, and those requiring it are sent on to the infirmary or other hospital or out-stations for the necessary treatment, the majority being cases of throat, nose, and ear, and eye disorder.

During the period under review I have operated on some 2,000 cases of "tonsils and adenoids" and treated a very large number with chronic suppurative otitis media. Incidentally 150 mastoid operations have been performed, 95 of which have been selected from those children with "runny ears." Formerly treatment of such cases was more or less haphazard, and many children went through their childhood and school period untreated, or at the least with half-hearted treatment for nose, throat, and ear affections, which accounts for the large number of deaf people among the less fortunate class to-day. As an example, many of the mothers bringing their children for treatment I find are dull of hearing, and some very deaf. War statistics also brought to our notice the large number of men suffering from chronic suppurative otitis media. By this treatment of school children there will, as the years go on, be much less deafness, also a decrease in sickness and incapacity, and an ultimate reduction of inefficiency and poverty in their after-life.

Vertical sections of the tonsil ranging from birth up to 2 years of age show that crypts, at first merely surface deep, as the tonsil grows and fills the tonsillar fossa extend by degrees into the tonsil until they almost reach the capsule; in the upper part of the tonsil these crypts tend to run obliquely down, whereas at the lower portion they are more or less horizontal. It is due to this anatomical structure of the crypts and their tendency to retain debris—dead cells, particles of food, and micro-organisms—that we get most of the pathological conditions in the tonsil. We rarely find diseased tonsils in infants, for the above structural conditions in the crypts only, by gradual development, become marked at about 2 years of age.

* An address delivered before the Gloucestershire Branch of the British Medical Association, February 22nd, 1925.

We have no certain knowledge why the tonsils hypertrophy. However, we often find it in a number of members of one family; this may be due to idiosyncrasy. On the other hand, a constant post-nasal discharge, such as would be present in enlarged adenoids—and as a rule we find them concomitant—or chronic retention in the crypts and recurring acute parenchymatous tonsillitis may be a cause. Certainly when they are hypertrophied they are more liable to pathogenesis owing to the great depth and tortuosity of the crypts. Nevertheless, it is not always the large or hypertrophied tonsils which are the worst offenders. Tonsils that cannot be said to be large may be very diseased, and have only a very small portion of the covering normal epithelium tissue. The crypts may show exuberant granulations round their entrance, be wide and run right down to the capsule, and be filled with decomposing tissue.

The tonsils may be a chronic focus of infection. The report by the Ministry of Health on the incidence of rheumatic disease concludes:

"In acute and subacute rheumatism tonsillar sepsis may be an important factor: of patients with acute rheumatism nearly 50 per cent. had enlarged or septic tonsils; only 2 per cent. of patients with acute rheumatism had had their tonsils removed."

However, we have to bear in mind that there are other such foci in the body—for example, middle ear, accessory sinuses, teeth, appendix, and bowels—and these have to be excluded as a possible source of systemic infection before resorting to tonsillectomy, unless there is direct evidence in the tonsil.

The modern method of removing the tonsils is either by the reverse guillotine or by dissection, the whole object being their complete removal from the sinus or bed, and not, as formerly, the shaving off of that portion projecting between the pillars of the fauces. Consequently of the "buried tonsil" more often than not only a third was removed.

By the reverse guillotine method, devised by Whillis and Pybus in England and Shuder in America, practically all tonsils can be completely enucleated by the surgeon who takes the trouble to make himself efficient in this method. One who has gained the knack and who knows the pitfalls will have very few failures. Certainly this applies to children and young adults, in whom the tonsil is more easily manipulated; in many older patients requiring removal of the tonsil, or a stump of a tonsil left from a former tonsillectomy, it would be quite impossible, owing to fibrous adhesions binding it to the walls of the fossa, to enucleate it by means of the guillotine, for only by dissection can the desired result be obtained.

In children I use the former method, whilst in adults I invariably dissect. [Specimens were shown from nine children operated on that morning with the guillotine and one adult by dissection. The tonsillar tissue was not in any way cut. One of the tonsils was still fixed in the guillotine as removed that morning, and when the cutting blade was withdrawn it could be seen that the inner surface of the tonsil was covered by the smooth capsule, whilst in the patient could be seen the clean tonsillar bed and the anterior and posterior pillars of the fauces standing out distinctly. Two large tonsils, dissected out, which were also shown, were intact and practically the same as those removed with the guillotine.]

There has been much correspondence in the BRITISH MEDICAL JOURNAL during the last twelve months by advocates of these different methods. The one side say that the only sure way to enucleate the tonsils is by dissection; there being less chance of injury to the walls of the tonsillar fossa and less chance of hæmorrhage, primary and secondary, because the vessels are ligatured at the time of operation. The other side say that with the guillotine, efficiently used, about 93 per cent. will be successful tonsillectomies; that it is much quicker, and does not require such a skilled anaesthetist. In general time should not be taken into account, though in busy clinics it is an important factor. Anyone who undertakes this class of work should make himself efficient in both methods. He will then be in a position to select the method according to the case.

When I first took charge of the throat and ear department in this hospital some five years ago my clinic was

inundated with cases of chronic suppurative otitis media. To-day these numbers are lessened to a great degree, and I can only attribute it to two causes: (1) That the throat and nose in children has been systematically treated at the outset, thus lessening the chance of acute middle-ear suppuration which may eventually become chronic; (2) the intractable long-standing cases of chronic middle-ear suppuration have had a mastoid operation with ultimate cure.

The usual plan is first to clear out the throat and posterior nares if indicated, or the nose, for one occasionally finds accessory sinus disease (ethmoid or antrum of Highmore); but even excessive and persistent nasal discharge—simulation sinus disease—clears up under the "tonsils and adenoids" operation or "adenoids" only.

The external auditory canal is cleaned out twice daily by gentle syringing with a mild antiseptic so as to remove all debris, followed by instillation of a 50 per cent. solution of rectified spirit which will dry the ear and cause shrinkage of any granulations about the drum. Occasional politization, by forcing pus into the meatus, tends to cleanse the middle ear. It is important that the ear be kept as dry as possible. In this way we help to keep the perforation patent, so allowing drainage from the middle ear and giving its lining membrane a chance to recover. Except in very large perforations I cannot see that much lotion can ever reach the middle ear, let alone the antrum and mastoid cells, the real seat of trouble in most of these long-standing intractable cases.

Our object, however, is free drainage from the middle ear primarily, for there is not much chance of pus or muco-pus draining from the mastoid cells, antrum, and attic if the middle ear is more or less dammed. Thus with the external auditory canal kept clear and the Eustachian tube patent, by attention to the throat and nose we have a double outlet for discharge, so giving a chance for resolution in the middle ear, antrum, etc. Quite a number of very chronic cases do clear up under this treatment. Nevertheless there are very many which resist. These, having had a fair trial of two months without cure, I put on the list for a mastoid operation.

Out of 168 mastoid operations I have done during the last five years 95 have been on school children. The operation, put in a few words, consists in thoroughly opening up the mastoid antrum. All diseased cells and lining membrane are removed from the mastoid, the drum and ossicles being left. In a few cases I have also removed the outer attic wall, but left the drum and ossicles intact. A flap is made of the posterior membranous wall of the external auditory canal; the meatus is enlarged and a drainage tube inserted to keep the flap in position and at the same time to ensure the large meatal opening for post-operative dressing. The post-auricular wound is permanently closed. The middle ear is made thoroughly aseptic by syringing through the aditus at the time of the operation. The wound is smeared with hipp, and through the tube in the meatus the cavity is packed with gauze.

[A child, aged 12 years, one of a type of these operations, was shown who had the first operation done on the right ear three months before; this was followed, two weeks later, by a similar operation on the left ear. Both ears were seen to be soundly healed and dry. The walls of the cavity made in the mastoid, seen through the meatus in each ear, were lined with skin. The perforations in the drums were healed. The drums were much scarred, but the child had quite good, if not normal, hearing, though it had had "running ears" for eleven years.]

There have been no complications in any of these cases, and with few exceptions the temperature has not risen above normal. The average stay in hospital has been two weeks. After this period the post-auricular wound is healed and the head bandage is removed and the patient sent home, the remainder of the dressing through the meatus being carried out at the out-patient department, until the internal wound is covered with skin, which takes about six weeks. On the other hand, some of these cases have not been cured by this operation; there is still a discharge through the drum or a sinus, and in eleven cases I have had to do a radical mastoid operation—that is, clearing out the attic and removing the drum and ossicles and the bridge of bone separating the middle ear from the antrum which had been left intact at the first operation. But

surely it is better to do the less severe conservative operation first with a good chance of permanent cure, as one can always fall back on the major or radical operation if the first is not successful.

Cases Followed Up.

I have lately visited all the schools in the district and seen the majority of cases I have operated on during these five years. I have talked with the masters and mistresses of the various classes, and asked their opinion as to the benefit or otherwise to the children so treated. Practically without exception they noted the change in their condition, physical and mental—for example, the disappearance in many of former listlessness and inattention (probably due to slight deafness); loss of attendance at school due to frequent colds or chills with throat troubles; and especially, fewer cases of "running ears."

Conclusion.

The question whether we are overzealous in our operative treatment is very pertinent. Some will ask, Is it necessary to remove all these tonsils and adenoids, ridding patients of lymphoid tissue which is possibly needful in their years of growth? So far all the cases operated on that I have followed up, and they number some hundreds, were in good health at the time of my examination, and certainly showed no signs of any deleterious effect from the loss of this lymphoid tissue.

In my visit to the schools I noted a great improvement in the children who had been operated on for chronic suppurative otitis media. A number suffered from a low form of toxæmia previous to operation, and the removal of this focus of infection had resulted in marked benefit to the child, quite apart from the improvement in hearing. Also, remembering what a large proportion of the tonsil and adenoid cases showed at the time of operation enlargement of the cervical glands, I carefully examined the necks of these children, and only in some few did I find any trace of these glands, and these only in those operated on during the last three months. I am sure that the general surgeon who can look back twenty or twenty-five years will remember the frequent occurrence of "cervical adenoma" in his morning operation list, and must have noticed the decrease in number during the last few years. The focal cause is now recognized and removed.

The systematic treatment of school children which is now carried out in all throat and ear clinics must have a great effect for good, and I feel confident that in the next decade there will be much less premature deafness in the adult.

EXPERIMENTAL RESULTS

SUGGESTING THE

PRODUCTION OF IMMUNITY BY FILTRATES FROM STREPTOCOCCI ISOLATED FROM THE VAGINA IN PREGNANCY.

BY

MADGE E. ROBERTSON, M.D.

(From the Bacteriological Laboratory, Public Health Department, Glasgow.)

WHILST inoculating mice with broth cultures of streptococci isolated from the vagina during the course of an investigation on the vaginal organisms in pregnancy, in which I have been engaged for the past fifteen months, I was struck by the very marked immediate effect produced on the animal when certain virulent streptococcal cultures were used.

The dose used in these inoculations was 0.5 c.cm. of a forty-eight hours broth culture given subcutaneously, and as a rule little or no disturbance was produced. But once or twice the inoculation had a very marked effect—the mouse seemed dazed, remained still, breathing rapidly and looking very ill. In a short time this condition passed off and the animal appeared normal until, perhaps twenty-four hours later, symptoms of a general septicaemia manifested themselves.

I thought that this immediate effect (since it was observed only when certain virulent streptococci were used)

must be due to a toxin produced in the broth by the streptococcus, and to test this conclusion I prepared broth cultures which were filtered through a Berkefeld filter after forty-eight to seventy-two hours' growth. Results obtained with the filtrates (tried first subcutaneously and later intraperitoneally) were similar to those obtained with the broth culture—in some cases little or no effect was produced, in others the animal appeared seriously ill for a short time. Virulence (in the ordinary sense) and toxicity appeared in a general way to run parallel. Ordinary broth—as a control used in the same dose and same way—produced no ill effect. About fourteen days later I made use of one of these inoculated animals along with another untreated animal in a streptococcus virulence experiment, and was surprised to find that the untreated animal (which was considerably the larger) died in less than twenty-four hours (the streptococcus being recovered from spleen and heart's blood), whereas the one which had had a previous toxin inoculation remained perfectly well, and when chloroformed a week later cultures from spleen and heart's blood were sterile. It should be mentioned, however, that the untreated animal received 0.75 c.cm. of the broth culture because of its unusual size; the treated one only 0.5 c.cm.—a dose which had been sufficient with this particular streptococcus to cause death in mice in twenty-four to forty-eight hours on two previous occasions. The streptococcus used for the toxin inoculation was one giving similar sugar reactions to the one used for bacterial inoculation, but had been isolated from a different patient (vagina in both cases). Both were slightly haemolytic.

I determined to try further streptococcal broth filtrate inoculations with a view to finding whether or not any protection was thus afforded against the streptococcus used in the production of the broth filtrate or other streptococci.

The first series of experiments was inconclusive, owing to uncertainty as to dosage, length of time protection might be supposed to last, loss of virulence in organisms used for the final bacterial inoculation, so that neither treated nor untreated animals died—though the results in the main pointed to some degree of immunity being acquired.

Results in the second series of experiments, however, though the numbers are much too small for final conclusions, suggest so strongly that protection against the vaginal streptococci may be afforded by previous inoculation with the filtrates from their broth cultures that it seemed worth while to make them known even in their present incomplete shape.

Experiments.

Four mice were used in the experiments to be described—three were of almost equal size, one was considerably smaller than the others. The organisms used were isolated from the vagina in two cases of pregnancy and showed the following reactions. The broth used in preparation of cultures and filtrates was the ordinary laboratory leuco broth.

Strain.	Haemo-lysis.	Lactose.	Salicin.	Glucose.	Saccharose.	Raffinose.	Mannite.	Inulin.	Litmus Milk.	
R.V2	+	-	+	+	+	-	-	-	Very faint trace of acid.	Virulent.
C.V2	-	+	+	Trace	+	-	+	-	Acid and clot (pink ring)	Slight virulence.

R.V2 had been obtained from the same patient on two occasions with an interval of months between, and had always been virulent, killing a mouse in twenty-four to twenty-eight hours. The strain used had been isolated on October 13th, 1925, and had been used in four previous virulence experiments on mice with the following results:

- (1) November 2nd.—0.5 c.cm. forty-eight hours broth culture subcutaneously. Mouse died on night of November 3rd. Streptococcus recovered in pure culture from heart's blood.
- (2) November 17th.—0.5 c.cm. forty-eight hours broth culture subcutaneously. Mouse died on night of November 17th. Streptococcus recovered in pure culture from heart's blood.
- (3) November 26th.—0.75 c.cm. forty-eight hours broth culture subcutaneously. Mouse died on night of November 27th. Streptococcus recovered in pure culture from spleen. Present also in large numbers in heart's blood, but mixed with contaminating spore bearer which outgrew it on plates.

(4) *December 9th.*—0.5 c.e.m.—forty-eight hours broth culture subcutaneously. Mouse died at 12 noon, November 10th. Streptococcus recovered in pure culture from heart's blood.

G.V2 was of only slight virulence, producing no apparent ill effects when inoculated into a mouse, but being recovered from the spleen when the animal was chloroformed.

The mice had been kept under observation for some days and all appeared very healthy.

Mouse 1 was inoculated subcutaneously on December 15th with 1 c.e.m. sterile filtrate from a forty-eight hours broth culture of R.V2, filtered through a Berkefeld filter, and on December 18th with 0.5 c.e.m. of the same filtrate. It was not very well for two days after the second inoculation.

Mouse II (very much the smallest of the four) was inoculated subcutaneously on December 15th with 1 c.e.m. filtrate from a forty-eight hours broth culture of G.V2, and on December 18th with 1 c.e.m. of the same filtrate. It remained quite well after both inoculations.

On December 23rd Mice I and II were inoculated with 0.5 c.e.m. of a forty-eight hours broth culture of R.V2 subcutaneously, and two other normal untreated mice (III and IV) were also inoculated with 0.5 c.e.m. of the same culture from the same tube.

Mouse III was very ill the following morning (December 24th) and died that night. The streptococcus was recovered in pure culture from spleen and heart's blood.

Mouse IV seemed well enough on December 24th, but became ill on December 25th, and died that night. The streptococcus was recovered in pure culture from spleen and heart's blood.

Mice I and II remained in good health and are still quite well. It is interesting that Mouse II, which was much the smallest of the mice and obtained only the comparatively non-virulent streptococcus filtrate, remained particularly lively.

Though I was not aware at this time of the details of the Dicks' work on scarlet fever (beyond a general knowledge of the Dick skin test), these results suggested to my mind the question whether an antistreptococcal serum to be used for the treatment of puerperal fever might not be more potent and give more satisfactory results if made up of two components—an antitoxic and an antibacterial—the one to be obtained by the injection of streptococcal soluble toxins, the other by injection of the bacteria themselves in the usual way.

The paper by Dr. Robb in the *BRITISH MEDICAL JOURNAL* of January 2nd (p. 11) on the results of treatment of scarlet fever (a disease in which the organism is so closely allied to those most frequently found in puerperal fever) with the Dick serum prepared in this way or by the injection of toxin alone decided me to publish the results of these experiments.

THE ELECTRICAL TREATMENT OF TIC-DOULOUREUX.

BY

W. J. TURRELL, M.D., D.M.R.E.,

PHYSICIAN IN CHARGE OF THE ELECTRICAL DEPARTMENT, RADCLIFFE INFIRMARY, OXFORD.

IN the *BRITISH MEDICAL JOURNAL* of March 6th (p. 417) a writer on the surgical treatment of tic-douloureux made the very sweeping statement that: "Of the various procedures which have been devised for the cure of this most distressing malady two only have stood the test of experience. They are: (1) Some form of alcohol injection. (2) Operation on the Gasserian ganglion by the Hartley-Krause method of approach."

There is at least one other method, of which a trial should be made before destruction of the nerve is attempted by the injection of alcohol, or before resort is made to the severe operation on the Gasserian ganglion. This is the administration of the constant current of as high an intensity as the patient can readily tolerate. Its principle is by no means new, but recently its details have been entirely altered. Formerly a current of from 5 to 10 milliamperes for ten minutes was recommended; now we employ a current of from 60 to 90 milliamperes, usually about 80 milliamperes, for thirty or forty minutes; this is equivalent to a dose of 2,400 milliamperes minutes, compared with 50 or 60 milliamperes minutes. No difficulty attends the administration of the treatment, but the employment of this high intensity of current should always be under the direct supervision of an experienced electrotherapist. As a rule, better results will be obtained in private practice, where the operator can devote the whole of his attention to his patient, than in a busy hospital department, where it is often difficult to secure the undivided attention that

is so essential for the administration of the current to its full and most effective intensity.

The following is a list of cases of tic-douloureux that I have treated in hospital and private practice.

1. A man, aged about 65, a private patient, was treated during 1912. He gave a history of trigeminal neuralgia of several years' duration. Two courses of "ionic medication" with sodium salicylate were given, with only some slight temporary benefit.

This failure was probably due to the employment of too weak a current. Owing to inexperience of the method I was then afraid to increase the current beyond 20 milliamperes. At that date the benefits of the method were wrongly attributed to the specific action of the drug, which it was presumed was electrically introduced to the affected area. Now it is generally admitted that the benefits obtained result from the reflex stimulation and its consecutive effects set up by the current; on this theory the need for an intensive current is more evident. In each of the other cases sodium chloride solution was employed, and no attention was directed to the polarity of the active pad beyond employing the pole which appeared to excite the greater irritation. The presence of a large mass of nasal polypi, not suspected until the conclusion of the last treatment, may have contributed to the failure.

2. A woman, aged about 65, also a private patient, had suffered from severe tic-douloureux for several years. She was treated in 1918 by thirty-three administrations of intensive galvanism—60 to 80 milliamperes for thirty to forty minutes.

In reply to inquiries, this patient writes as follows on March 9th, 1926: "After I had your treatment and came home I found the pain in my face was much better, and gradually it went away; I was able to eat, and then it went away entirely for four years; I had no trace of it at all. I had it again once or twice after those four years... but it was not in the same place; I never had it where I used to have it, but lower down my jaw. I am much fatter than I used to be, and have been able to sing at concerts and give my lectures... I had injections of alcohol at Hospital by Dr. —, but he did not hit the nerve, and they were useless."

3. A woman, aged about 20, a private patient, a recent but severe case, was incapacitated from following any employment. "The attacks would come very suddenly, and the pain was very sharp and cutting, so fierce that she used to shriek with the pain. Treatment given in December, 1920, consisted of seventeen applications of 50 to 70 milliamperes for about forty minutes. On March 14th, 1926, the patient's sister reported that she had not had any repetition of the tic-douloureux, nor any pain at all in her face since the electrical treatment was finished."

4. A woman, aged about 50, a private patient with twelve months' history of severe tic-douloureux, was still undergoing a course of treatment commenced in January, 1926. The treatment in this case consisted of a constant current, 70 to 90 milliamperes for thirty minutes, preceded by diathermy for ten minutes. The patient states that she is now "very much better; can eat comfortably now. No throbbing pain. I am getting on splendidly; only a dull ache at times, chiefly in the jaw bone."

5. A woman, aged 77, a hospital patient. This was a very severe case of more than twenty-five years' duration. Treatment commenced on June 1st, 1922—30 milliamperes for thirty minutes. Treatment was applied continuously, with improvement and relapses, until June, 1923, when the patient expressed herself as "a great deal better in every way." She continued to go on with only slight attacks of pain at long intervals until towards the end of 1923, when the attacks became frequent and more severe. She resumed treatment on December 25th, 1923, with a current of 60 milliamperes; she had considerably improved on January 6th, 1926, when an attack of bronchitis prevented her from attending for further treatment.

6. A woman, hospital patient, had had tic-douloureux for five years. Daily treatments of 40 milliamperes for thirty minutes were commenced on December 18th, 1924. The patient reported on January 1st, 1925: "Much better—better than it has been for a very long time; it does not affect my eye now." On January 13th: "Much better; wishes to attend a little less often." On February 2nd: "Quite well; no pain for ten days." No further history was obtainable in this case.

7. A woman, hospital patient, had had tic-douloureux for eight years. The pain was at times so severe that she was unable to eat. Treatment was commenced on August 26th, 1924—40 milliamperes for thirty minutes. On January 19th, 1925, she reported: "No severe pain now, but not so well last few days, tingling after washing face." January 31st: "Very little pain now, only in the early morning. Goes three or four days without any pain." In reply to letter of inquiry she wrote on March 16th: "It has not disappeared, but seems to have settled more in the lower jaw, and underneath same; should you advise trying the electrical treatment again?"

8. A man, aged 61, hospital patient, had had tic-douloureux since 1919; worse since he had his teeth out two years ago. "Can't eat anything or spit on account of the pain." Current to toleration for thirty minutes. Commenced treatment March 10th, 1925; treatment ceased on October 23rd, 1925, when he reported: "Getting on grand, just a twinge when I washes my forehead. Can spit fine." Called up to report progress on March 15th, 1926, the patient stated: "Ten times better than it was. Slight pull on gums."

AMBLYOPIA WITH HAEMORRHAGES DUE TO TOBACCO AND (?) LEAD POISONING.

BY

MARION GILCHRIST, M.B., C.M.,

ASSISTANT OPHTHALMIC SURGEON, VICTORIA INFIRMARY, GLASGOW.

THE following case presents many points of both medico-legal and clinical interest.

A plumber, aged 43, was admitted to the Victoria Infirmary, Glasgow, as a case of intraocular pressure. He complained of dimness of vision of four to five months' duration. His family history was good. His health was quite good until five years ago. He was never off school nor off work till then. Since then he has had giddy turns occurring frequently, which pass off in a minute or two. He states that he was once treated by powders for those turns, and they got less, till he had them only once or twice a year. He himself thought his attacks were due to constipation.

On October 7th, 1924, he fell from a height of 9 ft. and bruised his left shoulder, but this, under his doctor's care and massage, got all right. A month later he noticed a slight shaking, especially when writing or when he got excited. This was diagnosed as neurasthenia, and treated successfully. He began work about the middle of January, 1925, and one month later noticed that his sight was failing, the right eye being worse than the left. As this got worse he was sent to the Eye Infirmary, and, on the report of the surgeon there, was sent into the Victoria Infirmary.

The surgeon's report was as follows: "Right optic disc is greatly swollen with haemorrhages in the fundus and choked disc. The left optic disc is paler, with no haemorrhages in the fundus. I am of the opinion that he is suffering either from head injuries from accident or from glycosuria, which may be due to the accident."

The house-surgeon's report on his condition on admission to the Victoria Infirmary was as follows: "Temperature, pulse, and respiration normal. He lies comfortably in any position; his gait on walking is normal. Pupils moderate and equal, react to light and accommodation. Elbow and supinator and knee- and ankle-jerks exaggerated. Ankle clonus fully present. Plantar flexor in type, sensation normal. Circulatory system normal, except slight systolic murmur. Gastro-intestinal system: tongue furred and teeth in bad condition, and has pyorrhoea. Urinary system: uric acid specific gravity 1020; no albumin, blood, or pus; i.e. acetone; sugar 2 per cent. Latex trace of sugar only. Chronic suppuration in right ear and wax in left."

On August 19th I was asked to examine his eyes. His vision was very defective. An ophthalmoscopic examination of the right eye showed some neuro-retinitis, tortuous vessels, and many haemorrhages in the fundus, especially in the course of the inferior retinal artery. In the left there was also neuro-retinitis, tortuous vessels, and some small haemorrhages, and the optic disc was rather pale. From an ophthalmoscopic examination I diagnosed a fair amount of refractive error, worse in the right. His vision in the right eye was 0/60 and in the left 6/36. A correction of his refractive error gave him in the right 6/60 and in the left 6/24. I found that he smoked 6 oz. of black twist in a week, and I cut this off entirely. On August 26th his vision under correction right spherical +1.5 combined with cylinder 1.5 vert. gave him 6/36, and left under spherical +0.25 cyl. +1 D. vert. gave him 6/18. There were still many haemorrhages in the right eye and a few in the left. He was then put on to a mixture of potassium iodide and nux vomica.

On September 2nd his vision had improved to 6/24 right and 6/18 left. On September 15th it was 6/18 letters right and 6/18 letters left. On September 23rd 6/12 right and 6/12 left.

On October 12th it was: right 6/9 letters and left 6/12 letters.

On November 11th it was 6/9 in both eyes, and no fresh haemorrhages had appeared in the fundi. His vision, with distance correction, continued practically the same until January 6th, 1926. With additional right and left spherical +1.5 added to his distance correction he gets easily Jaeger 1 with both eyes. As he was anaemic I prescribed an iron tonic, and now his general health is good, and he has been passed as fit for light work.

The case had an important medico-legal aspect. If the lesions were due to a cerebral condition—connected with the fall—compensation was due, and this might have been quite wrongly awarded. It is certain that the fall had nothing to do with the condition.

It is unusual to find so much neuro-retinitis and so many haemorrhages in tobacco amblyopia.

The patient is a plumber and tells me he was constantly handling white lead, and often ate his "piece" or his meals without washing his hands; the question arises whether there was an element of lead poisoning in this case.

There is also the question whether the state of his teeth and the pyorrhoea had anything to do with the condition. I do not think so, for none of his teeth were removed, and, beyond brushing them every day, nothing has been done. It may be asked also whether the greater refractive error in the right caused that eye to be more affected than the left.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

GLYCOSURIA AND ARTIFICIAL SUNLIGHT.

A MARRIED woman, aged 22, was sent to me for treatment of a disfiguring rash on the face of six months' duration; she had, she said, been treated medically for it for three months at least.

The rash had begun on the side of the nose, and when seen the distribution of the patches across the bridge of the nose, on the left ala nasi—especially along the edge of the nostril—on both malar eminences, and on the point of the chin, combined with the appearance and duration of the lesions to suggest lupus. On August 30th, 1925, the original Hanau vacuum lamp was used for the first treatment at a distance of 2 feet for three and a half minutes, directed over the whole area of the face, the eyelids being held tightly shut.

Next day severe local reaction was evident in and around the eyes and nose, but the rest of the face showed only the degree of erythema anticipated. There was painful conjunctivitis in both eyes and oedema of the tissues surrounding the eyes and nose; here the skin was tense, red, glazed, and painful, and pitted on pressure, and for two days the patient complained of inability to see clearly, though she continued her duties as housemaid. Previous to treatment the urine gave a heavy precipitate with the usual Fehling's test. The conjunctivitis and oedema disappeared in four days and sight became normal; when examined six days after treatment all facial lesions except one very small patch on the left cheek had vanished. To remove this she was treated with a moderate dose of two minutes at 3 feet on the face only. The reaction on this occasion round the eyes was very mild, lasted one day only, and the skin of the face entirely healed.

The patient returned on September 21st, as a few nodules, more impetiginous in appearance, were showing further out on the cheeks, but none in the previous situations. She was given a general sun bath with the Hanau lamp—three and a half minutes at 3 feet back and front. There was little reaction, but as the facial lesions had not healed a similar dose was given on September 25th, after which they entirely disappeared. On October 7th four small spots had appeared on the face and she was given general treatment—four minutes each back and front at 3 feet. Two small lesions about the size of a sixpence had been present over the end of each radius on the flexor aspect of the wrist from the beginning of treatment, and these had never received special attention, and at this stage appeared to have slightly increased in size; on this occasion these received an extra four minutes at 18 inches.

Next day there was slight oedema round both eyes; she said the eyes felt "itchy" and that she could not see very well, but the conjunctivae appeared normal. On October 16th all skin lesions were healed and the patient not only looked better but remarked on the very great improvement in energy and health, so that she now felt "very well indeed and quite fit for work." There was, however, still a heavy precipitate with Fehling's solution in the urine.

This case is remarkable for various reasons. (1) The rapid effect of artificial sunlight on the chronic facial lesions which had resisted previous treatment. (2) The severe local reaction to a small dose of artificial sunlight which raised suspicion and led to the discovery of sugar in the urine. (3) The very definite improvement in general health and vigour of the patient, though the treatments given were of short duration and at infrequent intervals, and in spite of the fact that the amount of sugar in the urine remained apparently unaffected.

Newcastle-on-Tyne.

CHRISTINA BARROWMAN.

INTESTINAL OBSTRUCTION BY GALL STONE.

THE following case may be of interest, following on the series recorded by Mr. Bennett in your issue of March 27th (p. 565), and Dr. Coldrey's communication of May 1st (p. 783).

A married woman, aged 69, was on May 4th, 1926, admitted to the High Wycombe and District War Memorial Hospital suffering from abdominal pain and vomiting of forty-eight hours' duration. The abdomen was rigid; tenderness was most marked in the right iliac fossa. The conjunctivae were definitely, but not deeply, jaundiced. The vomit was doubtfully faecal. There had been no motion of the bowels for "several days"—a fact, however, which had not perturbed the patient until the onset of pain, as she had not uncommonly had but a single motion a week. Before seeking medical advice castor oil had been administered, but was rejected. An enema gave no results.

Laparotomy was performed by Dr. L. L. C. Reynolds. The appendix was found to be sharply kinked and bound down by adhesions; it was removed. At a point about six inches from the ileo-caecal valve the ileum was occluded by a solid body over which its walls were tightly stretched. The segment of gut above the obstruction showed the usual congestive and oedematous

changes resultant on blockage, but there was no extreme distension of the coils. On incising the bowel a gall stone was extracted, roughly cylindrical in shape; it was one inch in length, and its maximum width was seven-eighths of an inch. Its dry weight was 101 grains. The patient's recovery was uneventful.

So far as could be judged from appearances, the probability of the calculus negotiating the remaining six inches of ileum, or the ileo-caecal valve itself, seemed very small, while the patient's condition was critical when operation was undertaken. It is of interest that in Dr. Coldrey's case a considerably larger stone was passed by the rectum.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

EDINBURGH BRANCH.

THE CERTIFICATION OF INSANE PERSONS.

A MEETING of the Edinburgh Branch of the British Medical Association was held in the British Medical Association House, 6, Drumshough Gardens, on June 1st, when Dr. GEORGE KERRIE PATERNON, senior Vice-President of the Branch, occupied the chair. The President of the Branch, Professor G. M. ROBERTSON, P.R.C.P., physician superintendent of the Royal Hospital, Morningside, gave an address on "The certification of insane persons."

The work of medical men was always, he said, of a very responsible nature and of a very personal nature. In the course of it they were frequently exposed to the danger of an action for damages. In dealing with people of unsound mind they were exposed to additional dangers, as many such persons made only partial recoveries, and were apt to harbour delusions, as the result of which they brought actions against the doctors who certified them. This was so well recognized that in English law such actions could be dealt with in chambers, and were very generally quashed. Although there was no similar provision in Scotland, there was in reality as much protection against such litigation as in England. Only one action had ever been brought in Scotland for wrongful certification, and that should never have been brought.

Professor Robertson strongly advised every member of the profession to belong to the Medical Defence Union. No one would think of driving a motor car without being insured against accident; it was infinitely more foolish not to be insured against the liability of an action. As a matter of fact, the medical profession was as well protected against actions for damages as was wellnigh possible. Under Section 73 of the 1913 Act the medical man was not liable if he had acted in good faith and with reasonable care. In practice, it was sometimes very difficult to convince a jury that reasonable care had been exercised. He advised his hearers in all doubtful cases to pay a second visit to the patient. It could not then be doubted that reasonable care had been exercised. It was wise also to make notes of such cases.

Professor Robertson went on to discuss the meaning of the term "lunatic." In the eyes of the law there must be not only disease of the mind but a definite disorder of conduct. The term had been defined in the Scottish Act of 1857 (Section 3) as "a person so diseased or affected in mind as to render him unfit to be at large." The Act was less happy in describing what was meant by unfitness; but it was clear that unfitness as regards personal safety and conduct or the safety of the persons and property of others referred to safety in the widest sense, and not merely as regards danger to life. It meant safety from harm of all kinds.

In regard to the certification itself, it must be borne in mind that the certificate was a great deal more than a certificate of insanity. It required to be shown that not only was the person of unsound mind, but "a proper person to be detained under care and treatment." The reasons for certifying a patient as a proper person to be detained under care had been stated by Sir Claud Schuster, Permanent Secretary to the Lord Chancellor, in his evidence before the recent Royal Commission. These were

very similar to the answers given by Sir Arthur Mitchell before a Select Committee in 1877. The reasons stated by Sir Claud Schuster were fourfold: to protect the public from injury; to protect the patient from self-injury; to give treatment with a view to cure or amelioration which cannot otherwise be given; to protect the patient from sustaining injury due to want of care. These statements, however, did not help very much in practice.

There was one way in which medical men could get out of their difficulties, and that was by inducing their patients to enter a mental hospital voluntarily. The majority of patients at the back of their minds knew that they were not well, and could be induced to go as voluntary patients. At the Royal Hospital, Morningside, 60 to 80 per cent. of patients came voluntarily. He urged the adoption of this course as far as possible. At the close of his address Professor Robertson replied at length to numerous questions with reference to the subject of his address.

Reports of Societies.

THE ORIGIN OF TUMOURS.

At a meeting of the Section of Surgery of the Royal Society of Medicine on June 2nd, when the President, Sir LESTER CREATIE, was in the chair, Dr. W. E. GYE made a communication (postponed on account of the general strike) on the origin of tumours, illustrated by the epidiascope. When first he submitted the results of his work on this subject he had, he said, no idea how tenaciously pathologists held to the current views on what was known as the cellular hypothesis, the real meaning of which he declared he did not know. It was evidently felt that when a tumour was formed a change occurred in the internal mechanism of the cell, such as was induced by the action of tar or by some living virus. The evidence which, so far, had been advanced against the parasitic hypothesis of the cause of cancer had been negative only, which was useless for founding dogmatic conclusions. To be acceptable, any cause of cancer must fit into knowledge which had been definitely ascertained. The inoculation of the morbid material of cancer into another animal did not in itself cause cancer in the recipient animal if such animal was of a different species, nor in the same species when the cells were killed. Hence the position was not parallel with that of tuberculosis, for example, in which inoculation of Koch's bacillus into another animal produced in it the disease. The surviving spindle-celled sarcoma of the fowl, which Rous, of the Rockefeller Foundation, had been working on, could be filtered through fairly fine candles—not the finest—but the filterability was not a constant feature. From time to time filtrates prepared in precisely similar manner to those which were very infective were found to have scarcely any power of infection at all. This variability in filterability disposed of the argument which had been so widely advanced by pathologists that the fowl tumour could not be called a true cancer because it could be transmitted by filtrates. It was found that the tumour produced by filtrates bore a definite proportion to the size of the inoculum employed; measurement by weight was useless, owing to the varying involvement of surrounding tissue, therefore the rule measurement was used. Chloroform added to the filtrate was found greatly to inhibit its infectivity, and a sufficient quantity of it disposed of the infectivity altogether. But even with reduced infectivity the proportion of tumour formation in the two breasts was the same. The infectivity held in abeyance by chloroform could be restored by adding a culture from another tumour. Dr. Gye, in conclusion, said he felt now even more confident of his results, and of the soundness of the views founded on them given in the communication he had made to the profession last July.

The President, in thanking Dr. Gye for his masterly review of his work, said it would be particularly valuable to bear Paget's disease of the breast in mind in researches into the origin and nature of cancer. In cutting whole sections of breasts it was sometimes found that the only abnormality discoverable was Paget's disease of the nipple.

He hoped the discussion would embrace benign tumours as well as those essentially malignant. In so-called fibroadenomata of the breast the growth varied according to the particular tissues involved, and this variety of form was no argument against an infective origin.

Mr. J. JACKSON CLARKE spoke of a number of new growths which he had long held to be due to parasites or some living organism, and showed on the screen histological sections he had made many years ago.

Sir ALMROTH WRIGHT, who spoke in response to an invitation from the chair, said that comments on this research, to have value, should come from those engaged in the same kind of work. Dr. Gye appeared to have discovered some of the factors producing cancer, but not all of them yet. He expressed his admiration of the extraordinary skill shown in carrying out these experiments.

Sir CHARLES BALLANCE also had a word of high praise for Dr. Gye, and for the manner in which he was carrying on his research.

Dr. WILLIAM CRAMER, speaking as a worker in the same field, declared that Dr. Gye's discoveries had removed a number of the investigator's difficulties which had appeared insoluble. For example, Dr. Gye had established the correlation between Rous's fowl tumour and the ordinary animal tumours, the only difference being that the fowl tumour was more malignant than were ordinary animal tumours. After very careful consideration of the subject, he found himself now a convinced supporter of Dr. Gye's views.

Mr. ZACHARY COPE, following up the chairman's remark as to the relation of benign to malignant tumours, said that such growths as fibromyoma of the uterus, though not malignant, grew so rapidly that there must be a potent multiplying factor in operation.

Dr. H. J. B. FAX described an experiment in which 0.5 c.cm. of a subculture virus was injected with 0.5 c.cm. of chloroformed extract into one breast, and into the other breast 1 c.cm. of chloroformed extract was injected high up, and 1 c.cm. of virus into the lower part. In the first breast no tumour developed, but in the other a tumour formed midway between the two inoculation sites, and there only.

Dr. GYE, in a very brief reply, said the inquiry in regard to benign tumours was now going forward.

ADENOFIBROMA OF THE OVARY.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on May 6th, Mr. T. G. STEVENS, the President, in the chair, Dr. HERBERT SPENCER read a paper on adenofibroma of the ovary, and gave an account of two cases associated with multilocular cyst—in the first case in the opposite ovary, in the second case in the same ovary.

Dr. Spencer said that in the first case a large multilocular cyst containing masses of papilloma with proliferated epithelium had ruptured before the operation; the other ovary contained an encapsuled adenofibroma 1.5 cm. in diameter. The patient had had eleven children and one abortion. She was aged 62 at the time of operation, and remained well for sixteen years after removal of the ovarian tumours. In the second case the solid part (adenofibroma) weighed 4 lb. 4 oz.; the large multilocular cystic portion filled the abdomen. The patient, aged 77, had had five children and one abortion. She suffered from bronchitis and metrorrhagia, and died on the eleventh day after the operation (double ovariectomy and hysterectomy). The tumours were characterized by a dense fibromatous stroma beset with spaces filled with epithelioid cells, looking not unlike epithelioma, but there was no evidence of invasion of the stroma. The masses were for the most part solid, but in places were hollow in the centre; this was evidently due to degeneration of the central cells. In one section two gland spaces were found exactly resembling corporeal uterine glands cut across, with a single layer of columnar epithelium, but with no cytogenous stroma around them. In the second case the dense fibrous stroma was found immediately beneath the epithelial lining of the multilocular cyst. The thick degenerated stroma in places

somewhat resembled the wall of a blood vessel, suggesting at first sight the possibility of the growth being an endothelioma, but careful examination did not support this, the vessels in the growth showing no proliferation of the endothelium. Ovarian adenofibromata were rare. Three cases had been shown before the Section (by Macnaughton Jones, Darwall Smith, and Giles), in all of which doubts were expressed as to their malignancy. Dr. Spencer held that the appearance of the cells, the sharp delimitation of the epithelial masses from the stroma, the absence of any tendency to invasion and of small-cell infiltration, the slow growth, and the absence of recurrence (for two years, eleven years, thirteen years, and sixteen years), showed that the report of the committee of the Obstetrical Society of London, made twenty-seven years ago, that these growths were non-malignant adenofibromata, remained true, and that Pfannenstiel, Glocknor, and Orthmann were in error in attributing to these growths malignant characters. He observed that four out of the five English cases were associated with ovarian cysts. This association, as also the much commoner occurrence of simple fibromata in the walls of ovarian cysts (of which he gave two examples), was worthy of further study and research.

The paper was discussed by the PRESIDENT and Mrs. VAUGHAN SAWYER; and in reply Dr. SPENCER agreed with the President that small pseudo-mucinous cysts were rare; he had, however, met with one not bigger than a marble in a newborn child. He was not in favour of the suggestion that pseudo-mucinous cysts ordinarily developed from adenofibromata; the common pseudo-mucinous cyst was scantily supplied with fibrous tissue, and the pseudo-mucin was a secretion, and not a mere degeneration of cellular masses.

An Unusual Method of Caesarean Section.

Dr. F. J. McCANN read a paper on a new method of Caesarean section by removal of the placenta with the foetus contained in the unopened bag of membranes. The length of the abdominal incision should be sufficient to permit the uterus to be everted without difficulty. Six or seven inches would usually suffice, the greater part of the incision being above the umbilicus. After everting the uterus the abdominal incision was closed temporarily with volsellae or long Kocher forceps, and covered by a towel wrung out of hot saline solution. Another towel wrung out of hot saline solution was wrapped around the uterus, leaving the fundus exposed, and was clamped by forceps along the posterior uterine wall. All this was done with the utmost rapidity, everything necessary being in readiness before the abdominal incision was made. A medial incision six to seven inches long was made through the fundus uteri, being prolonged one inch further downwards anteriorly than posteriorly. The incision should be made accurately in the middle line with a sharp knife. After the fundal incision had been made the membranes bulged into the anterior half of the incision, and the placenta was exposed through the posterior half. The hand was then inserted and the placenta rapidly separated from the uterine wall. Whilst his assistant drew the two sides of the uterine incision apart, Dr. McCann compressed the uterus at its lower part through the towel and gently "milked" the uterine wall from below upwards, when the placenta and foetus contained in the unopened bag of membranes was shelled out of the uterus like a pea out of a pod. The bag of membranes was then slit, the child liberated, and the umbilical cord clamped and cut. The uterine incision was sutured with through-and-through linen sutures and superficial catgut sutures. The uterus was returned into the abdominal cavity, the omentum brought down and placed over the intestines behind the uterus, and the abdominal wall closed in layers. The patient made a smooth recovery, and her child, a boy, had remained well. This method prevented any escape of liquor amnii into the peritoneal cavity, and if the incision was made accurately in the middle line there was very little haemorrhage, and the operation could be completed with a degree of cleanliness difficult to excel.

Dr. HERBERT SPENCER remarked that the wisest of men had said "there is nothing new under the sun," and certainly this method of performing Caesarean section was

not new. It had some merit, but so many drawbacks that obstetricians, like himself, who had been acquainted with it for twenty-five years, had not been induced to employ it. As far as Dr. Spencer knew, it was first performed and recommended by Fournier of Amiens, in 1801; later he published many cases. Fournier called the operation "enucleation of the human ovum," and drew attention, as Dr. McCann had done, to the ease with which the uterus expelled the ovum, aided by slight pressure with the hands—as easily, he said, as a cherry-stone escapes when pressed by the fingers. The advantage of the method was that it prevented soiling of the peritoneum and wound with the liquor amnii, which would render it suitable for a case where toxins were being absorbed from a dead foetus. The disadvantages were: a long abdominal and uterine incision; delayed delivery of the child, which increased its risk; haemorrhage when the placenta was separated; difficulty of removal of the placenta, if adherent; difficulty of removal of adherent chorion through a fundal incision; and especially the greater risk of intestinal adhesions to the fundal scar, which had led to fatal ilios in several instances. For all these reasons Dr. Spencer considered the fundal incision and enucleation of the ovum far inferior, in a routine operation, to the usual anterior incision in the body, which he agreed with Dr. McCann was superior to the incision in the cervix.

Dr. McCann said, in reply, that he was not aware of the publication referred to, and that, so far as he was concerned, this method of Caesarean section was original. Dr. Spencer appeared to be quite satisfied with the usual method of Caesarean section, but there was always room for improvement; indeed, in Dr. McCann's opinion, every surgical operation could be improved. Adherence to routine was the curse of the medical profession, and new methods should receive at least a fair trial. The objections urged against this method of Caesarean section were easily overcome by careful technique, and the possibility of intestinal obstruction from adhesion of the small intestine was less than after myomectomy. Dr. Spencer had, however, stated his belief that in certain cases this method of Caesarean section would be useful. Dr. McCann claimed that a sagittal fundal incision was incomparably superior, both on anatomical and physiological grounds, to the transverse fundal incision of Fritsch. After the latter, several examples of rupture of the scar had been recorded, but he was not aware that any examples of rupture of the scar were recorded after a sagittal fundal incision. Dr. McCann had not seen gaping of the incision during this operation; on the contrary, the edges of the incision were pressed together during the uterine contractions, and he thought this would be so when the incision was made accurately in the middle line. Dr. McCann did not advocate this method for every woman requiring the Caesarean operation, but he thought that it was a method to be adopted in suitable cases. In the treatment of septic cases it offered obvious advantages, and might be the means of avoiding the sacrifice of the uterus. It was a method which was worthy of an extended trial, for the surgeon was able to unite the thick muscular wall of the fundus and so obtain a strong scar calculated to stand the strain of pregnancy and labour. It placed in the hands of the obstetric surgeon an alternative method of considerable value.

Total Transposition of the Viscera.

Dr. J. FORD ANDERSON, in a paper on total transposition of the viscera and its clinical importance, remarked that total transposition of the viscera was more than an anatomical curiosity and deserved more interest from clinicians. There were many cases recorded, chiefly in America, where ignorance of the presence of the condition had led to wrong diagnosis and wrong treatment and even disaster. It was of special interest to obstetricians in its causation and diagnosis at birth. Cases were fairly numerous, showing that total transposition and twins were allied abnormalities, both due to hereditary transmission. Virchow's observation, many years ago, was still valuable, that the vessels of the umbilical cord were wound from right to left instead of

from left to right, as was usual. This was an indication of the position of the liver, which, according to Serres, determined the "situs viscerum inversus." The importance of determining the frequency of the malformation was great, and practitioners should report such cases, while obstetricians were asked to note the presence of Virchow's sign of winding of the cord and report if it was associated with transposition of the viscera. The patient also should be warned of the abnormality.

Dr. HERBERT SPENCER had always accepted the teaching that the direction of the twist varied, but could not definitely answer the question from his own experience. He hoped some young obstetrician would set the matter at rest by careful examination of the direction of the twist in stillborn children.

RADIOTHERAPY IN BLOOD DISEASES.

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland on May 14th, the PRESIDENT (Dr. F. C. Purser) in the chair, Dr. R. STUMPF read a paper on Roentgen therapy in certain blood diseases.

Dr. Stumpf reviewed briefly the treatment of polycythaemia rubra vera, pernicious anaemia, and lymphatic leukaemia, and considered the subject of myelogenous leukaemia in greater detail. The treatment of choice was by x rays, especially combined with the administration of arsenic. There was never complete cure, but cases were known in which improvement sustained over many years had resulted from the x-ray treatment of this condition. Relapses occurred in weeks or months, each responding, but ever more slowly, to successive treatments. After each treatment there was a diminution in the size of the spleen, a drop in the leucocyte count, and an improvement in the patient's general condition. The focus for radiation was the spleen. The essential point to remember was that each case must be treated on its individual merits and no dogmatic scheme could be followed. Greater attention must be paid to the patient's general health than to attaining a rapid diminution in the size of the spleen and an immediate drop in the number of leucocytes. As regards technique, it was best to start with small doses, which were very carefully increased. The latest form of apparatus, with their greater uniformity of conditions and improvement of dosage, were superior to the older ones. In conclusion, a case of myelogenous leukaemia was reported.

A married woman, aged 23, showed for several months atypical symptoms, and suddenly developed a severe pain in her abdomen about a year ago. The spleen was found to be much enlarged, and the leucocyte count was 250,000 per c.mm. She had had three courses of x-ray treatment, during part of which time she also received injections of arsenic. In the course of treatment the leucocytes gradually fell from 250,000 to 25,000 per c.mm. This favourable figure had not been maintained, since it was not considered necessary to give sufficient exposures to the x rays to bring about this result, because the patient's general health was so excellent. Frequent blood counts were made, and only sufficient treatment given to maintain the leucocytes somewhere between 60,000 and 90,000 per c.mm. At the beginning of treatment the spleen reached to below the level of the umbilicus and extended across the middle line. It was now three fingerbreadths below the costal margin, and was well to the left of the middle line. The patient's weight had increased very considerably, and her general condition was excellent.

Dr. A. R. PARSONS said that his results had been much the same as Dr. Stumpf's as regards early improvement and subsequent failure to repeat the first success. He asked whether deep x-ray therapy had any advantage over "ordinary" x rays.

Dr. MAURICE HAYES said that with deep x rays the number of treatments was less, the intervals between treatments were longer, and the risk of damaging the skin less; also by deep x rays it was possible to get a more uniform radiation at the first dose.

Dr. J. SPEARES was doubtful whether x-ray treatment did in reality prolong the life of these cases. In the case of lymphatic leukaemia it was his experience that the patient might live a very long time indeed. He was at present treating a patient who had had the disease for twenty-one years.

Sir JOHN MOORE read an historical note on alkaptonuria, and radiograms of various diseases were shown by Drs. J. SPEARES, G. BEWLEY, and C. L. McDONOGH.

Reviews.

MORISON'S "INTRODUCTION TO SURGERY."

IN the second edition of *An Introduction to Surgery* Professor RUTHERFORD MORISON has the assistance of his old pupil Professor C. F. M. SAINT of Capetown University, who is responsible for the "Appendix," which comprises 78 pages out of the total 347.

Any reader of Professor Rutherford Morison's writings must be struck by his originality and his philosophy, and it is clear that this book is the product of much thought. In many of the chapters his old students will recognize the tone and teaching of Professor Morison's systematic lectures. He displays a thorough grasp of surgical principles, together with a knowledge of pathology both wide and deep.

Professor Morison aims at simplifying surgery by means of taking a view of the whole. For example, he emphasizes the importance of realizing that malignant growth and inflammation are disseminated in similar ways. The art of surgery is made to appear to be easy, for he shows it to be so if only the principles are first mastered. He endeavours to make the student think for himself by applying surgical principles to any problem which may present itself, either in the wards or in his book; and excellent illustrations of problems are given. He deprecates the student being overwhelmed with a mass of surgical detail.

One difficulty in reviewing this book is that it is so orderly and schematic; after the principles have been enunciated different diseases are discussed, but each one cannot be commented on here.

Though not a systematic textbook, of which there are many, but supplementary to these, it can be warmly recommended to all students. The print is good, the book is of a handy size, while the large number of illustrations are most helpful.

APHASIA.

IN the introduction to his *Aphasia*,² forming the second volume of the series "Psyche Miniatures," Dr. S. A. KINNIER WILSON says that the study of this complex subject, which should be the meeting place of the psychologist, the physiologist, and the clinico-pathologist, has been handicapped by terminological disagreement and controversy; further, the "tendency to appear exact by disregarding the complexity of the factors" involved is brought out by reference to the numerous schematic diagrams of centres and their connexions in aphasia. As the symptom-complex of aphasia should be investigated from three points of view—the anatomical site of the lesions, the physiological mechanisms involved, and the nature of the psychological disorder—these are carefully discussed in three successive chapters. The opinion that the faculty of speech is not localized in any area of the cortex is shown to be true only in the sense that psychical processes cannot be "placed" by application of the criteria of physiological localization; the implication that there is absence of a localized physiological setting for the arrangements essential to the faculty of speech is contradicted by Honschen's analysis of 1,337 cases, which conclusively points to the existence of a cortical speech centre. Macroscopical without microscopical examination is not satisfactory evidence of the absence of a cerebral lesion, and cases which appear to contradict the old localization of the speech centre may be explained on the hypothesis of "stock-brainedness"; thus aphasia from a right-sided lesion in a right-handed patient may be due to his belonging to a right-brained stock in spite of his right-handedness—in other words, ectopia of the speech centre may occur in some right-handed members of left-brained stock.

The closely reasoned account of the physiological and

psychological aspects of the subject is followed by a consideration of the classification of aphasic disorders, in which it is pointed out that, while an anatomical, a physiological, or a psychological scheme might be adopted, terms used to describe defects in one of these systems should not be transferred to either of the others. The ideal is a correlation of the anatomical, physiological, and psychological aspects; a purely psychological scheme ignores the pathological aspects entirely. He considers that a scientific classification of aphasia should be physio-pathological, but as this is not yet available the clinician must be content with an empirical clinical division, the utility of which outweighs its patent drawbacks. In the chapter headed "Some clinical types of aphasia" there is an account of expressive aphasia, or that usually termed motor, receptive, or sensory aphasia, agraphia, and spelling defects, and the relation of aphasia to apraxia and agnosia is discussed.

Consideration of the treatment of aphasia brings to a close a book the small size of which contrasts with its concentrated and logical discussion of an extremely difficult subject.

THE CONTRIBUTIONS OF CHEMISTRY TO MEDICINE.

IN *Lectures on Certain Aspects of Biochemistry*³ we are given the substance of three series of lectures delivered last year in the University of London. One series was given by Professors J. C. DRUMMOND and A. V. HILL of the University, and the other two by Dr. H. H. DALE of the National Institute for Medical Research and Professor L. J. HENDERSON of Harvard. The preface makes the rather lame apology that "the coincidence of so many lectures on different problems of biochemistry prompted us to put them together in a volume." The matter of post-graduate lectures is not always suited to the more permanent form of the printed word, and it would be disquieting if the habit grew of burdening the publishers' catalogues with too many such. In the present case, however, we must be grateful that the lecturers have been constrained to seek a larger audience than that for which their material was first prepared. Each of them deals with problems in physiology to which chemistry has, in recent years, made fundamental contributions, problems in which they have each a personal interest and on which they have very definitely something to say. With the exception of those of Professor Henderson, the lectures have not the completeness of monographs, but rather possess a gentle discursiveness which gives them a happy individuality.

The text of Dr. Dale is "The chemical control of certain bodily functions." The first lecture is devoted to the control of the capillary circulation by adrenaline, histamine, and the pituitary, and the second to the many other activities attributed to this popular gland. Two further lectures discuss the nature of the chemical control of carbohydrate metabolism by insulin. The author's own clear-sighted researches in all these subjects give him a unique authority which is enhanced by the engaging quality of all his public discussions.

In "The mechanism of biological oxidations" Professor Drummond approaches a subject of peculiar interest to the chemical mind. So useful a review will be generally welcome, for the subject is in process of extensive revision as the result of much current work. In his third lecture there are brought together under the title "The rôle of phosphates in the cell" subjects so diverse as carbohydrate metabolism, the nature of the blood sugar, alcoholic fermentation, and calcification in bone. A fourth lecture deals in an unconventional but happy fashion with the very popular question of the vitamins.

Professor Henderson's section of the book is the *pièce de résistance*. His analysis of the blood as a physico-chemical system is an epic—an epic in Cartesian co-ordinates. To those familiar with the brilliant theoretical contributions of the author to the physical chemistry of the blood this review needs no recommendation. All who would appreciate the factors controlling respiration, blood neutrality,

¹ *An Introduction to Surgery*. By Rutherford Morison, M.D., F.R.C.S. Edin., F.R.C.S. Eng., M.A., D.C.L., LL.D., and Charles F. M. Saint, C.B.E., M.D., M.S., F.R.C.S. Eng. Second edition. Bristol: J. Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. 1925. (Demy 8vo, pp. vii + 347, 181 figures. 15s. net.)
² *Aphasia*. By S. A. Kinrier Wilson, M.D., B.Sc. Edin., F.R.C.P. Lond. *Psyche Miniatures*, Medical Series, No. 2. London: Kegan Paul, Trench, Trubner and Co., Ltd. 1925. (Pott 8vo, pp. iii + 108. 2s. 6d. net.)

³ *Lectures on Certain Aspects of Biochemistry*. By H. H. Dale, M.D., F.R.S., J. C. Drummond, D.Sc., F.I.C., L. J. Henderson, A.B., M.D., A. V. Hill, Sc.D., F.R.S. London: University of London Press, Ltd. 1925. (Demy 8vo, pp. viii + 313; 20 figures. 12s. 6d. net.)

and the circulation will find in the effort of careful study which these lectures demand a rich reward.

Professor Hill engages us for an hour with a book of physical constants and we may be surprised to find that we have been entertained. He would persuade the biologist to find virtue in the enjoyment of mathematics. A second lecture reviews again the fundamental rôle of lactic acid in muscular activity.

We put down this volume with a reflection of some significance. There is evidenced throughout a confidence in the approach of the chemist to biological problems, a comprehensiveness, which gives the reader the feeling that the chemist has learnt to feel quite at home in his adopted field. He has reached adjustment of his chemical ways of thought to the appreciation of that kind of matter which is called "living."

In 1923 one of the best known of American organic chemists, Professor JULIUS STIEGLITZ, delivered in the Johns Hopkins Medical School a course of lectures which appear now in printed form under the title of *Chemistry and Recent Progress in Medicine*.⁴ The delay in publication is left unexplained, but, as opportunity has been taken to incorporate work published during the interval, the delay does not seriously detract from the value of the survey. The mere list of the synthetic contributions to therapeutics within the last few years makes an imposing claim for the service of organic chemistry. Sulpharsphenamine, tryparsamide, "Bayer 205," mercurochrome, acriflavine, rivanol, gentian violet—those to whom these names are familiar, and who are embarrassed by the claims and counterclaims which advocate their therapeutic use, may welcome an attempt to present briefly the investigations of the originators of these products. Chemotherapy has yet few principles to guide its labours, but what little chemical co-ordination is possible is succinctly put by the author. To these synthetic achievements must be added the progress in the purification of the active principles of the glands and of the immune bodies, subjects to which the second part of the book is devoted. The author concludes with an outline of the application to biological oxidation of the electro-chemical theory of organic oxidation reduction. Professor Stieglitz has long been an advocate of the electro-chemical view, and his discussion of the biological aspects is both wise and timely.

DISEASES OF THE GUMS AND ORAL MUCOUS MEMBRANE.

THE issue of a second edition of Sir KENNETH GOADBY'S *Diseases of the Gums and Oral Mucous Membrane*⁵ is proof of a very general appreciation of its merits, and we ought to have noticed its appearance before this. Though the book retains its original form, two important additions have been made—a section on the toxic heart in relation to the diseases of the mouth, and a chapter on vaccine therapy. The section on the toxic heart is welcome evidence that medical practitioners are ever becoming more alert to the dangerous possibilities of dental sepsis; the chapter on vaccine therapy epitomizes the indomitable and unremitting efforts of the bacteriologist to crown his work with the clinical success he feels sure awaits him. The section on the toxic heart gives us an unfortunate impression of superficiality, and that despite the fact that the illustrative electro-cardiograms (which would be more appreciated by the general practitioner if accompanied by legends explanatory of their lettering) are excellent, and the records of typical cases clear and well chosen. The chapter on vaccine therapy in oral disease bespeaks what the author himself might call a balanced phase of mind. "Too much is often expected of vaccine therapy in the cure of the local inflammatory condition of the mouth, and too little attention given to the essential surgical treat-

ment." "Judiciously spaced removal of teeth has the effect of auto-immunization . . . but any dentist who enquires into the after-history of operations such as extensive and deep scaling will discover many instances of an immediate exacerbation of chronic or intermittent disease such as muscular rheumatism . . ." The author, however, thinks that even the local treatment of a case of pyorrhoëa, entirely localized in its effects to the mouth, is helped by the intelligent application of vaccine therapy, and strongly advocates its use as an immunizing agent previous to extraction, especially in articular rheumatism or other chronic general disease. In reviewing the first edition of this work we asked for guidance in the selection of the probable offending organism. This the author gives in the course of the chapter on vaccine therapy in the form of a concise and valuable summary of his large clinical experience. "The majority of cases are streptococcal infections, but as the average mouth yields three to six varieties of streptococci, random selection of a strongly growing streptococcus is insufficient to secure success, and it is essential that the general pathology of the case be taken into account as well as the purely bacteriological investigation."

We recommended this book on its first appearance on account of its great clinical interest; perusal of the second edition has in no way diminished our appreciation.

THE ROUNDWORMS OF VERTEBRATES.

THE science of helminthology is one of the oldest branches of zoological knowledge, but it is only within recent years that it has been studied with the detail its importance deserves. The advances have been so rapid and in so many different directions that the literature has become to a large extent chaotic. An immense service has been rendered to parasitologists by the issue in America of the various parts of the *Index Catalogue of Medical and Veterinary Zoology*, an enormous work by Stiles and Hassall, which not only classifies all the papers in helminthology under their authors, but arranges them under their systematic headings—families, genera, and species. It has become an essential part of the equipment of every helminthologist, but it unfortunately notes all papers on the subject without in any way indicating their relative value. Classification also has been tackled by various workers in recent years: Looss, Railliet, Leiper, Travassos, and others have introduced a more rational system of classification of the parasitic roundworms, and so have enabled diagnoses to be more quickly made and relationships more readily understood. Professor WARRINGTON YORKE and Dr. MAPLESTONE have blended these classifications with the more important references to the morphology of the roundworms contained in the *Index Catalogue*, and the result is a most valuable book of reference, which is entitled *The Nematode Parasites of Vertebrates*.⁶

A compilation is always a thankless task, yet it is difficult to see how advances in any science may be made without it. In this case the workers have performed their task with great thoroughness and detail. They have used a system of classification (with keys to each group) which enables a genus to be diagnosed easily and rapidly. Each genus is illustrated by a figure of a typical species, but the other species are only mentioned by name and no attempt is made to provide specific diagnoses. An extensive generic and specific index is given at the end of the book, which on account of the rapid changes in nomenclature is an essential appendix. References for each genus are given and space is very effectively economized by using a numbered bibliography at the end and giving references to this by means of the number only.

There are over 300 line blocks in the text, and each block contains three or four figures. The great majority are good, but some could usefully have been omitted and others reduced in size without impairing the value of the book. A point of more importance, however, is the creation of new genera and species. In a work of this nature it is

⁴ *Chemistry and Recent Progress in Medicine*. By Julius Stieglitz. Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1925. (Demy 8vo, pp. viii + 62. 7s. net.)
⁵ *Diseases of the Gums and Oral Mucous Membrane*. By Sir Kenneth Goadby, K.B.E., M.R.C.S., L.D.S., D.I.C. Second edition. Oxford Medical Publications. London: Humphrey Milford, Oxford University Press. 1925. (Roy. 8vo, pp. xv + 408; 215 figures, 8 plates. £2 2s. net.)

⁶ *The Nematode Parasites of Vertebrates*. By Warrington Yorke, M.D., and P. A. Maplestone, M.D., D.S.Q. With a Foreword by C. W. Stiles. London: J. and A. Churchill. 1926. (Roy. 8vo, pp. x + 536; 307 figures. 36s. net.)

inevitable that new genera should be made; but the description of new species in footnotes in a textbook is a practice which may give rise to some inconvenience to workers who are accustomed to look for these in the pages of scientific journals. None of the changes in nomenclature affect medical zoology, although several new genera of veterinary interest have been created. Medical readers will be interested, however, to recognize the old *Filaria bancrofti* under its new name of *Wuchereria bancrofti*. The work will be more useful to the systematic zoologist than to the medical man, of course, but it will be an indispensable volume in every parasitological laboratory.

Dr. H. A. BAYLIS and Mr. R. DAUBNEY have also written a book on the classification of the roundworms, but it differs in many respects from the preceding. Its field is much wider and it includes not only the parasites of vertebrates but also free-living forms and those parasitic on plants—a very considerable number. It is not illustrated, however, and beyond mentioning the type species of each genus no species are given. The class Nematoda has been divided into five orders, and the remaining lesser groups have been much reduced in number, an arrangement which, the authors claim, gives the nematode classification a more accurate standing in relation to the other members of the animal kingdom. Within these orders are placed over 600 genera. Each genus is briefly defined, the habitat of its species given and various important papers discussing its morphology are mentioned. In addition a short discussion is often added, and an index to the genera and higher groups is appended. Like the preceding book, this is based largely on the *Index Catalogue*. It does not include genera proposed after 1923. The classification used by the authors will doubtless meet with some criticism, but the perfect system of classification has not yet been evolved, and there is no doubt that they have produced an invaluable work of reference for the specialist, although the absence of keys, illustrations, and lists of species will make it less suitable for use by the more general worker.

TEXTBOOKS OF GENERAL BACTERIOLOGY.

PROFESSOR E. O. JORDAN's *Text-Book of General Bacteriology* is better known in America than in this country. It has now reached its eighth edition,⁸ and in the sixteen years which have passed since it first appeared it has grown with the science it expounds. The present edition contains new material on the bacteriophage phenomenon, tularaemia, botulism, scarlet fever, and other subjects in which recent progress has been made. It gives a straightforward account of what the student needs to learn about bacteria and their behaviour, avoiding unessentials and pointing the way by means of footnotes to more extensive sources of information. A feature of the book which has made it particularly useful to public health students is the attention given to the bacteriology of milk and milk products and the bacteriology of air, soil, and water. An additional interest arises also from the chapters on the nitrogen cycle, bacteria in the arts and industries, and the bacterial diseases of plants. The book is more expensive than similar introductions to bacteriology published in Britain, but those who can afford the luxury of collecting a few reliable books on bacteriology should certainly consider this treatise, written by an experienced teacher and well known research worker.

Dr. BAUMGÄRTL's small book on the foundations of theoretical bacteriology⁹ provides a concise representation of the experimental basis of our present knowledge of the structure and life of bacteria. The author is a botanist, and directs his book to science students who wish to gain a clear view of what bacteria are and what they do. It is not the sort of book which medical students, even though

well acquainted with German, would find useful, but we draw attention to it because pathologists may be glad to know of its existence. It is divided into two parts, the first of which deals with the anatomy and the second with the physiology of bacteria. Many of the problems of the physics and chemistry of bacterial life are discussed more fully than is customary in textbooks of medical bacteriology.

NOTES ON BOOKS.

*Light and Health*¹⁰ is a book written by M. LUCKIESH, director of a lighting research laboratory, and A. J. PACINI, director of a department of biophysical research, both attached to the General Electric Company, U.S.A. The authors start with the assumption that solar radiation has been a powerful environmental factor in the evolution of life. "To assume that it is no longer of importance to the health of human races is as unreasonable as to assume that oxygen is no longer essential to the respiratory process." "Civilization has robbed mankind of much of the sunlight under which the organism and its many processes evolved." The material gathered by the authors has been presented in a manner as free as possible from specialized technical terms and as appeared best suited for general readers. There is a great deal in the book of interest to the general practitioner, such as the chapters on light and the blood, light and the skin, light and the skeleton (including the curative effect on rickets), light and the viscera (with an inclusion of the treatment of pneumonia by diathermy), the psychological effects of light, and lighting for health and happiness. An interesting story of Steenbock is told of spaghetti which used to be made in the Italian quarter of New York, and hung out to dry on the fire-escapes of the tenement dwellings. In this way it was sunned, and the antirachitic vitamin—that is, activated cholesterol—produced in it by ultra-violet radiation. The city fathers objected to this use of the fire-escapes, and consequently spaghetti was made in dark rooms, which led to a falling off in its nutritive value. Thus may the official mind unwittingly interfere with a health-giving instinct. A curious error of the authors is found on page 49, where they appear to regard haematin as the pigment in the skin, comparing the deposition of this with that of chlorophyll in the green leaf. The pigment, of course, is melanin, a derivative of the aromatic amino-acid products of protein decomposition, as correctly stated on page 107.

Much has been written in recent years on what is called by some "the newer cardiology," but the *Clinical Aspects of the Electrocardiogram*,¹¹ by Dr. HAROLD PARDEE, will be found quite a useful work by those who wish to have combined in one volume not only the interpretations of the records but also a practical guide to the working of the instrument. Such a book is probably of more value in America, where physicians who use the cardiograph are very numerous, but any work of Pardee deserves attention, as his researches in other departments of cardiology are well known. He adopts a systematic method of dealing with the subject. In the earlier chapters the significance and interpretation of the various deflections in the normal record are discussed, and thereafter the various abnormalities are considered seriatim. A considerable amount of theoretical matter is interspersed with the more practical applications of the electro-cardiograph, and illustrations of the records are numerous. The closing chapter gives a description of the type of instrument in common use in America, with clear details as to its adjustment and the avoidance of errors in its use. There is a short bibliography of works of historical interest in connexion with electro-cardiography. While obviously more adapted for physicians and students in America, the volume is well worth perusal by British readers.

A number of books have been written describing the structure and properties of the atom as revealed by the newer physical researches. Some of these are so well prepared as to leave little room for yet another writer, but the subject lends itself to varied forms of exposition. Dr. STEWART's *Recent Advances in Physical and Inorganic Chemistry*¹² is concerned with atomic structure and the history of the work that forms the foundation of present knowledge in atomic physics. It has, however, the distinctive merit of presenting the view most interesting to the chemist wherever that is distinct from the physicist's. It also

⁸ *A Synopsis of the Families and Genera of Nematoda*. By H. A. Baylis, M.A., D.Sc., and R. Daubney, M.Sc., M.R.C.V.S. London: The British Museum (Natural History) and B. Quaritch, Ltd. 1926. (Demy 8vo, pp. xiii + 277, 10s. 6d.)

⁹ *Text-Book of General Bacteriology*. By Edwin O. Jordan, Ph.D. Eighth edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1925. (Med. 8vo, pp. 752; 177 figures. 25s. net.)

¹⁰ *Grundriss der Theoretischen Bakteriologie*. Von Dr. phil. Transgott Baumgärtel. Berlin: J. Springer. 1924. (Demy 8vo, pp. xxxviii + 259; 3 figures. 2.30 dollars, bound, 2.50 dollars.)

¹¹ *Light and Health*. By M. Luckiesh and A. J. Pacini. Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1926. (Demy 8vo, pp. xviii + 302; 31 figures. 22s. 6d. net.)

¹² *Clinical Aspects of the Electrocardiogram*. By Harold E. B. Pardee, M.D. New York: Paul B. Hoeber, Inc. (Demy 8vo, pp. xiv + 222; 56 figures. 4 dollars.)

¹³ *Recent Advances in Physical and Inorganic Chemistry*. By Alfred W. Stewart, D.Sc. Fifth edition. London and New York: Longmans, Green and Co., Ltd. 1926. (Demy 8vo, pp. xi + 312; 29 figures, 5 plates. 18s. net.)

touches upon the theoretical considerations which still await the decision of experiment. The consequences resulting from the disintegration of an atom have a particular chemical interest as well as a physical, and are accorded due recognition. In the chapters on active hydrogen, active nitrogen, and certain new metallic hydrides much important and interesting matter will be found. The book contains a chapter on Tesla-luminescence spectra, and no outstanding recent work has been omitted. We recommend the volume as affording a complete and clear collection of the facts arranged in the form most suitable for the student.

THE ROYAL MEDICAL BENEVOLENT FUND AND THE BRITISH MEDICAL ASSOCIATION.

We have received the following letter from Sir Charters J. Symonds, K.B.E., M.S., treasurer of the Royal Medical Benevolent Fund:

Sir,

The discussion at Bath last year revealed certain misconceptions with regard to the relations between the two bodies which it is desirable if possible to correct. Of these, the most important is the impression conveyed by several speakers that a feeling of hostility exists. The history of the Fund shows that, while the two bodies have been from the first under independent administration, there has never been any hostility. On the contrary, the Association has supported the Fund in many directions, and the Royal Medical Benevolent Fund in dispensing the benefits has not taken into consideration the question of the applicant being a member of the Association, nor has this point been raised in filling vacancies on the Committee of Management of the Fund.

I begin with a brief note on the origin of the Fund.

At the first meeting of the Association, then called the Provincial Medical and Surgical Association, the question of establishing a charitable fund was raised. It was further considered at the two subsequent meetings, and at the fourth, held at Manchester in 1836, it was decided to create a fund under the title of "The Benevolent Fund of the Provincial Medical and Surgical Association." In 1856, when the name of the Association was changed to that of the British Medical Association, the Fund became the British Medical Benevolent Fund, and so remained until 1913, when, at the instance of Dr. Samuel West, His Majesty granted the title of "Royal." Since that date it has been known as the Royal Medical Benevolent Fund. Up to 1869 the annual report of the Fund was read at the Annual Meeting of the Association by the Secretary of the Association—not of the Fund—without any remarks. On the last occasion, however, an appeal for support was made by Dr. Hare. At this date the Fund held certain moneys invested in the names of trustees, and though no financial connexion existed with the Association it was considered by the trustees that even the slight connexion indicated by the presentation of the annual report should be discontinued. From this date the close association that had existed for thirty-three years was severed. This separation does not appear to have occasioned any ill feeling, nor to have withdrawn the support of the members of the Association, for the Branches continued to vote donations to the Fund out of surplus revenue.

When the Association was reconstructed and all subscriptions were gathered in the Central Office these Branch subscriptions ceased, and were not replaced by any direct grant from the Central Office. The Association has, however, rendered continual support to the Fund, by inviting the members through the annual circular to subscribe as individuals. Though the Branches discontinued to send subscriptions, this was not in any way due to lack of interest on the part of the members, but to the fact that under the new organization the Branches had no funds. Several of the Branch secretaries of the Association are also local secretaries of the Fund, and collect substantial amounts.

In view of the decision at the Annual Meeting of the Association in Bath to form a Charities Committee, and to show the importance attached by Dr. Samuel West to the influence of the Association, the following extract from his article in the *BRITISH MEDICAL JOURNAL* for December, 1905, will be of interest:

"If each Branch or Division had its local charity committee a further useful step in organization would have been taken."

At the time it seemed unnecessary to offer any reply to the criticisms, as the remarks made by the Chairman of Council (a member of the Committee of Management) and the defence of the Fund in the chairman's (Dr. Hawthorne, also a member of the Committee of Management) reply to these criticisms appeared adequate. As, however, a local secretary has written

to ask whether these criticisms can be met, it is clear that a reply is desirable. I beg, therefore, the hospitality of your columns for a brief rejoinder.

General Practitioners and the Management.

Dr. Walker complained "until recently the general practitioner was unrepresented on the Committee of Management of the Royal Medical Benevolent Fund." In reply to this statement, and going no further back than 1908, there were in this year nine general practitioners on the Committee; in the next year seven; five in 1911, 1912, 1913, 1914; six in 1915; five in the following year; two in 1917; three in 1918, 1919, 1920, and 1921; two in 1922; one in 1923; two in 1924. The decrease has not been due to any action of the Committee of Management, but to the difficulty of obtaining the services of those in general practice. It may be added that Dr. Haslip was a member from 1915 till the time of his death; Mr. Guy Elliston represented the Association till his death. At present the Chairman of Council (Sir Robert Bolam) and the Treasurer (Mr. Bishop Harman) are on the Committee, while Dr. Hawthorne sits as direct representative of the Association; and Mr. Ferris-Scott, the Financial Secretary of the Association, represents the Medical Agency, the most generous subscriber to the Fund. While the nominations have never borne any relation to the membership of the Association (such a point has never in my recollection been mentioned), it is of interest to note that of the present Committee eleven are, while ten are not, members of the Association.

Dr. Walker's next criticism was that "there was not a single representative of Wales, Scotland, or Ireland, and that was a lamentable defect." The necessity of having those on the Committee who can attend the monthly, and also the four quarterly, business meetings, makes the appointment of those living at a distance unwise. That the Fund has the support of Wales, it may be mentioned that the late Sir John Williams was, and Sir J. Lynn-Thomas is, a Vice-President; while in Scotland we have Sir R. Philip, Sir Harold Stiles, Professor Munro, Sir Donald MacAlister, all of whom are *ex officio* members of the Committee of Management. Ireland has its own Benevolent Fund. Another complaint of Dr. Walker is that "although the Fund has been in existence for 'forty years' only 7 per cent. of the profession had sufficient confidence in it to subscribe to it." The percentage is much higher, as can be judged from the amount received in donations and subscriptions by the parent Fund and the Guild in 1924—namely, £7,067, and contained in the eighty-ninth annual report. As a set-off against the charge of want of confidence might be brought many letters expressing approval, and many increases on previous subscriptions.

Apprised of the unjustness of his personal criticisms by Dr. Hawthorne's reply to the discussion, Dr. Walker, after saying that he "was sorry if any remark of his were construed as a personal criticism against the Benevolent Fund," added, "But could the Association be blamed, when it had made overtures to the Fund and had been severely rebuffed?" This, if well founded, would be a grave accusation. The only possible circumstance to which this remark can refer is to a conference called in 1922, at the instance of the late Dr. Haslip, at the time Treasurer of the Association and also a member of the Committee of Management, between the Association, Epsom College, and the Fund. The object Dr. Haslip had in view was to combine the charitable side of Epsom with the Royal Medical Benevolent Fund, and both these with a charitable fund, to be established under the aegis of the British Medical Association. Epsom was represented by the Treasurer (Sir H. Morris) and two legal members of the Council. They explained that an alteration of the charter would be necessary, and as they had only recently, by an alteration of charter, dropped the term "benevolent" as injurious to the College, and as the proposed amalgamation would revive this aspect of Epsom, they could not agree to the proposal.

The Royal Medical Benevolent Fund was represented by the President (Sir Thomas Barlow), the Treasurer (Sir Charters Symonds), and the Honorary Secretary (Dr. Newton Pitt). Our chief objection was that, seeing there were some 20,000 non-members of the Association, it was feared that many of the subscribers from this section of the profession might withdraw their support if such an amalgamation were to take place. Moreover, it was held that it would be unfair to Epsom should the Fund alone join the Association.

Dr. E. C. Douglas was of course quite right in stating that the Fund was a creation of the Association, but wrong as to the management of the Fund, as I have explained above. He gives his opinion rather than applies criticism, for while he considers Epsom "well worthy of support, he had nothing to do with the Fund." One cannot, and need not, support every charity, but good-will has its value, and encourages those who, whatever their deficiencies, are doing their best.

Dr. Singleton Darling contrasted the income of the Fund

unfavourably with that of the Irish Fund, and stated, "that in Ireland, with a very small number in the profession, they raised between £3,000 and £4,000." In the appeal recently issued by the Irish Fund the income for 1924 is given as follows:

Interest on investments ...	£	s.	d.
Subscriptions and donations ...	963	12	6
Other sources ...	620	15	6
	274	12	0
	1,859	0	0

If subscriptions and donations be compared, it will be noticed that, while the Irish Fund raised £620, our Fund raised £4,846, the Guild £2,221—or together £7,067. There are in Ireland 3,754 members of the profession. Mr. Souttar's remarks, while conveying a general dissatisfaction with the management, are some of them too indefinite for reply. One does not understand what is implied in the remark: "The Fund was managed under considerable difficulties, and, he thought, not always with great wisdom." Or again, that "The present arrangement was ridiculous." At the subcommittee to which he refers, he gathered, he stated, the view held was that "if the Fund had any official connexion with the Association the bulk of its subscriptions would be cut off." This is no doubt an unintentional exaggeration of what was urged by others, for there can be no doubt that the bulk of the subscribers are members of the Association. What we held was, that seeing there were between 16,000 and 20,000 non-members of the Association, it was reasonable to conclude that not a few would be offended, and the support of some of the largest subscribers might be lost. A reference to the historical summary at the beginning of this note will show that the Fund was always independent of the Association, and therefore it is incorrect to say that "the members of the Association had lost control." Finally, Mr. Souttar urges a course which would put an end to the existence of the Fund as an independent body. "Let the Association," he says, "have its own Charities Committee and obtain all the money it could, and then make terms with regard to this bulk sum." "When the Association had done what it could to find the funds it could regain control." If these criticisms mean anything, they signify mistrust of the management, especially of those whose daily duty it is to direct the business of the Fund.

I hope this simple statement of facts will allay some of the mistrust that has been aroused, and will result in encouraging a wider support to this and other medical charities. Above all, I trust that it will not arouse controversy, the last thing one desires in regard to any charitable undertaking, which should be above all party spirit.

Believe me, yours faithfully,

CHARTERS J. SIMMONDS,
Honorary Treasurer.

DANGEROUS DRUGS ACT.

A LITTLE over three months ago (February 27th, p. 391) we published an analysis of the Report of the Departmental Committee on Morphine and Heroin Addiction. The Home Secretary has now published, in the *London Gazette* for June 4th, formal notification that after the expiration of forty days from that date he will make new regulations amending the Dangerous Drugs Regulations, 1921. The principal effect of the new regulations is to carry out the recommendations contained in the report of the Departmental Committee above mentioned. Opportunity has also been taken to remove the ambiguity which existed as to the requirements of Regulation 5 of the principal regulations regarding the particulars to be inserted in prescriptions, and to include a new regulation requiring retail chemists to keep their stocks of dangerous drugs under lock and key. Draft copies of the regulations may be obtained on application to the Under Secretary of State, Home Office, Whitehall, London, S.W.1.

DRAFT AMENDING DANGEROUS DRUGS REGULATIONS.

In pursuance of Section 7 of the Dangerous Drugs Act, 1920, I hereby make the following Regulations amending the Dangerous Drugs Regulations, 1921, hereinafter referred to as the Principal Regulations.

1. Regulation 5 of the Principal Regulations shall be amended and shall take effect as if—

(1) for the words "the total amount of the drug to be supplied on the prescription" were substituted the words "the

total amount of the morphine, cocaine, ecgonine, or diaminophine or salt thereof, to be supplied on the prescription, except that in the case of a preparation which is contained in the *British Pharmacopoeia*, the *British Pharmaceutical Codex*, or the Drug Tariff issued by the Minister of Health for national health insurance purposes, and which is not combined with any other preparation of any of the drugs not so contained, it shall be sufficient to state the total amount of the preparation to be supplied and"

(2) at the end of the first paragraph shall be inserted the following new paragraph:

A prescription shall only be given by a duly qualified medical practitioner when required for purposes of medical treatment.

2. Regulation 7 of the Principal Regulations shall be amended and shall take effect as if the following proviso were added to paragraph (d) of the Regulation:

Provided that the last foregoing provision shall not apply to any drug supplied to a person for his use by a medical practitioner or in accordance with a prescription if that person was at the time of the supply in course of receiving treatment from a medical practitioner in respect of addiction to any of the drugs or otherwise, and of being supplied with any of the drugs by or on a prescription given by that last-mentioned practitioner, and did not disclose that fact to the first-mentioned practitioner before the drug was supplied to him.

3. Every duly qualified medical practitioner, registered dentist, and registered veterinary surgeon shall, if not already required to do so in pursuance of Regulation 9 of the Principal Regulations, enter or cause to be entered in a register kept for the sole purpose in respect of each supply of each of the drugs purchased or otherwise obtained by him, the particulars shown in Schedule 1 (a) to the Principal Regulations.

4. If the Secretary of State is of opinion that there is reason to think that a duly qualified medical practitioner may be supplying, administering, or prescribing any of the drugs either to or for himself or to or for other persons otherwise than as required for purposes of medical treatment, he may refer the case to a tribunal constituted in the manner described in the Schedule for examination and consideration, and if the tribunal so recommend, the Secretary of State may by notice in the *London* or *Edinburgh Gazette* withdraw the authorization of such practitioner to be in possession of or to supply the drugs, and may direct that the exception in Regulation 4 of the Principal Regulations in respect of drugs lawfully dispensed in pursuance of a prescription given by a duly qualified medical practitioner shall not apply in respect of prescriptions given by such practitioner as aforesaid.

5. Regulation 12 of the Principal Regulations shall be amended and shall take effect as if at the end were added the following sentence:

"Where such person is a duly qualified medical practitioner or registered dentist or registered veterinary surgeon, the Secretary of State may also, by notice given in the like manner, direct that the exception in Regulation 4 of the Principal Regulations in respect of drugs lawfully dispensed in pursuance of a prescription given by a duly qualified medical practitioner or registered dentist or registered veterinary practitioner shall not apply in respect of prescriptions given by such practitioner, dentist, or veterinary surgeon as aforesaid."

6. A medical practitioner, registered dentist, or registered veterinary surgeon shall not give any prescription for the supply of any of the drugs, if a direction has been given in pursuance of Regulation 4 or Regulation 5 of these Regulations that the exception in Regulation 4 of the Principal Regulations is not to apply in respect of prescriptions given by such practitioner, dentist, or veterinary surgeon.

7. Every person authorized in pursuance of Regulation 10 of the Principal Regulations to carry on the business of manufacturing, selling, or distributing the drugs shall keep the same in a locked receptacle of which the key shall be kept by himself or a qualified assistant.

8. These Regulations may be referred to as the Dangerous Drugs Regulations, 1926.

One of His Majesty's Principal Secretaries of State.
Home Office, Whitehall, 1926.

SCHEDULE.

Constitution of Tribunal.

England.—The tribunal shall consist of three duly qualified medical practitioners appointed by the Secretary of State, one of whom shall be nominated by the General Medical Council, one by the Royal College of Physicians of London, and one by the British Medical Association, together with a legal assessor appointed by the Secretary of State.

Scotland.—The tribunal shall consist of three duly qualified medical practitioners appointed by the Secretary of State, one of whom shall be nominated by the General Medical Council, one by the Royal College of Physicians of Edinburgh, and one by the British Medical Association, together with a legal assessor appointed by the Secretary of State.

British Medical Journal.

SATURDAY, JUNE 12TH, 1926.

AN IMPROVED MATERNITY SERVICE.

The lecture by Professor Munro Kerr on "Preventive medicine as applied to obstetrics," which we print in this issue (p. 977), directs the attention of the profession to a subject decisions on which are becoming more and more matters of public importance. A good deal of thought has already been given to this problem by the British Medical Association, and two specially appointed committees are now considering both the scientific and the administrative questions connected therewith. When these committees have reported, as they may be expected to do within the next twelve months, it will be desirable, even necessary, to make a fuller and more formal statement as to the attitude of the profession towards proposals for an improved maternity service than has hitherto been possible. Important decisions, indicating a general trend of opinion, have already been arrived at by the Council and Representative Body of the Association and by the Conference of Local Medical and Panel Committees, and have been embodied in the evidence given before the Royal Commission on National Health Insurance. No doubt such decisions will be open to review and in need of development, and as a contribution to the discussion Professor Munro Kerr's lecture is timely and valuable. Attention may also be redirected to a letter from Professor Louise McIlroy on "Obstetrics and local health authorities" which appeared in the JOURNAL of October 4th, 1924 (p. 642), and to the correspondence which followed during the ensuing fortnight. It is unlikely, however, that the administrative arrangements suggested by Dr. McIlroy and Professor Kerr, which have a good deal of similarity, will be endorsed by the profession as a whole.

The argument as the result of which these suggestions emerge appears to be as follows. There has been little or no reduction in puerperal morbidity and mortality over the past generation, during which the practice of midwifery has been mainly in the hands of general medical practitioners. General practitioners are in this regard badly educated, poorly equipped, and liable to be hasty and careless, whereas specialists are invariably both skilful and careful. Administrative arrangements should therefore be made for setting up, under the auspices of local health authorities, an extensive service of whole-time specialist obstetricians, general practitioners being either wholly excluded from this work (Professor Kerr) or admitted to it only after strict tests of skill and reliability applied by "some competent authority" and on an obligation officially "to furnish a detailed report of his treatment" to the superior officer (Professor McIlroy).

Neither the premisses nor the conclusion of this main argument can be accepted. It is, indeed, almost inconceivable that the profession would tolerate such a solution of the problem. Even the major premiss as to the non-reduction of the rates of maternal morbidity and mortality, though it has been too readily assumed since the wide quotation of certain sentences from the Ministry of Health's Report on Maternal Mortality by Dame Janet Campbell, is far from being universally true. No doubt circumstances vary, though it is admittedly difficult to get comparable figures. Those given in the Report of the Scottish

Departmental Committee give support to the contention, and these must be largely influenced by those of Glasgow and its neighbourhood, the conditions in which Professor Kerr no doubt had prominently in mind. But the official table in the Ministry of Health's report does not seem to support Dame Janet Campbell's statement based upon it, that "the maternal mortality rate is little lower than it was twenty years ago." Comparing the first with the last quinquennial period under consideration, the figures show a material reduction, the reduction in the sepsis rate being more than 20 per cent.; and no one who has a wide acquaintance with private practice during the past thirty years can doubt that the methods and results of obstetrical practice over at least the greater part of the country have immensely improved. In this connexion a pamphlet by Dr. C. E. Douglas relating to seventy years of midwifery practice in a Scottish rural area is of great interest and value. There is admittedly much room for improvement in the teaching given in this branch of medicine by some of the medical schools, though it is disappointing to find Professor Kerr, in his inaugural lecture to his own university class, expressing so complete a pessimism as to the results of further teaching with regard to the proper use of forceps. Admittedly, also, the lack of opportunity for gaining experience in the conduct of normal midwifery, owing to the increasing employment of midwives alone for normal cases, is somewhat disadvantageous—a disadvantage which Professor Kerr proposes to increase by the compulsory removal of all primiparae for institutional attendance. Admitting, however, that some practitioners may be imperfectly taught, and that all practitioners at the beginning of their career have a very limited experience, there is no justification for charging the body of general practitioners with any lack of skill and care in the conduct of maternity cases, and of requiring therefore that the great bulk of these cases shall be taken out of their sphere of practice. Even specialists begin by being inexperienced, and are not immune from fault. It seems much more likely that a further diminution of puerperal morbidity and mortality will be brought about by an improvement in housing conditions, and by increasing knowledge of possibly unknown factors of auto-infection, which are now the subjects of research. It is begging the question to assume, as seems sometimes to be done, that all cases of sepsis occurring in institutions or in the care of specialists are due to unknown, if not preventable, causes operating before they came under such care.

General medical practice is not, as a fact, developing on lines such as those which Professor Kerr indicates as, in his opinion, desirable. So far from restricting himself to pure medicine, afraid to use a knife or any other surgical instrument, shrinking from responsibility for a maternity case in any of its stages, antenatal, natal, or post-natal, the general practitioner, in partnership or association with his fellows, is finding it useful to his patients and advantageous to himself to undertake an even wider range of service than was at one time customary; and the results justify the method. Even if it were possible it would be lamentable to withdraw maternity from the purview of such a practice. The suggestions of the profession to the Royal Commission on National Health Insurance—suggestions endorsed by the Commissioners in their report—are in a contrary direction. They are that every pregnant woman should, early in her pregnancy, bring herself into relation with a general practitioner, who would be responsible for advising her during pregnancy, for attending her in confinement if she desired

it or if called in by a midwife, and for treating her during the puerperium. Along with this there should be an increase in institutional provision, but only for serious cases of ante-natal complications, for cases requiring major obstetrical operations, for cases where the home conditions are dangerous or quite unsuitable, and for cases where the isolation of septic infection is indicated. In such a scheme the consultant or specialist would have his more usual place, not as one set apart for the supervision of maternity to the exclusion of other members of the profession, and to his own exclusion from other spheres (gynaecology) now included in the same recognized branch of practice, but as one whose special skill, knowledge, and experience in his chosen branch of practice were available for such patients as might properly be admitted to an institution under his care, and for the help and guidance of practitioners who, in circumstances or cases of difficulty, appreciate such help and value it most highly. Such a scheme of public maternity service as that outlined by Professor Munro Kerr would, indeed, seem to involve, not only all the disadvantages of a too restricted specialism, but many of the most objectionable features which all public health schemes should endeavour to avoid as far as possible—namely, compulsory interference with the patient's choice and liberty, official reports and supervision of actual medical attendance, and bureaucratic regulation. Professor Kerr regards these lightly, but their effects both upon the public and upon the profession are very real.

THE IMPULSES PRODUCED BY SENSORY NERVE ENDINGS.

A COUPLE of months ago we gave some account of the history of the *Journal of Physiology* and of the changes in its editing rendered necessary by the death of Professor Langley, who, by his wisdom, knowledge, and unremitting care, raised it to its present position as one of the chief scientific journals of the world. Judging by the first two numbers of the new volume, it is not likely to lose that position under its present editorial control.

Among the papers published in these two numbers¹ is one by Dr. E. D. Adrian, F.R.S., on the impulses produced by sensory nerve endings. The researches on which it is founded were carried out in the Cambridge Laboratory of Physiology, and in it we are introduced to some of the most beautiful physiological work of recent years. By a combination of the capillary electrometer and a three-valve amplifier it has been possible to design an instrument with the capacity of responding to a change of potential of 0.01 millivolt lasting for one-thousandth of a second. All parts of the apparatus, including the preparation, are enclosed in a metal shield, which is earthed to the water pipes of the laboratory. Tests showed that electrical disturbances in the neighbourhood were without effect on the instrument. The possibility of distortion or of artefacts was finally ruled out by the comparison of tracings taken from different nerves.

By means of this instrument it has been possible to record the action-currents accompanying afferent impulses in the sciatic nerve of the frog when the gastrocnemius is stretched by a weight, in the cat's saphenous nerve when the skin is pinched, in the vagus of the cat and of the rabbit when the lungs are inflated, and in the cardiac depressor nerve of the

rabbit with each heart beat. The stretching of a muscle starts a stream of afferent impulses which last for as long as ten minutes, though becoming infrequent and irregular towards the end of this time. The flow of afferent impulses up the vagus continues so long as the lungs are held in an expanded state; deflation of the lungs, however, does not give rise to a renewal of the impulses. Afferent impulses appear to pass up the cardiac depressor nerve when the aorta is distended by the flow of the ventricular blood, and again, but to a lesser degree, when the aortic valves close. An analysis of the tracings leads to the conclusion that many of the oscillations represent the action-currents accompanying the afferent impulse of a single nerve fibre. A study of these shows that under similar conditions of temperature the form of the current is the same for all types of sensory nerve fibres. There is no infraction of the "all or none" law.

The second part of the paper is written by Dr. Adrian in conjunction with Dr. Zotterman. In the first part of the paper some of the conclusions about the behaviour of individual sensory nerve fibres needed qualification, for it was not possible to be absolutely certain as to the number of fibres actually involved. This defect has now been overcome by using the sterno-cutaneous muscle of the frog. It was found that the removal of successive portions of this muscle eventually left the experimenters with a strip which gave an action-current of perfect regularity, the period of each response being 0.03 second. Removal of a little more of the muscle abolished the response altogether, though what was left still responded to stimulation of the motor nerves.

From this crucial experiment the following conclusions are drawn. Pulling on the muscle does not excite the motor fibres. To a continuous stimulus, such as a weight attached to the muscle, the sensory end-organs do not respond synchronously. Impulses are started from different sense organs irregularly. A single end-organ, however, responds to a continuous stimulus with a regular series of discharges. Their frequency varies from 5 to 100 a second. This phenomenon introduces a property of the end-organ which is in direct contrast to that of the nerve fibre. As is well known, a nerve fibre only responds to a continuous current at the make or the break of the stimulus. No response occurs while the current is flowing, and, moreover, no response is obtained by increasing the current unless the gradient of the increase is sufficiently sharp. The nerve fibre is said to become adapted to the stimulus. This property of adaptation is much more pronounced in the nerve fibre than in the end-organ. It is, however, not absent from the end-organ, but is much more gradual in onset. An idea of its nature is gained from the fact that the frequency of the reaction of the end-organ has fallen to 50 per cent. of its initial value after ten seconds.

After an end-organ or a nerve fibre has responded, there follows a phase in which these structures are inexcitable. The duration of this refractory phase is found to be considerably longer in the end-organ (0.01 second) than in the nerve fibre (0.002 second). The result of this difference is that the nerve fibre can respond to every stimulus offered to it by the end-organ. The refractory period also enables us to understand how a continuous stimulus gives rise to a regular series of impulses. Furthermore, it is found that the response of the nerve fibre to each stimulus is a maximal one, and therefore follows the "all or none" law. Though there appears to be no grading in the

¹ *Journal of Physiology*, Vol. Lxi, Nos. 1 and 2, 1925. Cambridge University Press. Price 12s. 6d. net each. The *Journal* is the organ of the Physiological Society and is supplied free to members of that Society.

size of the impulse carried by each fibre, yet our sensations are graded. This investigation suggests one way in which the varying intensities of sensation may be brought about, since the frequency of the impulses aroused varies with the strength of the stimulus. Another interesting point is that when a muscle is so lightly loaded as to appear slack, yet about 3 to 8 impulses a second are aroused in the nerve, and this may be the basis of the slight degree of tonic activity that is always present in voluntary muscle.

In general it has been shown that the end-organ has the same properties as other excitable tissues. It is permissible to assume that all other sensory end-organs would behave in the same way. Finally, these same properties might be expected to be present in the synapse. Apart from their great scientific interest and the wonderful technical achievement they represent, these results are of immediate clinical importance. Previous work had rendered it almost certain that there must be this stream of afferent impulses pouring into the central nervous system. We have now indisputable proof that certain bodily states do arouse these streams of afferent impulses. We learn which are effective and which ineffective, and, moreover, their duration and frequency can be measured.

AMENDMENTS OF THE DANGEROUS DRUGS REGULATIONS, 1921.

THE Home Secretary has published in the *London Gazette* for June 4th formal notification that after the expiration of forty days from that date he will make new regulations amending the Dangerous Drugs Regulations, 1921. In the main the amendments carry out the recommendations contained in the report of the Departmental Committee on Morphine and Heroin Addiction. An analysis of that report was published in our columns on February 27th (p. 391), and the draft amendments in the Regulations are set out in full elsewhere (p. 998) in this issue. The most important change is that the Home Secretary will now have power to withdraw a doctor's authorization to possess and supply the drugs without a previous conviction in the courts, which is now a necessary preliminary, if he be so advised by medical tribunals to be set up in England and Scotland; they would consist of three duly qualified medical practitioners appointed by the Secretary of State, one of whom shall be nominated by the General Medical Council, one by the Royal College of Physicians of London (or Edinburgh), and one by the British Medical Association, together with a legal assessor appointed by the Secretary of State. The Home Secretary will also have power to deprive a doctor of his right to prescribe the drugs, either after conviction in the courts or on the advice of this specially constituted medical tribunal. Doctors who do not dispense, and who are not therefore under an obligation to keep any record, must, under the new regulations, keep a record of their purchases of the drugs. It is further provided that a prescription for the drugs shall only be given by a duly qualified medical practitioner when required for purposes of medical treatment. Each of these provisions was considered and agreed to by the Representative Body of the British Medical Association at its meeting at Bath in 1925. An important new restriction is made in Regulation 2 to prevent any person acquiring any dangerous drug from more than one source at the same time. To this no exception is likely to be raised by any member of the profession. Opportunity has also been taken to remove the ambiguity which existed as to the requirements of Regulation 5 of the principal Regulations regarding the particulars to be inserted in prescriptions, and to include

a new regulation requiring retail chemists to keep their stocks of dangerous drugs under lock and key. It is of interest to note that no steps are being taken to enforce notification of drug addiction, or to make compulsory the seeking of a second medical opinion in the treatment of cases of drug addiction, and that no authoritative rules have been issued for guidance in the use of the scheduled drugs. The British Medical Association raised strong objection to all these proposals. Its chief contention—that drug addiction is a manifestation of disease, frequently associated with nervous instability and requiring treatment, and not merely a vice demanding punishment—appears to be now definitely recognized.

THE GENERAL MEDICAL COUNCIL.

THE General Medical Council assembled on the afternoon of Tuesday, June 1st, to hear the address of its President, which was published in the *SUPPLEMENT* last week, and separated on the following Saturday, having completed the business before it. Perhaps the most striking feature of the session was the fact that—for the first time, we believe, in its history—a member who does not belong to the medical profession took his seat. There has never been any reason why a layman should not be appointed or elected to the Council, but neither the Crown nor the universities, the corporations, or the profession has ever thought fit to do so. The President in his address said that only fifteen out of thirty-eight members need possess a medical qualification, and that the Council would be pleased were His Majesty to nominate a member of his Council to the seat rendered vacant by Sir Francis Champneys's retirement after fifteen years' service. Such a nomination, Sir Donald MacAlister said, would mark the close connexion of the General Medical Council with the Privy Council, to whose official direction it was by statute committed. At the close of his address he said he had just received an intimation from the Lord President of the Privy Council that the Right Hon. Edward Hilton Young, D.S.O., M.P., had been nominated by the Crown to be a member of the Council. Mr. Hilton Young is the third son of Sir George Young, Bt., who was chief Charity Commissioner and vice-chairman of the Education Committee. He was at Trinity College, Cambridge, and graduated M.A. in 1907; he was called to the Bar in 1904, and went the Oxford Circuit. He served in the navy during the war, first in the *Iron Duke* and afterwards in the *Centauro*, taking part in the actions on January 22nd and May 11th, 1917. He was in the *Vindictive* at Zeebrugge Mole in 1918, where he was severely wounded, and was specially promoted lieutenant-commander. He received the D.S.O. for his services in command of an armoured train in the Archangel campaign. He entered Parliament as member for Norwich in 1915; was defeated in 1923, but was elected again in 1924. He was Financial Secretary to the Treasury in 1921-22, and British representative at the Hague Conference on international finance in 1922. We should be curious to know what Mr. Young thought of his new experience; we have no doubt he found the work of the Council useful and its proceedings decorous, but he may have thought them a little dull. There was a debate, interesting at least to medical readers, on the readjustment of the medical curriculum, in which some differences of opinion were disclosed, and the Council adopted a resolution with regard to the revision of the *Pharmacopoeia* after the matter had twice been discussed by the President, once in his address, and again in presenting the report of the Pharmacopoeia Committee, which referred briefly to the conference held last February between the Committee and twenty-three delegates from twelve medical, pharmaceutical, and scientific societies and bodies. After considering the representations made at the conference

the Pharmacopoeia Committee decided that an authoritative inquiry should be held to hear evidence and obtain information not now in its possession. It accordingly asked the Lord President to appoint a special committee, including members of the Council, for this purpose, and to make recommendations as to the alterations, if any, which ought to be made in the next edition to fit it to the requirements of the British Empire. That matter, which has excited widespread interest, seems, therefore, in the way of being adequately determined. A great part of the time of the Council was devoted to the consideration of a case under the Dangerous Drugs Regulations as they now exist. It was, the President said, the first case under those Regulations which had been brought before the Council; after the public inquiry had concluded the Council sat *in camera* for over an hour, and the President then pronounced its decision at some length. The upshot seems to be that the Council dismissed two of the three charges, but on the third, which had been the subject of proceedings in the law courts, it decided to give the practitioner an opportunity of showing during the next year that he was conducting his practice in a manner conforming to the Warning Notice the Council has issued.

FOOT-AND-MOUTH DISEASE.

TOWARDS the end of May an outbreak of foot-and-mouth disease was notified from a farm in Lanarkshire after Scotland had been free from the disease for two years. The origin of the infection has been definitely traced to pig carcasses received from the Continent, and subsequently other consignments of carcasses landed at Leith and Newcastle were found to be infected. The Ministry of Agriculture has issued an Order prohibiting the landing of all fresh carcasses or offals from the continent of Europe. There is no ban on meat products which have passed through some process which will have destroyed the virus—such as curing, drying, or cooking; and there is no ban on imported frozen meat from outside Europe. There is accordingly no danger of a meat shortage in this country, as the great bulk of our beef and mutton is obtained in a chilled condition from Australia, New Zealand, and South America. There will, however, be a shortage of fresh meat and pork; not enough is produced within this country to meet our own needs; and it is estimated that the value of the trade so prohibited amounts to about 4½ million sterling a year. It would seem possible, however, that with some effective means of *ante-mortem* inspection of such meat, a certain amount of fresh Continental meat might be introduced under licence. Holland, for example, denies that its portion of the consignment was infected, and declares that all the infected pigs were of Belgian origin. If this is the case it is probable that some arrangement such as we have indicated above might be adopted. Although this discovery indicates one source of the infection in this country, it is highly improbable that it is the only one, as has been assumed in some lay newspapers. On the other hand, it suggests one means by which the disease may be spread throughout the country. The virus is found in the characteristic vesicles on the mouth, feet, and udders. But it is also found in the blood. The French authorities have pointed out that the blood infection may be present before there are any definite clinical lesions; and accordingly an animal slaughtered at this stage may, if the carcass is removed to a market, be a possible disseminator of the infection to new localities. The country is still suffering from this very serious disease, which threatens to become enzootic. Last winter over a quarter of a million pounds was paid in compensation, and this represents only a very small part of the total loss to the stock-breeding industry. We are still

very much in the dark as to the virus, and consequently as to effective methods of prevention on scientific lines. The Foot-and-Mouth Disease Research Committee is still at work, although in the past week it has lost its chairman, Sir William Leishman, and Sir Stewart Stockman, one of its official members. Serious as these losses are, we hope that they will not be irreparable and that the work will proceed apace. It is of the utmost importance to find some means, based on sound scientific principles, of keeping the country free from the disease: this can only come from the laboratory. Britain is no longer an island, and it seems obvious that the pole-axe method cannot be indefinitely used to stamp out the disease. It has been fairly successful in the United States—but that country is a much more effective "island" than is this country, and there is less danger of its reintroduction there. We are in a less fortunate condition here, and we cannot afford indefinitely to pay large sums in compensation for what is only a destructive policy. On the other hand, we cannot afford to have the disease permanently with us. It is only by continued and intensive laboratory and field work that we can hope to find a solution, and it is through the intensive co-operation between medical and veterinary scientists that we believe that a solution may finally be found.

RATS, WORMS, AND CANCER.

WHILE the London Zoo exhibits a number of strange animals from abroad, none are more strange than the large unseen fauna which has received the attention of so many distinguished parasitologists in the past. In describing the helminths found in the Zoo rats, at a meeting of the Zoological Society on June 1st, Professor R. T. Leiper, F.R.S., drew attention to the occurrence of *Gongylonema neoplasticum* in these animals. This was the first occasion, he pointed out, that this most interesting form had been found in Great Britain. Fibiger studied material which had reached Denmark from the West Indies and South America—where it is enzootic—and doubtless the infection had originally reached the Gardens from the same region; although it is now established there, there is no reason to suppose that it is found elsewhere in Britain, or, indeed, at all generally in Europe. The parasite had for a time a somewhat sinister reputation, as Fibiger had shown that cancer was sometimes caused by its presence; it was at one time utilized to reproduce the disease in the laboratory, but has since been replaced by tar painting as a more convenient cause of experimental cancer. A few years ago it was claimed that there was a peculiarly irregular topographical distribution of gastric cancer, and that a group of these cases was associated with definite streets in certain villages in Italy. The hypothesis was advanced that there was some correlation between gastric cancer in man and gastric cancer in rats—the double assumption that *Gongylonema* occurred in the rat and man in these regions was utilized to explain the old "cancer-house" theory, which thus received a new lease of life. Professor Leiper pointed out that recent investigations in Italy failed to substantiate either assumption, although it had been shown that an allied species of *Gongylonema* was very prevalent in sheep, cattle, and pigs in these regions. The incidence of these parasites, however, could in no way explain or be correlated with the cancer-house theory. Moreover, this allied species—unlike the *Gongylonema* in the rat—never produces cancer in its definitive hosts; and in the few cases in which this species has been found in man there is no evidence that cancer resulted. Only on the assumption that *Gongylonema* in the rat was the same species as that in the farm animals could the association of vermin in "cancer houses" with cancer cases in man be explained. The material obtained from the Zoo was utilized to clear

up this point, and it was shown conclusively that when sheep were experimentally infected with cockroaches, previously infected with the *Gongylonema* of the rat, the resulting worms differed morphologically from the species naturally found in sheep, and were identical with the species of the rat. It is clear, therefore, that the widespread distribution of *Gongylonema scutatum* of sheep and cattle in the neighbourhood of cancer villages gives no ground for the assumption that the rat harbours *Gongylonema neoplasticum* or that it transmits it to man. This experimental work illustrates also the danger of assuming that, because an animal can be infected with a parasite experimentally, it is a carrier of such a species in nature.

GEORGE BUCHANAN'S SKULL AND PORTRAITS.

A PUBLIC lecture on the skull and portraits of George Buchanan (1506-1582) was delivered under the Henderson Trust in the Anatomy Theatre of the University of Edinburgh on June 4th by Professor Karl Pearson, F.R.S., Galton professor of eugenics in the University of London. Professor Sir E. Sharpey-Schafer, F.R.S., presided. Professor Pearson said that George Buchanan, tutor of Mary Queen of Scots, and Scotland's greatest scholar, had been a subject of controversy for over three centuries, for his character had been read in two different lights by men of opposite political and religious views. At the present day this was simply a matter of history, and he did not intend to approach the question directly, but to examine the various portraits reputed to be delineations of Buchanan by the aid of the skull which was preserved in the Anatomical Museum at Edinburgh. By this means light could be thrown upon the type which represented the man whose brain once worked within the skull. If he could settle that one portrait was fitted by the skull and that others were not, his task would be accomplished. The science of physiognomy, he said, was a matter of instinct guided by experience, and when character was judged by facial expression people were right in nine cases out of ten, but might be badly in error in the tenth case. As examples of his method photographs were shown of the authenticated skulls of Sir Thomas Browne and Henry Stewart, Lord Darnley, and of various portraits of them upon which tracings of the skull had been imposed. Buchanan's skull, as compared with those of Sir Thomas Browne and Jeremy Bentham, was by craniometric measurements small. It would be best to compare it with the average measurements of a large number of seventeenth century Londoners. There was really no difference between the craniometric measurements of the Lowland Scot as carried out by the late Sir William Turner and those of the average early Londoner. The nearest congeners of both were not Celts and Anglo-Saxons, but the Iron Age invaders of Britain who were common to both countries. Examining the skull of Buchanan by measurements, the cranial capacity was found to be below the average. The cranium was apple-shaped, with flattening of the back and a depressed nasal bridge, very much resembling the head of the statue of Socrates. The skull was as authentic as such things could be. It had been obtained by Principal Adamson of the University of Edinburgh within thirty years of the burial of Buchanan. Adamson had been a shrewd man not likely to be deceived, and had written a eulogium of Buchanan. The skull had also been mentioned by Sir Robert Sibbald in the seventeenth century. The pictures of Buchanan were divisible into two types, which corresponded in physiognomy to the two types of character attributed to their subject. Portraits and engravings corresponding to the "Cato" type of the National Portrait Gallery and of paintings in Edinburgh and St. Andrews could not be accepted. These represented a man with high cheek-bones,

long nose, long upper lip, the harsh ascetic appearance of a reformer, and did not in the least fit the skull, of which, in the tracing, the teeth came upon the nose of the portrait, while the other anatomical points were far from corresponding. The "Catullus" type of face, shown by the portrait in the Royal Society of London, corresponded entirely with the features of the skull, and Professor Pearson felt no doubt that this was the real portrait of Buchanan. It showed a man strong, coarse, and blind to what truth might lie in his opponent's views, a second Scaliger rather than an Erasmus, More, or Colet. Gratitude was due to old Principal Adamson, that unique academic body-suntcher, whose act had preserved a real criterion of the true features of George Buchanan.

ANIMALS AS PATIENTS.

THE last "social evening" of the season at the Royal Society of Medicine took place on June 7th, when about 500 Fellows and guests were received by the President, Sir St. Clair Thomson. During the evening a lecture was given by Mr. Frederick T. G. Hobday, C.M.G., president of the Section of Comparative Medicine, on "Our animal friends as patients." Mr. Hobday emphasized the close analogies between veterinary and human medicine. He declared that every branch of medicine represented by the twenty-four sections of the society had its counterpart in veterinary practice, not excluding even psychiatry, for neurotic and hysterical animal patients were often met with, and the psychology of the horse and the dog in particular deserved study. It was not so widely known as it ought to be, Mr. Hobday continued, that the only person who was entitled to call himself a veterinary surgeon was one who had gone through an established course of study occupying from four to six years, and had obtained a diploma from the Royal College of Veterinary Surgeons enabling him to practise. In this and other countries women were now taking up this career, though it was a closed profession to them until after the war, and the pioneer, Miss A. Cust, sister of Sir Charles Cust the King's equerry, could not become qualified until 1922. There was now, in addition to Miss Cust, a second woman veterinary surgeon in this country, and there were quite a number of women students at the Royal College, some of them in their final year. He believed that in canine and feline practice particularly women had a great future; they seemed to have a greater capacity than men for establishing friendship with the animal patient. The diagnosis of disease in animals was in some respects more difficult than in the human subject, because the animal could not describe its condition, and reliance had to be placed upon observation and upon the history afforded by an observant or an unobservant owner. On the other hand, the veterinary surgeon had this advantage, that his patients could not mislead him about their symptoms. Mr. Hobday went on to describe and illustrate the various mechanical arrangements for restraining animals during the administration of anaesthetics, and the different patterns of operating tables in use. Anaesthetics, he said, were as generally used in animal as in human surgery, and various types of chloroform inhalers, adapted to the anatomy of the nostril, were employed; x rays were largely used to demonstrate fractures or foreign bodies. Some animals, especially young dogs, had a propensity for swallowing nails and other hard substances. One dog brought to him had disposed of several florins in this way, and from another, a dachshund, sixteen large-headed nails were removed. Some diseases from which animals suffered were contagious for man, including certain skin troubles. With Dr. Arthur Whitfield he had traced twenty-nine cases in which persons, mostly belonging to associated families, had become infected with mange through contact with other

dog. Ringworm also was transmissible from the dog, the cat, and the calf. He went on to describe some experiences in animal dentistry; he had provided dentures for dogs, and he caused amusement by telling how the dog's false teeth were taken out at night and put in water. Glass eyes also had been fitted, and still more frequently artificial limbs in the case of dogs and some farm animals, in the use of which they became quite expert, the dogs even using their wooden legs to whack an antagonist. Medicine given to animals was as far as possible concealed in tempting morsels of food, but animals were often too ill to take any food at all, and then more vigorous measures had to be taken to secure the administration of the pill. Drugs had diverse effects upon animals. For example, morphine on the dog had a narcotic and soporific effect, so that even major operations could be done under its influence, supplemented by some local anaesthetic, while, on the other hand, the horse and the cat under the influence of morphine became delirious.

THE SCIENCE OF WEIGHT AND MEASUREMENT.

An exhibition of weighing and measuring instruments was held last week at Westminster in connexion with the annual conference of inspectors of weights and measures. To judge from the exhibition, by far the most important thing to be measured in modern civilization is petrol. Of the eighteen firms exhibiting, nearly one-half confined themselves to petrol pumps capable of delivering exact quantities of the spirit, and, what is equally important, of assuring the motorist by some infallible indication that he has received the expected quantity. The kerbside pump from which the motorist obtains fresh supplies without fuss or delay has come, deservedly or not, under some suspicion, and several of the exhibiting firms had taken a good deal of pains to prove that the measure given could be relied upon. Diverse as were the pumps shown in construction and action, they all claimed the utmost degree of mechanical accuracy, and had recording devices to show the motorist that he got full measure. Apart from petrol pumps, many other objects in the exhibition exemplified the extraordinary skill and precision with which the science of weighing and measuring now proceeds. There were instruments so conscientious as to furnish one hundred times greater accuracy than that required by any Government regulation, and instruments so adaptable that after registering a load of two or three hundredweight they could turn with equal facility to the task of weighing an 18-grain cigarette. The work assigned by the prophet to the Divinity, of comprehending the dust of the earth in a measure, was here performed by scales of such fine limits that the weight of a pencil stroke or a human hair could be recorded by the movement of a pendulum, which had to be viewed through a microscope in order to be appreciated; in addition to these instruments for the chemical laboratory, there were others of a capacity which lent some colour to the further prophetic passage about weighing the mountains in scales and the hills in a balance.

THE HOME AMBULANCE SERVICE.

The annual report of the Home Service Ambulance Committee of the Order of St. John of Jerusalem and the British Red Cross Society states that the steady and consistent growth of the work of the Home Ambulance Service shows clearly that it is usefully and efficiently filling a place in the service of the country. In the past twelve months the Ambulance Service has again set up a new record in regard to the number of sick and injured carried. The increase is probably due to the large number of accidents that occur on the road, consequent on the increase in the volume and speed of traffic. There is also a growing

tendency among doctors to have their patients removed for treatment from their own homes to hospitals and nursing institutions. In this matter the supply of ambulances has undoubtedly increased the demand. It has been decided not to replace any of the old ambulances now on loan unless they are in charge of units of the Order of St. John or the British Red Cross Society, which ensures that they are served by an organized body of trained attendants who give their voluntary services to the aid of those who are laid low by sickness or accident. The capacity for rapid expansion in the Ambulance Service to meet emergencies was shown during the general strike, when, at short notice, the duty of providing transport for hospital patients in the London area was undertaken at the request of the Government. The work necessitated the use of a number of vehicles far in excess of the normal strength. The difficulty was met by the immediate enrolment of some eighty private cars, the use of which was offered by their owners. The transport of in-patients to and from hospital, of out-patients for treatment and return to their homes, and of a large number of maternity cases, was successfully carried out. The x-ray car has been actively employed throughout the year; the number of cases attended from April, 1925, to the end of March, 1926, shows an increase of 50 per cent. as compared with the previous year's work. The apparatus used is practically equal to the equipment of the working x-ray department of a large general hospital. Its adaptability for bedside work, without any detriment to its efficiency, is of the utmost importance where the patient must not be removed from the bed, as in such cases as intracapsular fracture of the hip and acute chest conditions. The Potter-Bucky diaphragm has been added to the equipment during the past year. From the report it is evident that the committee is carrying on work of very great value to the community.

THE PLANT AS SANITARY ENGINEER.

An interesting lecture under the auspices of the Chadwick Trust was delivered in the Chelsea Physic Garden on June 3rd by Professor J. McLean Thompson, of the Hartley botanical laboratories, Liverpool University. Professor Thompson, whose subject was "The plant as a sanitary engineer," began with a comparison of animals and plants, describing the former as the parasites of Nature, taking from her the food they required, producing nothing for themselves, and being exploiters in every sense, whereas the higher plants had a much more creditable record. The plants were self-supporting; taking from the soil from which they sprang and from the air surrounding them the absolute minimum for the needs of their existence, and making of it the greatest possible use. The plant being a stationary and not a nomadic organism, its problem was to meet the conditions of life in the open, and so it had to adapt its construction to withstand climatic disturbances. The plants which did this successfully survived. A plant such as seaweed had little difficulty, being supported by the fluid in which it existed, but the higher we went in plant life the more did the difficulties increase. The forest tree, for example, was exposed to the winter gales and had to bear the weight of branch and leaf and fruit, and it had evolved within itself such a mechanical construction as to make this possible. It was required to bend and recover, to yield that it might conquer; its elastic limit must be such as to stand the strain, and when taxed beyond that limit it was shattered. Economy was as important in plant life as in bridge-building or house-making. The plant, said Professor Thompson, had to manufacture its own materials out of soil and air, and there was a lesson for engineers in the economy with which this was accomplished. The plant had two methods of maintaining its form and position. The first was by

turgescence—inflating a soft mombrano with air or fluid and then surrounding it by a tougher wall of tissue. A lettuce, which was about 90 per cent. water and 4 or 5 per cent. firm tissue, was a good example of this method. The second method was by a mutual tension of tissues maintaining the body in firmness. There had been also other methods evolved for specific purposes, but always the problem was to maintain form and rigidity and yet not to be so hard as not to yield to pressure, atmospheric or other, or to retard growth and expansion. In the higher plant forms, the lecturer went on, came the interlocking of fibro tissues—dovetailing, in fact—to secure those two essential qualities of firmness and elasticity. The strength and elastic recovery of such substances as hemp fibre, flax, and garlic were compared with silver wire and wrought iron and steel. The comparison showed the plants to be superior in elastic recovery, but the metals to be superior in breaking strain. The principle of reinforced concrete had first been evolved by the plant, in the form of the distribution of strong fibrous rods through a mass of softer tissue. He also compared the surface resistance of leaves with textiles, showing the superiority of the plant to the woven substance in this respect. The plant, he claimed further, got down to the A B C of living, making its own food from water, air, and mineral salts, just to the amount required, with no waste, and with no noise in the process, whereas the animal fed extravagantly on the elaborately produced vegetable foods of the earth. One of the greatest problems of man's social existence was the removal of the waste caused by the production of energy in animal life, but the plant had solved this problem by converting waste into wood for hardness, and by taking the impurities from the air and combining them with the salts of the earth to make its own nutriment. In fact, the plant had proved itself, not only a sanitary engineer in respect to its own economy, but also the bringer of sanitation for the benefit of the animal.

THE VICTOR HORSLEY MEMORIAL LECTURE.

THE second Victor Horsley Memorial Lecture will be delivered at the House of the British Medical Association on Friday, July 9th, by Mr. Wilfred Trotter, M.S., F.R.C.S., surgeon to University College Hospital. The subject of the lecture is "The insulation of the nervous system." The chair will be taken at 5 p.m. by Sir John Bland-Sutton, President of the Royal College of Surgeons of England. Members of the profession desiring to be present will be admitted on presentation of a visiting card. The first Victor Horsley Memorial Lecture was delivered by Sir Edward Sharpey-Schafer in 1923, and was published in our issue of October 27th in that year; its subject was the relations of surgery and physiology. The fund was established in 1921, largely through the initiative of the late Mr. E. J. Domville, and the object in view was to commemorate the services of Sir Victor Horsley to science and the Empire. Subscriptions were received from all parts of the world, and a sum of £1,000 was collected. This sum was invested in the name of trustees, who undertook to appoint every third year a person to deliver the memorial lecture in London.

COMPLIMENTARY DINNER TO SIR STCLAIR THOMSON.

His fellow laryngologists entertained Sir StClair Thomson, President of the Royal Society of Medicine, at a complimentary dinner on June 4th, when a distinguished company of more than 200 ladies and gentlemen assembled in the King Edward VII Rooms, Hotel Victoria, under the chairmanship of Dr. W. H. Kelson, president of the society's Section of Laryngology. Dr. Kelson, in proposing the health of the guest, recalled his first acquaintance with

their guest, which was in 1893, when they both took the Fellowship of the Royal College of Surgeons. He went on to describe the successes Sir StClair Thomson had gained in many fields—first of all as a specialist in diseases of the larynx, then as author of a textbook which must be called the laryngologists' "bible," a fluent interpreter at international congresses, and a very good host at the Royal Society of Medicine, also a golfer of some repute, and a practised artist in the ballroom, where he was seen to advantage at the social assemblies during the Annual Meetings of the British Medical Association. In all these directions he had compelled their admiration, and for his personal charm and kindness he had gained their love. Laryngologists to the number of 175 had subscribed for the presentation of a handsome silver loving-cup, which he had the honour to hand to their guest. It bore the inscription: "Presented to Sir StClair Thomson by members of the Section of Laryngology to commemorate his presidency of the Royal Society of Medicine, and as a recognition of his services to laryngology." Sir StClair Thomson, having first taken a deep draught from the loving-cup, expressed his great appreciation of the presence of so many distinguished colleagues, among them the President of the Royal College of Physicians (Sir John Rose Bradford) and two vice-presidents of the Royal College of Surgeons. It was a coincidence that one of them, Mr. Walter Spencer, began as a laryngologist, and the other, Sir Charles Ballance, as an otologist, although they had both wandered since into wider fields. Then he rejoiced to see his successor, the president-elect of the Royal Society of Medicine, Sir James Berry; the orator of that year's summer meeting of the Section of Laryngology, Sir William Willcox; and many friends with whom he was associated before there was a Royal Society of Medicine at all, among them Sir James Dundas-Grant, Dr. William Hill, and the senior survivor of the presidents of the old Laryngological Society, Dr. de Havilland Hall. When he had the good fortune to ascend the chair of the Royal Society of Medicine nearly two years ago a friend remarked that it was a nice finish to his career. He did not appreciate that at all, and even that night's gathering he could only look upon as another milestone, and not as a finish. Bacon said that when the populace applauded you it was time to ask yourself what faults you had committed. But this was hardly the case when the applause came from one's own colleagues. There were various ways of succeeding in the medical profession. One, a very dull way, was to survive one's contemporaries. Another, a very mean way, was to depreciate one's colleagues. For his own part he liked to think that a successful career in medicine was exactly the reverse of that pictured by one writer in a different connexion: "First she got on, then she got honours, and last of all she got honest." The first thing was to be and to remain honest, and after that some got on and a few got honours. He himself had had two ambitions. One was to till to the best of his ability the small corner of the field of medicine in which he worked, and the other was to accomplish it in such a way as to keep the esteem and regard, and if possible the affection, of his fellow workers. He had tried to follow the advice of Shakespeare in *The Taming of the Shrew*, to "do as adversaries do in law, strive mightily, but eat and drink like friends." In all these respects his endeavours had fallen far short of his desires, but the reward that evening greatly exceeded anything of which he had dreamed when he started as a laryngologist thirty-three years ago. He accounted himself in nothing so happy as in the number of his good friends. The only other toast was the health of the chairman, proposed by Mr. Herbert Tilley, and the floor was then cleared for dancing, which was indulged in until a late hour. Those present in addition to those already named included Dr. Logan Turner, Dr. F. Howard Humphris, Dr. A. A. Gray, Mr. G. J.

Jenkins, Mr. Harold Barwell, Sir Henry Simson, Mr. P. J. Franklin, Mr. Norman Patterson, and Mr. L. Ferris-Scott; and amongst those who sent apologies for inability to attend were Sir John Bland-Sutton and Sir Dawson Williams.

We deeply regret to have to record the death, at the age of 72, of Sir Frederick Mott on June 8th. Last Wednesday week (May 26th) he was taken ill in the train whilst travelling to Birmingham to visit the laboratory of the Hollymoor Asylum in the course of his duties as honorary director of research on mental disease for the Corporation and University of that city. On arrival at Birmingham he was taken to the General Hospital, where he was under the care of Dr. W. H. Wynn. It was found that he had a widespread cerebral thrombosis, from which he never rallied. We intend to publish a detailed biographical notice in our next issue.

At the annual meeting of the Royal Society of Tropical Medicine and Hygiene, to be held at 11, Chandos Street, W.1, on Thursday, June 17th, at 8.15 p.m., the Manson Medal will be presented to Professor Ettore Marchiafava of Rome in recognition of the part he took in the elucidation of the life-history of the parasites of human malaria.

The foundation stone of the new house of the London School of Hygiene and Tropical Medicine, the gift of the Rockefeller Foundation, will be laid at 3.30 p.m. on Wednesday, July 7th, by Mr. Neville Chamberlain, Minister of Health.

The conversazione of the Royal Society, which was postponed owing to the general strike, will be held on the evening of Wednesday next, June 16th.

THE SPAS OF WESTERN GERMANY.

The Englishman in search of health or change of air no longer knows much about the resources of Germany for these purposes. Hydrology, as practised in French and Czechoslovakian resorts, has attracted attention; it may be of interest to know what signs of progress are to be found in German spas. We have availed ourselves, therefore, of an opportunity for obtaining information about some of the principal spas in Western Germany, the state of their equipment, the facilities they offer for treatment, the measure of comfort provided for visitors, and the cost of a "cure." Such information may be of value to practitioners in this country, especially those who practise balneology or hydrotherapy. The views of German investigators who are trying to place hydrology on a scientific basis are of interest; and a study of the results of the inclusion in Germany of spa treatment amongst the benefits obtainable by insured persons should be useful to those who are contemplating similar benefits under our National Health Insurance Acts.

THE INDICATIONS FOR TREATMENT.

It is, perhaps, unfortunate for hydrology that in all countries there is a tendency to make excessive claims about the range of diseases which can be treated at each spa. The tendency befalls the practitioner who wishes to prescribe a suitable place for his patient, and it lowers the prestige of the spas. Most of the places visited have established reputations for the treatment of particular diseases, whether as the result of old-established custom or of definite therapeutic value of the waters, climate, or regime. Thus Nemeenahr is suitable for diabetes and for digestive troubles, and Ems, with its alkaline waters, for diseases of the respiratory mucous membranes. At Wiesbaden rheumatism and gout are treated. Langenschwalbach's chalybeate waters and peat baths are useful in chlorosis and women's diseases. Schlangenbad is said to be suitable for nervous irritability; it looks, indeed, a quiet, restful beauty spot. At Kissingen

digestive and other troubles are treated. The fame of Nauheim for heart disease is wide. The waters of Wildungen are diuretic; they are bottled and exported. Pyrmont treats diseases of the female pelvic organs, and has a reputation for the cure of sterility. Oeynhausen is full of innumerable bath chairs, motor and hand driven; its patients suffer chiefly from nerve diseases, organic and functional. It is strongly asserted that the symptoms of tabes, and even of syringomyelia, are alleviated. In all these spas, however, other diseases are treated; but in many cases the claims are of doubtful validity. The waters of nearly all the spas come from a great depth, are warm, and are impregnated with CO₂, free or loosely combined; but they vary in the nature and amount of the salts they contain.

THE EQUIPMENT OF THE SPAS.

In Germany spa treatment is taken far more seriously than in England. In all the places visited, with the possible exception of Wiesbaden, the "cure" is the only *raison d'être* for the town. Treatment is provided even for the insured person, as will be shown later. The equipment of each spa is very complete, covering in most cases the whole range of hydrotherapeutic treatment. In addition to the completeness of installation, a feature of the German spas is the concentration of the hotels and bathing and other establishments within a compact area, generally in and around a beautifully laid out garden. The completeness and concentration are probably due to the fact that a large number of the spas are owned by the State. However poor the individual German may be, the State seems to have plenty of money to spend. Even in spas directed by a company, such as Pyrmont, the State is the landlord, and with the county (*Kreis*) and municipality owns the bulk of the shares. The large hotels are well appointed and comfortable; the food is good, and arrangements are made for supplying suitable dietaries; in one of the Neuenahr hotels there is a triple menu daily—ordinary, diabolic, and digestive. In many places the spa water is laid on to one or two of the hotels, so that the baths may be taken without going to the spa bath-house. The springs for drinking are usually, situated in a large and lofty *Wandelhalle*, where the patients can stroll or sit, and can listen to an orchestra while sipping their daily doses of water. In Pyrmont the *Wandelhalle* is enclosed by a series of huge glass panels, which can be slid along rails and stacked at the end of the building. Thus in warm weather the building is thrown open, and becomes a sort of colonnade.

The baths are made of various materials. At Kissingen Professor Haertl has experimented in an old bath-house with the different materials in use. He considers the porphyry bath most durable, but it has the disadvantage of taking time to become warm. The English porcelain bath is very good, but too expensive. The iron bath, enamelled, is satisfactory and easily heated. At Ems copper baths are used, and in many places the material is an Australian wood, stated to be a kind of eucalyptus. Sometimes the baths are made of pine wood, and are cleaned with acid. The tile-lined bath is thought to be objectionable because of the crevices between the tiles and the greater difficulty in cleaning. Peat or mud baths are generally given in movable wooden tubs, the bath being wheeled out of the bathroom for filling and emptying. In Wiesbaden the mud bath is fixed; the peat mixture is forced into the bath through a large tap, and the used material washed into the drains. There are usually from 100 to 300 bathrooms, or even more, in a bathing establishment, and the number of baths given in a day may reach 3,000 or 4,000. At Nauheim it was stated that 6,000 baths could be given daily. It was interesting to find that rooms for rest after the bath were almost non-existent. Even at Nauheim patients with heart disease are sent straight back to their hotels for rest. When the water needs heating steam pipes are generally used. At Kissingen an ingenious steam-pipe apparatus is fixed above the bath, is lowered into the water, and is withdrawn when the required temperature is reached. At many of the spas Turkish or Irish baths can be obtained, and fango packs are used.

In the douche room a convenient table, from which sprays and douches of various kinds can be directed at will, is a frequent form of equipment.

In addition to the baths and springs most of the spas provide an inhalatorium, with a room filled with vapour impregnated with a medicament, rooms for throat and nose spraying, a gargling room, and in some cases one or more pneumatic chambers. Naturally this equipment is most complete at Ems.

Amongst the accessory equipment available at some of the spas are rooms for x-ray and electro-cardiograph work, Zander apparatus, and institutions (generally under a Government official) for laboratory work in connexion with the waters and with clinical examinations. In one or two places an apartment still remains labelled "radium emanations" 1 Milk-cure establishments are attached to some spas, and the idea that longevity is promoted by the Bulgarian bacillus and by kephir seems still to linger in Germany.

RECREATION AT THE SPAS.

To each spa there is attached a *Kurhaus* or casino. This building reaches the name of magnificence in Wiesbaden, where the decoration does not err on the side of quietness. In the *Kurhaus* there are one or two concert halls, reading and writing rooms, rooms for so-called "games of skill," and an excellent restaurant. The cost of musicians seems to be a serious worry to Kur directors. Tennis courts are provided; but the only golf course discovered was at Kissingen, though faint remains of a pre-war course were visible amongst the hills of Wildungen.

THE COST OF SPA TREATMENT.

Owing to the disappearance of much wealth during the period of inflation, the expenso of living in first-class hotels appears to differ very little from that in second- and third-class establishments. The average cost of living in Germany seems to be high; to live in first-class stylo is cheap. Thus it is possible to live in the best hotel at 12 to 15 marks a day. If a bathroom is attached to the bedroom the cost may rise to 20 or 25 marks. In a second-class hotel the charge is 1½ marks and in a third-class hotel 3 marks cheaper than in the first-class. Every visitor to the spa pays a *Kurtax* of 40 marks. This gives him free use of the springs and of the *Kurhaus*, including admission to the concerts. Where a theatre or opera house exists there is, of course, a charge for admission. The cost of the baths is from 3 to 5 marks; a peat bath costs 7 or 8 marks. The doctors' charges are not high; generally 15 marks, at the most 20 marks, for the first visit, and anything from 3 to 10 marks for subsequent attendances.

THE NEED FOR SCIENTIFIC INVESTIGATION.

There is no doubt that many spas are deficient in having no proper institution for the scientific investigation of the effects of the waters. This remark applies also to spas in England. The treatment is in most cases empirical; and from this cause arises much of the scepticism with which spa treatment is regarded. At Ems, however, there is an excellent laboratory under the charge of Dr. Diener. At Kissingen Professor Haertl, a chemist who has specialized in mineral water engineering, and has worked with Dr. Baudisch under the aegis of the Rockefeller Institute, is carrying on interesting investigations and displaying great ingenuity in invention. His interests, however, are mainly constructional. At Nauheim Professor Weber has a well equipped institution, and is carrying on good work. There are, however, too many places where no such institution exists; very often only the simplest clinical examinations can be carried out.

The statement is made that such and such waters and baths, and a particular diet, are found suitable in certain cases, but no one knows why. In one place the electro-cardiograph has been relegated to the cellars, no skilled operator being available. Without scientific institutions it is impossible to answer questions as to the effect of baths loaded with carbonic acid gas. In most of the spas visited the water was warm, and contained much free and partially combined gas. It was asserted that the expired air of a patient in a bath of these waters contained more

CO₂ than the normal. One professor declared that the increase was due to absorption by the skin. Another said that the bubbles of gas covering the body prevented excretion of CO₂ by the skin, and so increased the amount in the expired air. A third suggested increased metabolism in the tissues. It is clear that nothing but experimental investigation can settle this point, or clear up the further question whether a "bubbly" bath of carbonic acid gas has any therapeutic effect whatever. Similarly with the other constituents of the water. Does the presence of calcium chloride in addition to ordinary sodium chloride make any difference in the treatment of heart disease by baths? Or is the drinking of water of more importance than bathing? Or, on the other hand, was the statement made by a spa practitioner, that the temperature of a carbonated water is of greater effect than its saline content, correct? Furthermore, if it is true that natural CO₂ has a different effect from that artificially produced, the first lowering blood pressure, the second raising it, is the difference purely mechanical and dependent on the size of the bubbles deposited on the skin? An assertion of this kind needs experimental proof; at the same time it would be interesting to know whether CO₂ collected from the earth in cylinders is natural or becomes artificial. Where institutions for proper investigation exist, much interesting work can be done. Thus the depicting on chest walls of the contraction of dilated hearts by means of ausculto-percussion has now been exploded. It has been found that the areas of dullness, mapped out by various distinguished observers, not only differ from one another, but in every case are totally different from the result obtained by x-ray examination and the orthodiagram. It is clear that much experimental investigation is necessary; and the antiquity of the profession of the balneologist does not justify silence on the scientific aspects of his art.

THE INSURED PERSON AND THE SPA.

In Germany every person whose income does not exceed 5,000 marks a year must be insured. There are four categories of insurance: (1) Sickness, which is in the hands of the *Krankenkassen*, bodies which correspond to our approved societies. (2) Accident, similar to our workmen's compensation. (3) Partial disablement, death, and dependants (*Invaliden Versicherung*). (4) Black-coated insurance for clerks, and so on. In addition to this, people with more than 5,000 marks a year can become voluntary contributors; and this class in Germany is sufficiently numerous to perturb the medical profession. The voluntary contributor can get his treatment at insurance rates.

The *Krankenkassen* seem to share with the State the possession of such wealth as exists in Germany. Consequently, while paying to the doctor's societies the princely annual sum, apparently, of 11½ marks for attendance on a working man and all his dependants, they are able to embark on schemes for giving the insured person additional benefits in the shape of magnificent Heims or convalescent homes.

The *Invaliden Versicherung*, or third category of the insurance organization, takes charge of the insured person when his disability has extended beyond the twenty-six weeks for which the *Krankenkasse* is responsible. Moreover, this category is supposed to have preventive functions; and it is in this connexion that spa treatment is brought in, even during the time that the patient is receiving his benefit from the *Krankenkasse*. Large hotels have been bought up at spas, and are now run for the benefit of the insured person; so that Homburg, once the resort of kings and emperors, is said to be largely used for insurance treatment. The insurance authorities hold the view that control is even better than waters in the management of patients! Consequently the insured person is usually sent to a spa at which the authorities have an institution; though it is not disputed that waters have a specific action, so that where the indications are sufficiently clear the patient is sent to the appropriate spa, whether the insurance authorities have a home there or not. In many cases these homes have whole-time doctors, who are sometimes allowed to do consulting work outside the institution. In spas without an institution the *Invaliden Versicherung* has a list of spa doctors

from whom the patient may choose. The doctors are paid a lump sum, varying in different places from 20 to 50 marks for a six or seven weeks' "cure."

Apparently the German doctor does not mind accepting these cases; but he is perturbed about the voluntary contributor, who, as we have said, can obtain his spa treatment on the same terms as the compulsorily insured person. It appears that 80 per cent. of the German population now come under insurance, so that the scope for private practice is narrowing. And as the fee that can be taken from a member of the Krankenkassen at all events is fixed by the Government at 9d. for an attendance and 1s. 6d. for a visit, it would appear that the German doctor has to work hard for his living. It is interesting to note that the system of payment by attendance in Germany has resulted in protests by Krankenkassen and specialist that the patient's doctor keeps the patient under his care as long as possible, instead of sending him to a spa. On the other hand, a capitation system might possibly flood the spas with insured persons, notwithstanding the efforts of the insurance referees to stem the tide.

If the time should come when spa treatment will be considered necessary or advisable for insured persons in this country, and will be offered as an additional benefit by approved societies, it will be necessary for the British Medical Association to watch carefully the arrangements made. There can be little doubt that the panel doctor in this country is in a better position than the insurance doctor in Germany, and for this position he has to thank the Association. In Germany the doctors' societies, which came into being after—and as a result of—the establishment of the Krankenkassen as approved societies, have a difficult task in fighting these well established bodies. Presumably the introduction of spa treatment as an additional benefit in this country would have to be discussed with the approved societies; and it is from such direct dealing with the Krankenkassen that the troubles of the German doctor have arisen.

CONCLUSION.

In conclusion it may be said that spa treatment is organized in Germany on a much larger scale than in England, that it is most complete, and very well equipped. The treatment is no more expensive—possibly somewhat cheaper—than in this country, though the mark is now equal to the shilling. At the same time, there is no startling novelty to be observed; and though efforts are now being made to establish laboratories for scientific investigation under Government officials the treatment remains mainly empirical.

HERBERT JONES TESTIMONIAL.

THE presentation of the testimonial to Dr. Herbert Jones was made at his residence at Hereford by Dr. GERARD STEEL, President of the Herefordshire Medical Society, who was accompanied by Dr. John Steed, honorary treasurer to the society, and Dr. J. R. Bulman, honorary secretary to the Hereford Division of the British Medical Association. Dr. James Wheatley, medical officer of health for Shrewsbury, who was to have represented the Society of Medical Officers of Health, was unfortunately prevented from attending by sudden illness. The testimonial took the form of a Sheffield plate casket, which was suitably inscribed, contained a cheque for £250, and was accompanied by a list of the names of the subscribers.

Dr. Steel, in asking Dr. Herbert Jones to accept the casket, said that he must call him "a dear old friend," not on account of his age, but because of the number of years over which their friendship had lasted. He referred to the privilege and honour conferred upon him in that it fell to his lot to present the casket and its contents as a token of the esteem in which he (Dr. Herbert Jones) was held by the whole profession. He then read extracts from letters which had been received from subscribers to the testimonial, and continued: "You must feel great satisfaction in hearing these many expressions of gratitude for the good work you have done. They are a certain proof that the whole of your professional life is approved and

acknowledged by your confreres, who sincerely wish you the peace and comfort in your retirement which you so richly deserve. At the same time they hope that your help will always be available in cases of difficulty, when your ripe knowledge, experience, and judgement will be invaluable, as has ever been the case; for you have never failed your professional brethren by your tact and kindness to one and all."

Dr. HERBERT JONES said that he was unable to make a long speech, but he thanked everyone who had helped in the testimonial. The work had ever been a labour of love, and he never had any idea of any such reward as this. In glancing through the names on the list of subscribers he was much touched to notice the names, not only of many old friends, but of several men who were scarcely known to him.

After partaking of tea the deputation withdrew.

Final List of Subscribers.

£10 10s.—West of England Branch of the Society of Medical Officers of Health; Midland Branch of the Society of Medical Officers of Health (per Dr. Ridley Bailey).

£3 3s.—Sir William H. Willcox, K.C.I.E.

£2 2s. 6d.—Dr. Alexander Robb (Edinburgh).

£2 2s.—Drs. H. Hanslow Brind (West Byfleet), *Mabyn Read, *P. H. Stirk.

£1 1s.—*Dr. George Adkins, *Dr. F. J. Allan, Sir Robert Bolam (Newcastle-on-Tyne), *Dr. Joseph Coates, Dr. Howard Davies (Pontypridd), Dr. R. Green (Stroud), Dr. H. W. Harding (Edmonton), *Dr. A. Bostock Hill, Dr. T. E. Hinks (Hay), *Dr. J. Johnstone Jervis, Dr. C. Courtenay Lord (Orpington), Dr. Edward H. Nash (Cranford), *Dr. H. Cooper Patten, *Dr. W. G. Savage, *Dr. C. E. Tangye, Dr. T. M. Tibbets (Old Hill, Staffs), Dr. W. W. Wells (Bromyard), *Dr. James Wheatley (Shrewsbury), and Dr. J. Arthur Wood (Rugby).

10s. 6d.—Dr. H. Dundas McCall (Leominster).

THE PREVENTION OF HEART DISEASE.

Discussion by the Society of Medical Officers of Health.

A DISCUSSION on the prevention of heart disease was held in Glasgow a few months ago at a meeting arranged by the Society of Medical Officers of Health, and a full report has now been published.¹ It was remarkable in part for the constructive proposal referred by the meeting to the council of the society, and in part for the rather merciless light cast on the existing situation. Dr. A. K. Chalmers, until recently medical officer of health for Glasgow, who opened the discussion, dealt with the administrative aspect of the problem, and indicated some of the many questions which must be solved before preventive measures can be put on a sound basis. He felt sure that if local authorities in Scotland possessed the power of providing hospitals for rheumatic diseases it would not remain for long inoperative. Dr. George A. Allan, who followed, put the physician's point of view. He began by saying that he had been given to understand that by "heart disease" rheumatic heart disease was intended; consequently he restricted himself to the field thus defined. He touched on the etiology of rheumatism so far as understood, laying stress on the danger to the heart of the subacute form, its usual manifestation in childhood. This form, which may be attended merely by slight joint pains, with or without fever, occurring at an age when the heart is specially vulnerable, is liable, he said, in the absence of appropriate care, to cause grave or permanent cardiac damage. Dr. Allan urged the value of prompt treatment, prolonged rest, and after-care for these early conditions, the possible forerunners of heart disease, and commended the issue of instructions to parents, teachers, and the medical profession itself regarding the signs of danger. He believed that effective co-operation between clinicians and administrative medical officers would lead to a prompt decline in the prevalence of rheumatic heart disease. Dr. Allan's

¹ *Public Health*, April, 1926, pp. 203-224.

observations conveyed an impression of clearness. It is no disparagement of the other principal speakers to say that he seemed to surpass them in this particular: and it is no disparagement of Dr. Allan that his outstanding lucidity was due in some measure to the fact that he had taken the precaution to limit his discourse to one type of heart disease. He could name the cause of this type, and could describe its precursors. He was therefore in a position to advance suggestions for its prevention which stood in pertinent relation to the conditions they were designed to combat. The other speakers, taking a wider survey, addressed themselves, not to a single form of cardiac lesion, but to the problem of heart disease as a whole. They furnished statistics and quoted experiences of great general interest, but none of their points, though excellent otherwise, bore very closely on either causation or remedy, for the expression "heart disease" includes forms of illness whose origins are still uncertain, and there can be no apt remedy under such conditions. This aspect of the question appears to have been in the minds of at least two subsequent speakers. Sir Leslie Mackenzie, dealing with the statistical side, said, "I have never found the statistical material at this stage anything more than an indication that something should be done"; and Dr. J. J. Buehan, touching on the clinical side, said it was for the clinician to describe accurately what exactly was the heart disease which caused the 50,000 or 60,000 deaths which annually occurred.

During the discussion a proposal was advanced, along the line already suggested by Dr. Chalmers, that local authorities should provide special beds for heart disease. Dr. Chalmers, in replying to the discussion, so far accepted the suggestion as to appear to approve the establishment of rest hospitals for children suffering from conditions which might be called "pre-rheumatic" but did not come within the definition of rheumatic fever. The proposal that local authorities should provide special hospitals was referred to the council of the society for consideration.

TREATMENT OF TUBERCULOUS EX-SERVICE MEN.

A conference was held at Edinburgh on May 31st, under the auspices of the Tuberculosis Committee of the British Legion (Scotland), to discuss the formation of a village colony for the after-care of tuberculous ex-service men in Scotland. Lord Glentanar, chairman of the British Legion in Scotland, presided, and among those present were Field-Marshal Earl Haig, K.T., and Countess Haig. Earl Haig, in recalling the resolution passed at a previous conference for assisting tuberculous ex-service men in Scotland, said that there were still 4,500 of these, and he was grateful for what was already being done on their behalf. He paid a compliment to the work of the British Legion, which, he said, was a society described as one of the greatest organizations for doing good by aiming in a non-political and non-sectarian fashion at perpetuating in civil life those principles of liberty and justice for which the nation fought during the war. Its ideals were loyalty, good fellowship, and service, and hence in the recent industrial crisis the members of the British Legion had been on the side of law and order, and their attitude had exercised a powerful effect on the spirit of the nation. The adequate medical treatment of ex-service men was one of the most important aims of the Legion. There had been 75,000 men who, at the time of their discharge, were suffering from tuberculosis. Of these, 20,000 were now dead. The remainder asked for sanatorium treatment, combined with industrial training, and, finally, life in suitable cottages and suitable factories. A Legion settlement and training colony had been established at Preston Hall in Kent, and he hoped that a scheme might be evolved on similar lines for tuberculous ex-service men in Scotland, of whom 1,849 were not receiving treatment of any kind. An institution was needed in Scotland where a tuberculous man could receive after-care, and where he could live in healthy conditions while working at some trade or occupation which would enable him to avoid the detrimental effects of enforced idleness. The committee realized that for any hope of success sufficient capital and a full measure of support from the medical profession must be secured. It hoped for

financial assistance from Government and local authorities, and proposed to acquire a mansion house with suitable grounds to be used as an administrative building, around which would be placed open-air huts or shelters, hostels, dining and recreation halls, and other accommodation required by tuberculous patients. Sir Robert Philip said that Great Britain was very well forward in the treatment of tuberculosis, the country being provided with a complete service of preventive, curative, and relief agencies such as did not exist anywhere else. Sir George Beatson said that three factors materially helped the defensive power of the body against the advance of tuberculosis—fresh air with sunshine, good food, and rest with suitable exercise. These could only be got in a sanatorium, and he was strongly in favour of having in Scotland such an institution for tuberculous ex-service men. Some of the mansion houses which had been used by the Red Cross during the war, and on which money had been spent to make them suitable for hospitals, would be ideal for this purpose. Sir Leslie Mackenzie, of the Scottish Board of Health, said that if 1,800 men were without treatment the fault lay with themselves and their friends. There was nothing to prevent any man who needed treatment from getting it. While he could not commit the Scottish Board of Health, he was quite sure that the Secretary for Scotland, who had every sympathy for the ex-service man, would be desirous of doing whatever was practicable in the most complete way open to him. Dr. MacGregor, M.O.H. Glasgow, expressed the opinion that a number of patients in sanatoriums were not suffering from tuberculosis, and emphasized the importance of proper diagnosis before admission. It was quite easy to run a colony with non-tuberculous persons, and he was afraid that in a number of cases that had been done. In Glasgow it had been found that ex-service men who had been diagnosed as tuberculous were now roughly divisible into two classes—those whose disease was practically arrested and who were able to continue in their ordinary occupations, and those whose disease was in a quiescent condition but who were also suffering from chronic bronchitis. He had been very much struck by the fact that ex-service men of the best type were often very well cared for by their employers. The proceedings terminated with a vote of thanks to Lord and Lady Haig for their attendance, and to Lord Glentanar for presiding.

SCOTTISH VITAL STATISTICS.

During the first quarter of 1926 the births registered in Scotland were 26,171 and the deaths 17,928, equivalent to rates of 21.6 and 14.8 a thousand respectively. The birth rates for the corresponding quarter were—in England and Wales 18.2 and in Northern Ireland 22.1. The death rates were—in England and Wales 13.6 and in Northern Ireland 16.6. The Scottish birth rate is the lowest on record for the first quarter of the year, four years excepted. In civil counties it ranged from 24.9 a thousand in Lanark to 11.1 in Argyll. In the larger burghs the highest rate, 27.2, was in Hamilton, and the lowest, 17.6, in Dunfermline. The Scottish death rate is 2.4 below the mean of the first quarters of the preceding five years. Only once before since the institution of national registration has the death rate of the first quarter fallen below 15. In civil counties the range extended from 19.1 in Selkirk to 11.3 in West Lothian. Among larger burghs the highest was Glasgow, with 18 a thousand, and the lowest, the joint burgh of Motherwell and Wishaw, with 11.2. There were in all 9 deaths from enteric fever, 41 from encephalitis lethargica, and 25 from cerebro-spinal meningitis. Deaths of children of less than 1 year of age numbered 2,520. The infantile mortality rate was 96 a thousand births. This rate is lower by 24 than the mean of the first quarters of the preceding five years. In England and Wales the infantile mortality rate of the first quarter was 85, and in Northern Ireland 95. Among the larger Scottish burghs the infantile mortality rate varied from 124 in Glasgow to 37 in Falkirk.

SIR WILLIAM MACEWEN MEMORIAL.

A Sir William Macewen Memorial Oration will be given in the Bute Hall of the University of Glasgow on Wednesday, June 23rd, at 11.30 a.m., by Professor Archibald

Young, Sir William Macewen's successor in the Regius chair of surgery, on "Sir William Macewen." During the ceremony busts of Sir William Macewen will be presented to the University and to Lady Macewen.

GIBSON MEMORIAL LECTURE.

The George Alexander Gibson Memorial Lecture will be delivered before the Royal College of Physicians of Edinburgh on Wednesday and Thursday, June 23rd and 24th, by Dr. John Cowan, physician to the Royal Infirmary, Glasgow, who has chosen for his subject "The failing heart." He will discuss the mortality bills of heart disease, the effects of disease of the coronary arteries, of chronic valvular disease, and of acute endocarditis, the causes of death in these diseases, and the recognition of the failing heart.

Ireland.

THE LOCAL AUTHORITIES BILL (IRISH FREE STATE).

In the debate in the Dail on the Local Authorities Bill (Irish Free State) Sir James Craig, M.D., expressed the hope that it would be passed. It was one of the most important measures the Government had brought forward, and it would be most disastrous if it were delayed at that stage. He felt sure the Minister would agree to Deputy Johnson's suggestion, that the two or three best men should be placed on a panel and recommended to the local authorities for election. Dr. Hennessy also urged the necessity for the bill. The Free State was a food producing country, and, unfortunately, it had an unsavoury reputation in their chief market, where it was said they had no county officers of health to look after the food supplies. He did not agree as to the selection of a panel. It had not been received with favour from the medical profession. The bill should provide for the election of the best man. They did not want any camouflage. Ceann Comhairle (Speaker) said it was worth while experimenting to see whether the bill could be amended in committee without any lengthened debate. It might be arranged that the committee stage should be fixed for a fortnight ahead and provide that amendments should be handed in by a certain date. The movers of amendments and the Minister could then have time to come to agreement.

MEDICAL BENEFITS IN NORTHERN IRELAND.

In the Northern House of Commons recently a vote of £90,000 for national health insurance was moved, in committee of supply, by the Parliamentary Secretary to the Ministry of Labour. Mr. Kyle moved a reduction of the vote by £100 to call attention to the neglect of the Ministry of Labour in not bringing in some scheme of medical benefits for insured persons in Northern Ireland. Mr. Devlin said it was a great mistake that they did not have medical benefits under the national health insurance scheme in Northern Ireland from the very start. Professor Johnstone, F.R.C.S., said he was opposed to medical or any form of benefits on the same lines unless the people concerned were prepared to pay for them. He believed if a thing was worth having it was worth paying for, and he was sure that they could have medical benefits here at any time when the workers and employers were prepared to pay for them as they paid for them in Great Britain. The Minister of Labour said he had kept an open mind on this question. A commission had recently reported on a continuance of medical benefits in Great Britain, and he, the Minister, had felt that he would not be justified in asking that House to proceed to legislate on the matter until he had had the advantage of knowing what the views of that commission appointed by the Imperial Government were. The matter was somewhat complicated by the fact that a Home Office inquiry was going on in regard to many matters affecting local administration. Among the matters which were being investigated by that commission was the question of the application or otherwise of medical benefits to Northern Ireland. The wide dispensary system, already in existence, was a great advantage to the poor people, and the suggestion

Young, Sir William Macewen's successor in the Regius the medical benefits introduced as well. That, however, would not be keeping in step with Great Britain, and there would also be the difficulty in finding the money for both systems; in Great Britain there was only one system. The times were difficult, and he had hesitated to ask workers and employers to bear an additional burden, though not a heavy one. However, his mind was open, and when he was convinced that it would be to the advantage of the workers of Northern Ireland that medical benefits should be extended to it, and when he was satisfied that the workers desired them, he would not hesitate to ask his colleagues to approve the introduction of a bill to give effect to that view. On a division the amendment was defeated by 18 votes to 4, and the vote was passed.

England and Wales.

HONOUR TO A METROPOLITAN MEDICAL MAYOR.

It is a common reproach to the twenty-seven boroughs of London that their local patriotism is small, but, to judge from a complimentary dinner to the Mayor of St. Pancras, Alderman Dr. E. A. Gregg, at the Holborn Restaurant on June 3rd, this does not apply to that borough. The dinner was also in a sense to be regarded—although it had a much wider character—as the first annual dinner of the St. Pancras Division of the British Medical Association, the members of which attended in large numbers. Altogether 300 of his municipal and professional colleagues, many of them accompanied by ladies, were present. On the municipal side every public activity in St. Pancras appeared to be represented, including, of course, the borough council and the board of guardians, and various social and philanthropic institutions. The six members for St. Pancras on the London County Council, and the three members of Parliament for the borough (one of whom, Sir Richard Barnett, presided), were all present. The chairman, in proposing the health of the guest, said that they had come together to honour one of the greatest of St. Pancras citizens. Dr. Gregg was an Ulsterman, and represented the best qualities of Ulster—modesty, tenacity of purpose, and fighting spirit. Dr. Gregg, while still a young man, had attained the highest honour that St. Pancras could give him, and it could not be doubted that further honours awaited him in wider fields. Dr. Geoffrey Evans, chairman of the St. Pancras Division, who also spoke to the toast, referred to Dr. Gregg's assiduity on numerous committees. His public work had been of a diverse character, but all of it was informed with a desire to render social service to the community. He was well known as a lecturer on nursing, hygiene, infant welfare, and ambulance, and in these and other ways he was an interpreter of medicine to the larger public. Dr. Evans saw in Dr. Gregg the promoter of new developments in medicine whereby some of the hospitals in St. Pancras would become centres for post-graduate instruction, and centres also for consultation and investigation, so that the work of the general practitioner would be furthered. The toast was received with great enthusiasm, and Dr. Gregg, in his response, expressed himself as being made both proud and humble by the number of friends whom that gathering had called together. Their names were to him a kind of epitome of sixteen or seventeen years' work in St. Pancras. He went on to mention by name several of those present, including Dr. G. C. Anderson, Deputy Medical Secretary of the British Medical Association, his first home and gathering place in his professional life; Dr. Cardale, chairman of the London Panel Committee, who had had a good deal to do with giving him an interest in and incentive towards public work; and Sir Thomas Noell of the London Insurance Committee, a redoubtable opponent with whom he had had many a contest. Public life had many disappointments, criticisms, and misunderstandings, but an evening such as that went a long way towards recompense. Lord Riddell, proposing a toast to the borough of St. Pancras, mentioned incidentally that it had more hospitals within its boundaries than any other borough in London.

Several aldermen and councillors joined in the eulogies of their borough and their mayor, and the proceedings ended with a dance.

THE STANNINGTON SANATORIUM EXTENSIONS.

On May 28th the Duke of York visited the Stannington Children's Sanatorium, near Newcastle-on-Tyne, to open the Joseph Brough wing, the new nurses' home, the building for the treatment of tuberculosis by artificial sunlight, and the farm colony buildings. This sanatorium was the first British sanatorium for tuberculous children, and the extensions, which were urgently needed, have entailed an expenditure of £26,000, of which £16,000 has so far been raised. The sanatorium was opened in 1907 by the late Duke of Northumberland; it provided accommodation for forty patients. A second wing was later erected by the late Sir William H. Stevenson and his daughters, and in 1920 three large new wards and school premises were added, bringing the accommodation up to 250 beds. The waiting list is, however, very long, and the present extensions are, therefore, of great value. The new wing, presented by Mr. J. W. Brough at a cost of £6,000, will increase the number of beds to 312. Treatment by artificial sunlight has been given in the sanatorium for the last six years, and the new building now opened will enable it to be employed more effectively in a larger number of cases. The new model dairy farm will supply all the milk required by the patients. The Duke of York referred warmly to the value of the work carried on by the sanatorium, the boys' farm colony, and the open-air school, and called attention to the need for a seaside branch of the institution.

Correspondence.

AMBULATORY TREATMENT WITH TUBERCULIN.

SIR,—Your editorial commentary (p. 953) on Dr. Camae Wilkinson's letter on the tuberculin dispensary in the *JOURNAL* of June 5th is welcome evidence of a movement to raise the specific treatment of tuberculosis out of the apathetic condition into which it has fallen in this country. In Germany, as the recently published third edition of Dr. Klemperer's book on pulmonary tuberculosis shows, critical curiosity is very much alive on the subject, but in England the situation still seems to be dominated by the damaging and now long antiquated Brompton Hospital report of 1898, and the most that is conceded to tuberculin therapy is a grudging and illogical admission that in certain cases, "where ordinary methods fail and which seem to stick half-way," tuberculin, in selected cases and in special circumstances, may in some mysterious way be responsible for "getting a move on"; but, so it is stated, "so indefinite are the results that it is generally conceded that it is a waste of time and expense for patient and physician to use it as a routine procedure." As for tuberculin diagnosis by its most effective method—namely, subcutaneous injection—it is concluded that "when reliable, the use of these tests is fraught with grave danger, and that when not fraught with grave danger they are unreliable." Such is the current position.

One therefore welcomes Dr. Wilkinson's experienced support and ardent reiteration of Koch's matured claims on behalf of tuberculin in both directions of diagnosis and treatment.

There is, however, something to be said in opposition to the proposed ambulatory treatment at the tuberculin dispensary. Certainly it cannot be sound clinical practice, however interesting as a comparative experiment, to submit open cases of pulmonary tuberculosis among the wage-earners in large cities to a process of intensive active immunization, and that in the face of coexisting disease, while such patients are actually in continuation of their more or less arduous daily work. This is asking too much from the human system. Nor is there any justification for so doing. With all the public money which is now being spent on tuberculosis, not to mention the funds available under the National Health Insurance Act, all cases undergoing this treatment should be placed for a few months at

least in enjoyment of such conditions of rest, food, and housing as should give to each patient fair conditions for treatment. I am aware that ambulatory treatment can be carried out while the patient continues at work, and I have personal experience of the possibility of so doing, but I regard it as an unfair disadvantage. It must be remembered that intensive tuberculin treatment is a method of active immunization, and active immunization carried out in the teeth of a virulent and insidious enemy. It exploits the vital properties of the body, and of the body more or less devitalized by disease. It is an active poison which benefits only by consequent recovery from the poisonous action. Tuberculin therapy of an intensive character in accordance with Koch's matured directions, and illuminated by the experience of subsequent workers, may certainly be carried out elsewhere than in sanatoriums; but it is best carried out under, as much as possible, sanatorium conditions. Given sufficient corroboration of Koch's original claims, which corroboration, with its developments, should be the objective of all who desire to advance the cause of humanity in this direction, there should be no difficulty, between the resources of existing tuberculosis schemes and National Health Insurance funds, in the way of securing the most suitable conditions with complete relief from daily toil for at least a few months.

I am not writing in opposition to the method of intensive tuberculin treatment or specific diagnosis: far from it—these methods have my personal adherence; but they should be supported up to the hilt by every other possible useful adjunct, especially during the acquisition of the initial immunity to tuberculin.—I am, etc.,

ROBERT CARSWELL, M.A., M.B., Ch.B.

Wandsworth, June 7th.

THE PROPHYLACTIC VALUE OF SCARLET FEVER ANTITOXIN.

SIR,—In the *JOURNAL* of May 22nd a paper appears under the above title, in which the authors, Drs. Harries, Hervey, and Fellows, draw a conclusion from defective premisses that the practitioner can now exercise a "prompt control of an outbreak of scarlet fever" by the use of the Dick test and antitoxin injections. They report that a definite case of scarlet fever arose in a diphtheria ward. This is not an uncommon experience, but it is uncommon in such an event for the disease to extend to any considerable number of contacts, or otherwise to show urgent need for control by an extraordinary method. A search being made for any causing case amongst the other patients in the ward, one was discovered in a diphtheria case that was also peeling on the hands, and with the history of a rash on back and legs suffered some twenty-seven days previously, she having been in the diphtheria ward six days for her later complaint.

There were sixteen contacts in the ward, of which fourteen were Dick-positive. It is assumed, without any corroborative control evidence, as by the exposure of as many other equally susceptible persons to the same infection without antitoxin treatment, that cases of scarlet fever must have occurred amongst those fourteen but for their being injected with antitoxin. There is no warrant for any such assumption. The proposition requires the expectation that every "outbreak of scarlet fever," in which the case is permitted contact with a considerable number of other people, will result in an extension of the disease. After an experience of thirty-five years as medical officer of health, I can give an emphatic contradiction to this supposition. It is a common experience, with quite free home contact, for the disease to be limited to one sole individual, and desquamating cases are not infrequently discovered in children attending a school without any obvious result of their contact with their fellow scholars, although this may have been continued for several weeks. In such circumstances possibly another case or two may arise, and that is about the limit and end of the matter as a rule. Epidemics from such a source may be imagined, but have very rarely come to pass.

The limits of liability of extension from most cases of scarlet fever are so marked as to cause a number of us more experienced medical officers of health to be now questioning the value of hospital isolation for this disease, and our

evidence on this score is in the hands of the Ministry of Health, which sent out a questionnaire upon the subject about a year ago.

The degree of infectiveness of the particular case that is in a position to spread scarlet fever is so germane to any such experiments as those I am criticizing, that for it to be ignored is sufficient of itself to vitiate the results whatever they may be. The seriously infective scarlet fever case is an occasional case, or an occasional condition occurring in a case. What this condition is has not been plainly shown. A particular strain of micro-organism may be surmised. According to the matter reported, fourteen persons were due to get scarlet fever as evidenced by the Dick test. It is a pity the authors did not divide them into two sevens, operating on the one seven and reserving the other seven for control. Then, that either of the seven untouched would have developed scarlet fever is improbable. They had all fourteen been exposed for six days to such infection as there was, before the experiments began.

In fact, expectancy of further cases as evidenced by a positive Dick test, and expectancy of further cases according to the experience of a medical officer of health; are at wide variance, and until they have been brought more into coincidence, experience being more valuable than theory, I suggest that to attempt a "prompt control of an outbreak of scarlet fever" by the use of the Dick test, and antitoxin injections, is inadmissible, both logic and best regard for the welfare of the children requiring it to be eschewed.—I am, etc.,

J. H. GARRETT, M.D., D.P.H.,
Medical Officer of Health, Cheltenham.

May 24th.

THE SPAHLINGER TREATMENT.

SIR,—I have not impugned the good faith of the Science Committee, but I have criticized the tone of the original article (May 1st, p. 805) and the attitude of mind displayed by the committee. If the committee thinks it its duty to discredit the treatment, it is completely within its rights in so doing: no charge of "bad faith" can be made against it, although its wisdom may be questioned with equal legitimacy.

I submit that nobody could read that article without forming the opinion that the committee is hostile. The committee is as responsible for the general tone of a communication as it is for the facts contained in it.

Dr. Hawthorne (May 8th and 15th, p. 846) has invited our co-operation, and I have previously stated some facts concerning the proposed financial position as they were given to us. I am sure the Salford Committee will be only too pleased to co-operate with any body that is disinterestedly trying to bring this matter to a head—that is to say, to procure an investigation in this country.

We have already discovered some obstructions which have been created by various parties concerned in this matter. We have already in our possession a number of scraps of information—most of them confidential—which throw an interesting light upon some aspects of the business and which lead us to believe that the obstructions in this many-sided problem are not all coming from the same direction.—I am, etc.,

C. E. JENKINS,
Honorary Secretary, Salford Division.

Manchester, June 2nd.

THE DEFINITION OF BLINDNESS.

SIR,—If Dr. Tivy will do me the favour of reading my article again, and then his own letter, I think he will perceive that article and letter deal with different subjects. In my article I am concerned with one point only—the definition of blindness. In his letter he deals with local administrative arrangements, and he shows by examples how bad these can be when the determination of the state of blindness is left in the hands of lay persons, whether pension officers or others. Ophthalmic surgeons have never wavered from the belief that certification should only be made by qualified practitioners, and that their services in this regard would be a saving to the State.

Dr. Tivy raises another point—the remuneration for adequate certification. I judge from his statement he is giving certificates of blindness gratis. That is his own fault. Note has been made in the JOURNAL more than once that the Ministry has made arrangements for obtaining the opinion of an ophthalmic surgeon when it so desires, and for paying a proper fee. But these local matters have nothing to do with the discussion of what constitutes "blindness."—I am, etc.,

London, W.1, June 5th.

N. BISHOP HARMAN.

ANGINA PECTORIS.

SIR,—Your notice of Mr. Fowler's *Dictionary of Modern English Usage* (BRITISH MEDICAL JOURNAL, May 22nd, p. 877) revives a controversy that was eagerly debated in my undergraduate days. I mean the quantity of the second syllable of the word "angina."

I have not yet had an opportunity of reading the book, but you quote Mr. Fowler as writing: "Since the ailment that he [the scholar] long insisted on our calling *angina pectoris* was discovered to be *angina* after all, his pleadings are suspect."

I should think that all of us who are old enough to have been spanked at school for making a false quantity will wonder at Mr. Fowler's marking of the first syllable of the word as short. Most of us will remember that a vowel preceding two consonants (other than a mute and a liquid) must be long according to the rules of Latin prosody.

But the question of interest is the metrical value of the "i" in the second syllable of "angina." When I was a student in Dublin this question was raised, and it became the fashion to pronounce the word "angina." I searched the classical scriptures, and could only find the word in the work of one Latin poet, and that a mere Silver Latin author. Unfortunately I kept no record of the name of the author, and I admit that his line was a thoroughly bad hexameter. It was as follows: "Hanstum angian tibi mistum sale poscit acetum."

This was accepted among the staff of my hospital as settling the question in favour of the old-fashioned pronunciation "angina." I am now unfortunately too much out of touch with the minor poets of later Rome to verify the quotation, but perhaps some of your more scholarly readers will identify the line, or tell us what authority Mr. Fowler has for saying that the word should be pronounced *angina*.

Horace was fond of medical terms, and mentions the "polypos" in the nose of one of his ladies. In one of his Epistles also occurs the phrase, "Nisi cum pituita molesta est." If the word "angina" had really been a dactyl he could hardly have resisted ending one of his "Archilochians" with "angina pectoris." But he never did.—I am, etc.,

Sheffield, June 3rd.

FRED. E. WYNNE.

* * In Bailey's edition for English readers of the Facciolati-Forcellini Latin Lexicon the "i" is shown long, but the illustrative quotations do not include a line of verse. We have therefore appealed unto Mr. E. E. Sikes, President and classical lecturer, St. John's College, Cambridge, who has kindly sent us the following reply, at once authoritative and light in touch:

"Scholars have often for the last hundred (or perhaps thousand) years pointed out that the *i* in *angina* is short. This is settled by Plautus, *Trinummus*, II, iv, 139:

"Sues moriuntur angina (hic) accerrime"

"and by the end of a hexameter in Lucilius *ap. Non.* 35, 10—

"..... Una angina sustulit hora."

"Personally I have not any views, being accustomed to many scientific words which, as a living wit once remarked, 'are compounded of two languages and one false quantity,' and *angina* errs only in the latter defect. But there may still be purists in country rectories who would deplore the popular diagnosis on more grounds than one."

Obituary.

LIEUT.-GENERAL SIR WILLIAM LEISHMAN, Kt.,
K.C.B., K.C.M.G., M.B., F.R.C.P., F.R.S., LL.D., K.H.P.,
Director-General, Army Medical Service.

By the untimely death of Sir William Leishman, which occurred, after a short illness, on June 2nd in Queen Alexandra's Military Hospital, Millbank, the whole scientific world has been deprived of one of its most brilliant workers, and the army of one of its greatest benefactors. Born on November 6th, 1865, in Glasgow, William Boog Leishman was educated at Westminster School and at Glasgow University, of which his father was the distinguished professor of midwifery. He graduated in medicine and surgery there in 1886, and in the following year entered the army as surgeon. Until 1890 his service was at home stations. He then went to India, where he served until 1897, with the exception of a year at home on sick leave in 1892-93, and took part in the Waziristan expedition of 1894-95, receiving the medal and clasp. Promoted to the rank of major, R.A.M.C., in 1899, he was appointed in the same year assistant professor of pathology in the Army Medical School, Netley. Almoth Wright was at that time the professor of pathology, and Leishman succeeded him in 1903 on the transfer of the school to London. It was during the association with Wright that his work on anti-enteric vaccines commenced. The years of his professorship, which he held till 1913, were memorable for the brilliant advances made in elaborating and perfecting the means of preventing enteric fever by prophylactic inoculations. Leishman's method became world-renowned and was copied in other countries, notably and with great success by the United States of America. The value of this work can be realized when we compare the relative incidence of enteric fever in the South African war and in the great war. But for the prophylactic measures so widely applied in the latter it has been estimated that the cases of enteric fever would have reached the enormous total in all theatres of war of some 551,000, with over 77,000 deaths, had the troops been affected in the same ratio as in South Africa; the actual incidence was only 20,139 cases during the years 1914-18 in all theatres, with 1,191 deaths, or about one-seventh of the total deaths, 8,022, from this group of diseases in the war in South Africa. This is a measure of the debt of gratitude the country owes him.

On the termination of his professorial appointment his researches into the etiology and prevention of disease did not cease, for he was appointed the expert in tropical diseases on the Army Medical Advisory Board in succession to Lieut.-Colonel C. Birt, and had ample scope for continuing his research work in the laboratories of the Royal Army Medical College. He retained his membership of the board during the great war, although most of his time was spent in an advisory

capacity in France, for, when there was much anxiety on account of the unexpected prevalence of tetanus, gas gangrene, and the graver forms of sepsis among the wounded, he was sent to the Expeditionary Force early in October 1914, with the designation, a few months later, of adviser in pathology. He remained in France until April, 1918, when he was recalled for duty at the War Office, and, on the reorganization of its Army Medical Department and the creation of the two new directorates of hygiene and pathology in June, 1919, was appointed director of pathology, a post which he held until selected to succeed Sir John Goodwin as Director-General on July 29th, 1923.

During his career in the army Leishman's brilliant scientific attainments were widely recognized. In 1905 he obtained a brevet lieutenant-colonelcy on account of the

distinction gained by him in Oriental investigations and research, and in 1909 he received the honour of knighthood. In 1910 he was elected a Fellow of the Royal Society. After promotion by seniority to lieutenant-colonel's rank in December, 1911, he was gazetted in October, 1912, to a brevet colonelcy, and became colonel in the long list of promotions to that rank in March, 1915. In October, 1918, he was gazetted major-general, and, on his appointment as Director-General, lieutenant-general. In 1912 he became an honorary physician to the King, and in 1914 a Fellow of the Royal College of Physicians. He was also M.R.C.P.Ed. and F.R.F.P.S.Glas. Glasgow University and McGill University conferred on him the honorary degree of LL.D. For his services during the great war he was thrice mentioned in dispatches, was created C.B. and Commander of the Legion of Honour in 1915, K.C.M.G. in 1918, and received from the United States of America the Distinguished Service Medal. After he became Director-General he was created a K.C.B., and was promoted to the grade of Knight of Grace of the Legion of Honour. He was also a Knight of Grace of the Order of St. John of Jerusalem. An honour which he greatly prized was his election to the Athenaeum at the end of last year on account of his eminence in science and his public services.

In 1902 Sir William Leishman married the elder daughter of the late Lieut.-Colonel E. Gunter, of the 59th Regiment, who survives him with one son, now studying medicine at Oxford University, and three daughters.

Leishman's activities in the domain of scientific research were not limited to his work in the army, although he was never seconded for duties outside the R.A.M.C. at any period of his career. He was an examiner in pathology for Oxford and in tropical medicine for Cambridge University. In 1910 he was Harben lecturer and in 1925 Liacre lecturer, Cambridge. Many scientific committees, including the Medical Research Council, claimed his services. Among others he was chairman of the Foot-and-Mouth Disease Research Committee of the Ministry of Agriculture, was this year elected president of the Section of Comparative Medicine of the Royal Society of Medicine, and was to

SIR WILLIAM LEISHMAN, K.C.B., M.B., F.R.S.

have presided next month at the sessions of the Section of Pathology and Bacteriology at the British Medical Association's meeting in Nottingham. He contributed widely to scientific literature, his best known work being on the parasites of kala-azar and Oriental sore to which the name of leishmaniasis has been attached.

Until he became Director-General Sir William Leishman had held no administrative appointment or command in the R.A.M.C., and some fears were expressed lest this lack of administrative experience and the many years devoted to pathological and bacteriological research would unfit him for the duties of Director-General; but these fears were soon dispelled by the marvellous grasp he at once took of the responsibilities of his office and the broad views he brought to bear on the problems with which he was faced. If there was any proved advance in medicine he strove to place it at the disposal of the army at large; and he always took a human view of whatever affected the welfare of the soldier. No problem of administration, however difficult, was shirked by him, and as a member of the committee appointed by the Cabinet, under the chairmanship of Sir Warren Fisher, to consider the shortage of medical officers in the Services, he devoted hours of anxious thought and endeavour to present a just and true estimate of the situation in the R.A.M.C., and of the eogeneity of removing the causes which were preventing candidates from coming forward.

His quiet manner, calm intelligence, and sound judgement created a feeling of confidence amongst the members of his staff, and encouraged them to take broad views of the problems with which they had to deal. To all these qualities his success as an administrator must be attributed. They added to the lustre of the renown already achieved by him in the domain of science, and his loss will be felt deeply by all ranks of the Royal Army Medical Corps, whose interests he had so much at heart, by his many friends in the army, and by his fellow workers throughout the world. He was not only a great scientist, but also a great administrator.

In response to our request we have received from Professor ROBERT MUIR, F.R.S., the distinguished occupant of the chair of pathology in the University of Glasgow, the following:

I readily respond to the request of the Editor to add something of a personal nature to the account which has been given of Sir William Leishman, though I fear that what I have to say is of an incomplete and fragmentary character. I first came to know Leishman some twenty-five years ago, and since then our friendship has been one of growing intimacy. It began shortly after his powers as a scientific worker were becoming evident—his research work, it is noteworthy, started at a later period of life than is usual. In the years following, his results of investigation were obtained in rapid succession, and he quickly earned a world-wide reputation. But it is not my purpose to review his scientific work. It is of permanent value, suitably commemorated by the word "Leishmania"; and his powers in training and in administration, revealed especially during the war, would likewise be sufficient to ensure for him a lasting place in medical history. His achievements in these two departments are so outstanding that some others are apt to be overshadowed.

I should like to refer to his work as a teacher. For a year or two just before the beginning of the war I acted as examiner of his students at the Royal Army Medical College. The standard reached, especially in the examination for promotion to the rank of major, was remarkable, and almost uniformly so—I may say that I have scarcely seen it equalled in any other examination. And this was the outcome, not only of Leishman's ability and powers of inspiration, but also of his painstaking effort, attention to details, and interest in his students. One does not care for the word "conscientious," but in its best significance it applies to Leishman in every capacity. I think that hardly too much emphasis can be laid on the fact that it was largely due to his quiet and untiring work in teaching and training that the Royal Army Medical Corps was so fully prepared to deal with the problems of disease which met it at once on the outbreak of the war.

Those who have attained are sometimes content to rest on their oars, and render service by the magic of their names. To such an attitude nothing could be more dissimilar than Leishman's. His ideal of work demanded much, and he never spared himself in response. Recently we have been members together on research committees in connexion with cancer and with foot-and-mouth disease, and I have constantly marked his devotion to the elucidation of what was in hand. This devotion has been recognized by all his colleagues. Youthful in outlook; impatient of the non-progressive, suggestive in proposals, and full of unselfish interest, he has freely given all in his power, and his death means an irreparable loss.

A man such as Leishman could not fail to win the affection and stir the enthusiasm of younger men who worked with and learned from him; he had indeed a rich reward in the devotion which he inspired and in the service returned. His interest in them and in what they were doing was great, and there was no more appreciative listener at meetings of societies. He possessed in no small degree a literary taste and the power of expression; he was an excellent speaker, forcible in argument and graceful in phrase. It is not unworthy of mention that, with the receipt of over-increasing recognition and honours, Leishman remained unchanged, and showed in no way that he was sensible of what he had accomplished. His was a charming personality, modest, kindly, courteous, wise in counsel. He was the same when I last saw him as when first we met.

Dr. ANDREW BALFOUR, C.B., Director of the London School of Hygiene and Tropical Medicine, writes:

The scientific work of Sir William Leishman, whose untimely death is so greatly deplored, was marked by care, caution, accuracy, and thoroughness. In the three outstanding lines of research by which he will be remembered these qualities were evident. He may not have had the intuition of genius, but he possessed in no small measure the patient, persevering spirit of the born research worker, coupled with a cool and critical judgement, and controlled by sound common sense. Much of his work was devoted to practical ends. He was not content to make a discovery; he endeavoured, where possible, to apply the knowledge gained. Thus he was a distinguished hygienist as well as a successful pathologist, bacteriologist, and protozoologist. The best example of this combination is seen in his work on anti-typhoid inoculation. He did not initiate this revolution in immunology—Professor Almroth Wright and Major Semple started the ball rolling; but Leishman, sure and steady, proved an invaluable colleague to Wright; with whom he became associated when assistant professor of pathology at Netley. He was an excellent technician with a clever pair of hands, and was an artist of no mean ability. Hence it is no wonder that he improved upon the Romanowsky stain and employed it to good effect. It was characteristic of Leishman that, when he wrote on this subject, he gave full credit to Maurer. Indeed, he was punctilious to a degree, careful to give credit where credit was due, modest and unassuming, yet conscious of his abilities and prepared to defend his opinions.

No doubt his technical skill aided him in his discovery of the parasite of kala-azar, a discovery made in 1900 in a case of so-called Dum-Dum fever, but about which he published nothing until May, 1903, when some idea of the true significance of his observations occurred to him as the result of studying a case of trypanosomiasis in a laboratory rat. In films from this rat he noted forms like the bodies he had seen in the spleen smears from the human case of fever and cachexia, and he hazarded the suggestion that trypanosomiasis of man occurred in India. He was nearer the mark than some who, as Leishman's discovery was confirmed by Donovan and others, imagined the parasite to be something very different from what it eventually proved to be. Leishman, indeed, eventually came to the conclusion that it was the involuted stage of a flagellate. It was Sir Ronald Ross who suggested that the kala-azar bodies should bear Leishman's name, a happy thought, which has given us the term "leishmaniasis" applied to the group of diseases associated with the presence

in the tissues of Leishmania, as Ross named the genus. Still it is strange that, for a time, no one remembered that Lieut.-Colonel Cunningham of the I.M.S. had, long before, in 1885, seen and described in Delhi sore the organism now known as *Leishmania tropica*, which was rediscovered by J. H. Wright. Leishman's work on kala-azar led to great and momentous developments and is one of the landmarks in the history of medical protozoology, and indeed of tropical medicine.

His third notable piece of research, the most difficult, the least satisfying, is that on the developmental cycle of *Spirochaeta duttoni* in the African tick, *Ornithodoros moubata*, first published in 1909. He made his observations on what he called the granular phase of this spirochaete in ignorance of the fact that Dutton and Todd had already drawn attention to this spirochaetal segmentation, but he went much further than they had done and explored the whole question of the life-cycle of the organism. His work was interrupted by the war, but he returned to it after the cessation of hostilities, and it formed the subject of an interesting and suggestive lecture before the Royal College of Physicians in 1921. The question of a granule stage in the life-history of spirochaetes remains unsettled, but it is significant that recent work in various fields, both bacterial and spirochaetal, seems to point to the fact that Leishman's views were sound. These three lines of research by no means exhaust Leishman's contribution to science. He wrote largely on bacterial vaccines in addition to his work on typhoid fever, he dealt with tetanus and tetanus antitoxin, he described cell inclusions in blackwater fever, and he was a valued member on a multitude of committees.

His courtesy and kindness made him exceedingly popular, especially amongst the younger workers, whom he was always ready to help and advise. He was a clear and convincing lecturer, and did a great deal to kindle enthusiasm and to promote useful lines of inquiry in the Army and elsewhere. Many hoped that, when his period of service as Director-General ended, he would again be seen in the laboratory where he was truly happy and for which his gifts specially fitted him. It has been willed otherwise, and his death leaves a great gap in the senior ranks which cannot be filled, but his memory will be kept green, not only by the record of his work, but by those personal traits which endeared him to his colleagues and his students.

We are indebted to Colonel D. HARVEY, C.M.G., Director of Pathology at the War Office, for the following appreciation of his predecessor's scientific work in the army.

Captain Leishman was one of the few officers who at the period when he proceeded to India for his first tour of foreign service took a microscope with him, knew how to use it, and made good use of it there. Even at that early age—for he graduated at 21 and came straight into the service—he disclosed that inquiring turn of mind which must always distinguish the great research worker. On his return to England he was posted to Netley—a most fortunate posting, for this move determined his future and gave to science one of its most distinguished servants. He was in charge of wards in the Medical Division at Netley, a duty he discharged in a most efficient manner; his disciplinary methods were the admiration of the surgeons on probation under his command. He spent his leisure time, however, in the laboratory, where Wright and Semple were then at work, and on the departure of the latter to India Leishman succeeded him as assistant professor of pathology. During his tenure of this office much of his best scientific work was accomplished in the laboratory at Netley and the foundation of his world-wide reputation laid. Among other work may be mentioned his association with Wright in the beginning of the preparation of typhoid vaccine and its final establishment in the form in which it is now used all over the world with so much success and with so large a preservation of valuable lives.

At this time also he prepared the stain which is now known everywhere by his name. This stain was a modification of Romanowsky's stain, but it has been truly described as a great advance on previous methods of staining as the breech-loading gun was an advance on the

muzzle-loader. This stain was not the work of a day or a month, but evolved after many months of patient investigation, guided by a most acute and critical mind. By means of this stain the way to the discovery of the parasite of kala-azar was made easy for such a worker as Leishman. At the post-mortem examination of a soldier, dead of this disease, which he himself carried out, he made several smears from the spleen pulp and was able to demonstrate clearly the small parasite, to which his name has been given.

Among other of his duties at Netley was the preparation for the army of antitoxic serums, such as that for diphtheria, and here again he was able to improve methods by his exceptional technical skill. At this time also he perfected his method of estimating the phagocytic power of the whole blood—a most ingenious method which has been largely used since in various researches.

On coming to London as professor of pathology he continued his researches, but much of his time was, of course, spent in teaching the various classes passing through the Royal Army Medical College, and leisure for research was, indeed, limited. In spite of this his was the guiding mind and hand in the further perfection of prophylactic vaccines against typhoid fever and other bacterial diseases, and in this matter he not only showed his well known powers at the work bench, but foreshadowed administrative abilities of the highest order and of a most courageous character, for there were many obstacles to be overcome apart altogether from the difficulties in the laboratory.

During this period Major Leishman continued his researches into kala-azar, a disease which naturally greatly interested him. In one of his earliest publications he suggested that the parasite discovered by him "might be a stage in the life-history of a trypanosome." If he had said "flagellate" he would have been correct, for I well remember a dramatic day in the college laboratory when a telegram was received from Calcutta from Rogers, saying that he had succeeded in developing flagellates in a culture of the kala-azar parasite.

Much of his spare time at the college was spent in a very laborious investigation of the fate of the spirochaetes of relapsing fever in the tick, work which employed him for some years, and owing to his masterly technique—a technique which was the despair of his assistants and colleagues—he was able to demonstrate the granular stage of these spirochaetes, which has been so fully exploited by other and later workers.

After leaving the college and relinquishing the post of professor, Sir William could rarely find time to return to actual laboratory work; but it was always pathetic to see how he longed to return to actual practical work with those skilled hands of his, and with what regret he laid down his tools. However, as adviser in pathology and later as director, he was an inspiration to all workers, not only in the army but in the much wider circle which he reached during the war and as a member of the Medical Research Council and numerous other scientific committees.

His last contribution to the *Journal of the Royal Army Medical Corps* was published in December, 1925, under the title "Research in the medical services," and embodies his views and is an epitome of his life.

It may not be generally known that Sir William, in addition to being a skilled bacteriologist, was also an accomplished artist and musician: one of his favourite recreations on his brief holidays was landscape sketching and painting.

Major-General Sir WILLIAM MACPHERSON has sent us the following tribute to Sir William Leishman's services to the Royal Army Medical Corps:

The sudden and unexpected death of Sir William Leishman has brought more poignant sorrow to the Royal Army Medical Corps than has ever been experienced in the whole of its history. He had won for himself the loyalty, devotion, and affection of all ranks to a degree seldom vouchsafed to the head of the Army Medical Service; and this not only because of his world renown in pathological science and his dominating influence in wide branches of medical research, but also because of his humane and wise . . . Army Medical Corps, since he . . . in 1923, and

his single-hearted efforts for its welfare. His interest in everything concerning the Corps in work and in sport never flagged. Before he became Director-General he was known to it chiefly for his far-reaching work in the prevention of enteric fever in the army, and for pathological research and organization, and those who attended his lectures when he held the post of professor of pathology at the Army Medical College never ceased to speak of the value of his teaching and his charm and lucidity of expression. All his research work, which gained for him such wide fame, was carried out while performing active duties in the Corps, and what he did to enhance its reputation, both within the army and throughout the medical profession, cannot be expressed in words. When he became Director-General his great ambition was to see all ranks of the Royal Army Medical Corps closely united in word, thought, and deed, with a view to maintaining the high reputation it had won for itself in the great war. He initiated the Royal Army Medical Corps Association as the first step to achieve his purpose. It was only the other day that he expressed how much he had this at heart, when he took the chair at the reunion dinner of the warrant officers and sergeants of the Royal Army Medical Corps on April 10th. Others are more able to write of his immense activity in the field of scientific research; but to us of the Corps what we valued most was his great heart and his loyal and abiding friendship, qualities which can never fade from our memory of him. He has died in harness, and at a time when his loss to the Royal Army Medical Corps is irreparable.

An impressive funeral service was held with military honours on June 5th in the chapel of Queen Alexandra's Military Hospital, and in the presence of a large and representative gathering of mourners. The street along the frontage of the hospital was lined by a battalion of the Grenadier Guards, with colours and band, and the drive from the chapel to the street by nursing sisters, and officers and men of the R.A.M.C. The hearse moved from the chapel after the service at a slow pace, accompanied by the pall-bearers, along these lines to the strains of Chopin's soul-stirring funeral march. When it reached the end of the line the military part of the service broke off, and the interment afterwards took place privately in Highgate Cemetery.

The service was conducted by the Rev. A. C. E. Jarvis, Chaplain-General to the Forces, assisted by the Rev. C. C. Thacker, chaplain to the hospital, and the Rev. P. McCormick, vicar of Croydon. The choir boys of Westminster Abbey attended. The chief mourners were Lady Leishman, her son and daughter, and other members of the family. The King was represented by Colonel C. E. G. Norton, the Queen by Sir Edward Wallington, and the Duke of Connaught (Colonel-in-Chief of the R.A.M.C.) by Colonel Douglas Gordon. The pall-bearers were Lieutenant-General Sir Arthur Sloggett, Lieutenant-General Sir Hugh Jeudwine, Major-General A. A. McHardy, Major-General Sir William Macpherson, Surgeon Vice-Admiral Sir Joseph Chambers, D.G. (R.N.), Major-General G. J. Farmer, Air Vice-Marshal David Munro, and Major-General J. W. O'Dowda. Others who attended the service included:

Countess Roberts, Lord Dawson of Penn, Group-Captain A. L. Godman (representing the Secretary of State for Air), Surgeon-Commander Lewis Smith (representing the Medical Directorate, the Admiralty), General the Hon. Sir Neville Lytton and Major-General Hugh Sutton (representing His Majesty's Commissioners, Royal Hospital, Chelsea), Lieutenant-Colonel Sir William Prout, Lieutenant-General Sir John Goodwin, Sir Lisle Webb (representing the Ministry of Pensions), Sir Matthew Fell, Colonel Barrow, Colonel Harvey, and Colonel Fawcett (representing the R.A.M.C.), Major-General Sir Alfred Blenkinsop (representing the British Medical Association), General Sir Walter Braithwaite, Major-General Sir Francis Treherne, Major-General Sir Wilfred Beveridge, Sir Walter Fletcher (representing the Medical Research Council), Air Vice-Marshal Sir Philip Game (representing the Air Council), Colonel Sir Reginald May, Sir Ronald Ross, and Sir William Simpson (representing the Ross Institute), Sir John Parsons, Sir Robert Firth, Sir Arbutnot Lane, Sir Alaroth Wright, Sir Anthony Bowlby, Sir St. Clair Thomson (President of the Royal Society of Medicine), Sir William Smith, Sir Arthur Stanley and Brigadier-General H. Bateman-Champain (representing the British Red Cross Society), Sir Richard Luce, M.P., Sir David Bruce, Professor Ledliegham, and Dr. Arkwright (representing the Lister Institute), Sir George Makins and Sir John Ross Bradford (President of the Royal College of Physicians) (representing the Army Nursing Board); Dr. H. H. Dale (representing the Royal Society), the Dean of Westminster, Mr. E. F. Knapp-Fisher, Dr. H. P. Newsholme, Dr. E. W. Morris (representing the Minister for Defence for the Commonwealth of Australia), Captain G. S. Elliston (representing the Society of Medical Officers of Health), Miss Hodgins (matron-in-chief), Miss Osborne (principal matron), Miss Haldane.

Many floral tributes were sent, and amongst other touching messages of sympathy and regret was one from the Pasteur Institute in Paris, signed by Professors Roux, Calmette, and Martin.

DONALD FRASER, M.D.,

Consulting Physician to the Paisley Mental Hospital and the Royal Alexandra Hospital.

We regret to record the death of Dr. Donald Fraser at Woodlands, Elderslie, the residence of his son-in-law, Mr. Gardner, on May 19th, in his 86th year.

Dr. Fraser commenced his medical education at Glasgow University in the last years of its location in the old buildings in High Street, and graduated M.B. in 1867, C.M. in 1868, and proceeded M.D. in 1870. At the Royal Infirmary he studied under Lister, an experience which was one of his most cherished memories. His reminiscences of that time and his profound admiration for his teacher reflected Lister's nobility of character and his inspiring influence on his pupils. Shortly after graduating Dr. Fraser settled in Paisley, and in that town and neighbourhood for over half a century his high professional skill, progressive spirit, and inspiring personality gained for him a very extensive practice. In his earlier years he had fought cholera and typhus, and later he took a leading part in work for the prevention of tuberculosis, being president of the local branch of the National Association for the Prevention of Consumption. He strove successfully as a lecturer to awaken the public mind to its responsibilities in the prevention of this disease. Dr. Fraser's activities also found a congenial sphere in the study of mental and nervous disorders. He was a profound admirer of Hughlings Jackson, and always said he owed much of his success to the teachings of that master mind. In his presidential address, delivered on October 11th, 1897, to the Glasgow Pathological and Clinical Society, of which he was one of the original members, he took as his subject hysteria as a psychosis. As early as 1878 he had made a special study of this subject, and was one of the first in this country to take an interest in psychotherapy. For over fifty years he was actively associated with the Paisley Mental Hospital at Riccarton as visiting physician. While conducting one of the largest practices in the West of Scotland, he yet found time to devote several hours a day to work in this hospital, where he early introduced methods of treatment and investigation which have only recently become universal. With unabated enthusiasm Dr. Fraser visited the hospital as its consulting physician two days before his last illness and saw several patients. At the time of his death he was engaged in the preparation of a volume embodying his ripe experience of psychological work and bringing under review the theories of Freud and his school. In November last he went to winter in Kilmacoll to be near his old associations and to carry on research into the psychology of epilepsy at the Bridge of Weir Colony of Mercy, of which he was one of the medical directors. On giving up general practice about twenty-three years ago for reasons of health, he devoted more and more time to mental work, and in 1910 became a consultant in mental and nervous diseases in Glasgow. A serious illness stopped his work in Glasgow seven years ago and he retired to the country, but studying and writing still occupied much of his time. As a result he published a book on epilepsy based on clinical studies in epilepsy, which was reviewed in our columns on October 11th, 1924 (p. 671). It was his hope that it would serve in some measure to dissipate that professional pessimism as regards the cure of epilepsy which demoralizes both patient and doctor.

Dr. Fraser's status as a physician was early recognized by his election in 1875 to be a Fellow of the Royal Faculty of Physicians and Surgeons and by his appointment as examiner in medicine in the University of Glasgow. He

was elected to the staff of the Royal Alexandra Infirmary, Paisley, in 1885, and at his death was still attached to it in the capacity of honorary consulting physician. He maintained a truly remarkable alertness and freshness of mind in his later years, and the most recent lines of advancement and research always found in him a keen student and critic, especially in the department of psychological medicine; it is an attestation of his vigour and enthusiasm that he attended a post-graduate course on mental deficiency and crime at Birmingham at the age of 80. He was a member of the British Medical Association. As was natural to a man of such wonderful vitality and to whom life was so full of zest, Dr. Fraser had many interests outwith the realm of medicine. In every situation in which he found himself—in his house, in his garden, on his farm—his conversation was brilliant and enlivened from a retentive memory of men and matters; there are many to whom his name and the privilege of his friendship will remain a grateful memory. As a physician he was trusted and beloved by rich and poor alike, on whom he expended his sympathy and skill without distinction.

Dr. Fraser, who was predeceased fifteen years ago by his wife—a sister of the late Professor Joseph Coats—is survived by a family of five daughters, one of whom is Dr. Kate Fraser, Deputy Commissioner to the Board of Control for Scotland.

SIR STEWART STOCKMAN, M.R.C.V.S., Chief Veterinary Officer, Ministry of Agriculture.

We regret to announce the sudden death, at Glasgow, of Sir Stewart Stockman, the chief veterinary officer of the Ministry of Agriculture.

Sir Stewart Stockman was born at Edinburgh in 1869, and was educated at the Royal High School and the Royal (Dick) Veterinary College. He became a Member of the Royal Veterinary College in 1890, and shortly became professor of pathology and bacteriology in his old college. This appointment was held for a few years only, as he resigned to serve in the South African war. At the end of the war he was for a short time in India, but was then appointed principal veterinary officer in the Transvaal. In 1905 he became chief veterinary officer to the Ministry of Agriculture, an office which he occupied at his death. It was largely due to his administrative ability that this country remained free from some of the serious animal plagues prevalent abroad. In addition to controlling such purely animal diseases as swine fever and mange, his department had a share in the eradication of rabies from Britain, and, with the co-operation of the Royal Army Veterinary Corps, for the exclusion of glanders. His name is probably best known to the medical profession, however, in connexion with foot-and-mouth disease. He was mainly responsible for the execution of the drastic "slaughter" policy which this country adopted in order to stamp out the disease. In the execution of the onerous duties which this policy entailed he was unsparing of his own health, and he had only recently returned from the Argentine, where he had been investigating the methods of control practised there. He was a member of the committee recently appointed under the chairmanship of Sir William Leishman to investigate the disease.

Although Sir Stewart Stockman was primarily an administrator, his work was not confined to routine duties. He was director of the research laboratory of the Ministry of Agriculture at Weybridge, where, in addition to research work into the diseases of animals, a considerable amount of routine diagnostic work was carried on, and large quantities of serum and vaccines were produced. This laboratory is an integral part of the veterinary health service of this country, and made considerable demands on the time of its director. He was able, however, to assist in the production of the *Journal of Comparative Pathology and Therapeutics* and to edit a *Textbook of Meat Inspection*. He had long been a member of the Council of the Royal College of Veterinary Surgeons, which elected him president two years ago. He was president also of the National Veterinary Association.

Sir Stewart Stockman was a brother of Professor Ralph

Stockman of Glasgow University. He is survived by Lady Stockman, who is a daughter of Sir John McFadyen, and two daughters.

Dr. WALTER COURTENAY RIVERS, who died on April 23rd, aged 51, received his medical education at Charing Cross Hospital, where he was Roan exhibitor in 1892; he obtained the diplomas M.R.C.S., L.R.C.P. in 1898, and the D.P.H. of the Royal Colleges of Physicians and Surgeons in Ireland in 1903. Before the age of 20 he had developed pulmonary tuberculosis, which handicapped him severely for the remainder of his life. He held the appointments of house-surgeon at the Stamford, Rutland, and General Infirmary, senior clinical assistant at the Throat Hospital, Golden Square, resident medical officer to the Newcastle-on-Tyne Sanatorium at Barrasford, and assistant tuberculosis medical officer for the Barnsley district. He had also held a commission for some time in the Royal Army Medical Corps. His literary interests were varied, and he published articles on tuberculosis and sex psychology in particular; he had a strong bent for journalism and wrote on a great variety of subjects, with a critical attitude, which at times became caustic. In recent years he had contributed occasional paragraphs to our *Epitome of Current Medical Literature*. His last book, entitled *Through a Consulting Room Window*, was reviewed in the *BRITISH MEDICAL JOURNAL* of April 10th (p. 661). Dr. Rivers was one of the founders of the Yorkshire branch of the Tuberculosis Society; he took a keen interest in politics and social problems.

We regret to announce the death of Dr. HENRY SIMPSON of Brencley, Kent, on May 30th, as the result of a motor accident two months earlier. He was born at Market Weighton, Yorkshire, sixty years ago, and received his medical education at Cambridge and St. Thomas's Hospital. He was a scholar of St. John's College, Cambridge, gained a first class in the Natural Sciences Tripos, took the diplomas of M.R.C.S., L.R.C.P. in 1891, and graduated M.B., B.Ch. in 1892. After holding the appointments of assistant house-surgeon and clinical assistant in the ear department of St. Thomas's Hospital, he practised for a time in Yorkshire, and then, after spending some years as a ship surgeon, settled in Brencley, where he practised for some twenty-five years. He was an active member of the British Medical Association, and at the time of his death was chairman of the Tunbridge Wells Division. During the time he spent at Brencley he had built up a large practice and was deservedly successful, for he was a sympathetic doctor, a hard worker, a man who read largely in professional subjects, and gave much anxious thought and care to his patients. The result of all this was that he was very popular and greatly trusted by all, and his untimely end was a cause of sorrow to the whole district, as was well shown by the large attendance of mourners at the funeral. He leaves a widow, one son, and two daughters. In his life we have another instance of an able man who was content to settle down single-handed in a country practice and keep up the traditions of his profession by hard work and devotion to duty.

The Services.

I.M.S. DINNER.

The annual dinner of the Indian Medical Service will be held at the Trocadero Restaurant on Wednesday, June 16th, Lieut.-Colonel R. H. Elliot in the chair. Tickets and all particulars may be obtained from the joint honorary secretary, Colonel J. J. Pratt, I.M.S. (ret.), 28, Nevean Mansions, Warwick Road, London, S.W.5.

TERRITORIAL ARMY AMBULANCE CHALLENGE SHIELD.

The annual competition for the Territorial Army Ambulance Challenge Shield will take place at the Duke of York's Headquarters, Chelsea, on Saturday, June 26th, at 2 p.m. The competition is open to squads of Territorial Army medical units and of recognized stretcher bearers borne on the establishment of other units of the T.A. The following units will compete: 128 (W. Yorks.), 131st (Home Counties) Field Ambulance, 152nd (Highland) Field Ambulance (holders), 152nd (Highland) Field Ambulance, 164th (West Lancs) Field Ambulance, 164th (West Lancs) Field Ambulance, 170th (Cavalry) Field Ambulance, and 2nd (London) Casualty Clearing Station.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons resumed on June 1st after the Whitsuntide Recess.

The House of Commons has this week been four days in Committee on the Finance Bill, and discussions have arisen on the medicine stamp duties, optical glass duties, and motor duties. The Parliamentary Medical Committee met on June 8th. At a meeting of the Unionist Health and Housing Committee at the House of Commons on June 8th, Dr. Fremantle in the chair, Lord Newton spoke on the Smoke Abatement Bill, claiming that it was a distinct advance on the present law, which was fifty years old. He said the English were a clean people, but their country was the dirtiest in Europe, and this grime engendered social discontent. At present the country was only clean during coal stoppages and on Bank Holidays. Dr. Vernon Davies, speaking of smoke in the cotton industry in Lancashire, said that in one town where new methods of stoking, said to abate smoke, were introduced from Chicago, the fuel consumption of the mills increased by 13 per cent. Other speakers questioned this figure. Sheffield members denied that the bad reputation of that city for smoke was deserved.

Lead Paint Poisoning Bill.

Sir William Joynton-Hicks moved, in the House of Commons on June 4th, the second reading of the Lead Paint (Protection against Poisoning) Bill. While total prohibition of lead paint would be the most complete means of prevention, there was a great demand for lead paint, and employers who used it said the substitutes were not in all cases satisfactory, though the use of substitutes was increasing. Consequently the bill proposed regulation, not prohibition. The regulations had been agreed upon between employers and employed. They would enable substitutes to be used, and would reduce the possibility of poisoning by lead paint. Mr. Rhys Davies said the Joint Industrial Council of the painters and decorators had declared that it could not support any bill which gave less protection to persons employed in painting than the Convention adopted at Geneva provided. Cases of white lead poisoning were increasing in this country (in 1919, 207; in 1922, 246; in 1923, 337; and in 1924, 486). How could the Home Secretary enforce regulations on wet rubbing down, the use of overalls, the cleaning of finger-nails, when 70,000 painters and decorators were distributed among 20,000 houses? The Home Secretary replied that he was going to ask for more factory inspectors. Mr. Harney said that white lead represented 20 per cent. of the lead output of the world, and 90 per cent. of white lead was converted into paint. The danger was in the dust of lead. In factories the dust, disease, and death were appalling at one time, but regulations were applied, and there was now no extraordinary danger in working in lead factories. Lord Henry Bentinck said the regulations would be useless to check the spread of disease. Wet rubbing down of paint was a fraud as a safeguard. Mr. Clayton hoped the regulations would insist that the working overalls of painters were not to be taken to their homes. In chemical works the men's overalls were washed on the premises. Mr. Viant said that paragraph (d) of the regulations under the bill was to provide for the medical examination of persons employed in painting with white lead. Who was to maintain the painter and his family when he could not get a clean bill of health? He did not think the Workmen's Compensation Act provided for this. Mr. West Russell said that Sir Thomas Oliver, a physician who had done so much to bring before the country the dangers of lead paint, had declared that before prohibiting white lead in paint the regulations should be given a longer trial and fresh investigation made. Captain Hacking (Under Secretary for Home Affairs) said that if a workman was suspended from employment on the ground that he was suffering from lead poisoning he would be entitled to compensation under the Workmen's Compensation Act, but where suspended as a precautionary measure would not be entitled to compensation.

The House read the bill a second time by 131 to 56.

Midwives and Maternity Homes.

On June 8th the House of Lords considered the Midwives and Maternity Homes Bill in committee. (The bill was read a third time in the House of Commons on April 27th; see *Journal*, May 1st, p. 810.)

Part I amends the Midwives Acts, 1902 and 1918. Clause 1 provides that if any person, of either sex, not certified under the bill, attends a woman in childbirth otherwise than under the direction and personal supervision of a duly qualified medical practitioner, he or she shall, unless the court is satisfied that the attention was given in a case of sudden or urgent necessity, be liable on summary conviction to a fine not exceeding £10.

Lord Stanmore moved an amendment to provide that this should not apply in the case of a person who, while undergoing training with a view to becoming a duly qualified medical practitioner or a certified midwife, attended a woman in childbirth as part of a course of practical instruction in midwifery. It was possible that, in the future, the courts might hold that the words "personal supervision" implied the actual presence of the qualified medical officer. If that were to be the case the present system of midwifery training would become unworkable. It was very unusual, where a student had to deal with an emergency case, that the delay of an hour or so before a qualified practitioner came had any bad effect on the patient. The student, having had training, was in a position to give general treatment. No authority on obstetrics would consider it necessary that a student should be accompanied by a medical man in all the cases that he had to attend. On the contrary, he could not learn his work properly without having responsibility during his period of training. The case of the pupil midwife was very similar to that of the student. Training was carried out under the superintendence of experienced midwives who were recognized by the Central Midwives Board. It was not only undesirable that they should be subjected to the personal supervision of a medical man in all these cases, but if that supervision was insisted on it might have the effect of greatly reducing the number of midwives.

Viscount Knutsford, in supporting the amendment, said that only the other day all the medical schools in London met and proposed that an amendment should be moved, to the bill very similar to that of Lord Stanmore's. The amendment might be accepted with the certainty that the women who were being treated would be properly attended to, and that the pupils or students would be properly taught. He thought the word "training" in the amendment should be strengthened by the substitution of the words "training recognized by the General Medical Council or the Central Midwives Board."

The Marquess of Salisbury said it was quite true that since this bill was read a second time very strong representations had been made to the Ministry of Health and the Government in regard to this particular point. It had been represented to them that if the clause passed in its present form it would lead to considerable difficulty in the training both of medical students and pupil midwives, and would really constitute a great disadvantage to the public interest. On the other hand, the women concerned must be adequately protected. Lord Stanmore had sought to steer a middle course between two extremes, and had on the whole succeeded. As regarded the words suggested by Lord Knutsford, it might be considered between now and the report stage whether they were necessary. He thought Lord Stanmore's amendment was required; there was no desire to interfere with the medical schools; that was a matter of national importance. It was a tremendous charity which these women were receiving, because they were attended by the medical students and pupil midwives for nothing. He understood that no medical student would be allowed to act on these cases except towards the end of his training. In other words, the medical student was almost a qualified doctor before he was allowed to attend midwifery cases. The pupil midwife was not allowed to attend them except in the presence of a trained midwife, who showed her how to do her work. Adequate care was therefore taken.

Lord Dawson of Penn said that the remarks of Lord Salisbury as to whether the public were adequately protected in the course of medical education was of considerable public interest. It was very important that the public should be reassured on that point. The public were adequately protected. To begin with the medical student when he started his training had been through several years of preliminary education. He had been trained in the basic sciences on which medicine was built. That was one advantage he had over the midwife. Before he was sent out to practise midwifery he was put through a course of education in the hospital where he was given actual instruction in maternity cases. Having got so far it was very important to send the student out so that he could learn to be self-reliant. One of the most delicate questions in regard to medical education was as to the right moment when the medical student should be sent out to cases alone, with the right sort of advice in the background. But when he did go out he went with the full knowledge that if the case to which he went was abnormal or any difficulty presented itself he could immediately send for a highly skilled person. It was far better that a medical student should be trained in the habit of self-reliance during his period of education than that he should postpone it until he went into practice and had no one behind him. In actual practice the system worked extremely well. The service was very popular. The patients themselves were attached to the students largely because they found themselves coming into contact with the innate friendliness which seemed to be part of the make-up of the British medical student. The students, on the other hand, found how closely allied were the human and scientific sides of their art. Altogether it was an excellent arrangement, not only in regard to the training in medicine, but also the training in the management of people. The patients got very fond of the students, and the latter generally ended their week on duty with larger hearts but certainly with emptier pockets. He had been through this training himself. Before now he had washed a baby and baptized a baby, how efficiently he did not know, but he rather thought he found the baptism more easy than the washing. (Laughter.) He thought that the machinery of medical education and the public interest would both be damaged if some sort of amendment as that proposed by Lord Stanmore was not inserted in the bill.

The amendment was agreed to, and Clause 1 as amended was added to the bill.

Lord Strachie moved to leave out Subsection (1) of Clause 2, which provides that where a midwife has been suspended from

practice in order to prevent the spread of infection she shall, if she was not herself in default, be entitled to recover from the local supervising authority such amount by way of compensation as is reasonable in the circumstances of the case. The amendment was moved, he said, at the request of the County Councils Association, but so far as was known no injustice had ever been done. Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health) had defended the clause because he said that one or two authorities in the past had not acted fairly to the midwives who were suspended; he did not say what authorities, nor did he describe the circumstances of the particular cases. If there were only one or two cases this clause was not necessary.

The Marquess of Salisbury said it was vital to remember that if there was the least temptation on the part of those concerned to conceal possible contact with infection, grave risks would be run. Although he was a very great advocate of local government independence, the Government was more concerned with the safety of the patients and was very anxious to go the whole length it could in order to protect them. Lord Strachie had truly said that the great body of county councils would act with due regard to the interests of the patients and in a proper public spirit in matters of this kind. The Government wished to reassure the midwives themselves, to make them certain that they would get compensation. For that reason the Government desired to go to the extreme length that it could, and he hoped the amendment would not be pressed.

Lord Strachie thereupon withdrew the amendment.

In Part III of the bill, Clause 11, in which the expressions used are interpreted, the term "maternity home" is defined as not to include "any hospital or other premises for the conduct of which a duly qualified medical practitioner resident therein is responsible."

The Archbishop of Canterbury moved an amendment providing that there should be lodged with the local supervising authority a certificate signed by two duly qualified medical practitioners, practising or residing in the county, not being in partnership with the first-mentioned practitioner or each other, and having no financial or other interest in the home, to the effect that the premises and their equipment were in all respects suitable for the purpose, and that the medical practitioner carrying on, or proposing to carry on, such a hospital was a fit and proper person. The provision in the clause, as it stood, practically said that any man who had attained due qualification in medical work was to be exempted from inspection if he opened a home for the purposes referred to in the bill. He yielded to no one in his whole-hearted admiration for the medical profession. No profession in the world stood higher in regard to the character of its members, and in regard to their public spirit and desire in all cases—and their qualification in almost all cases—to act in the public interest and to do what was right. But even in that great profession there might here and there be a man who, while possessing the technical qualifications, could not be regarded as altogether relieved from the possible suspicion of having other motives in what he might be endeavouring to do. In order to protect the homes, the medical men, and the public, there ought to be some modification of the complete exemption which was offered to a man who might be opening a home dealing with this delicate and difficult matter, entirely on his own responsibility. He had taken the wording of the proposed safeguard from the General Purposes Act of the London County Council (which the body had the same matter to deal with), which laid down the restrictions in its case. Lord Banbury supported the amendment. There should be some safeguard to prevent a person starting a home of this sort merely in order to make money out of it. He was not quite certain that all these nursing homes were what they should be.

The Marquess of Salisbury said that there was no difference of opinion between the Government and the Archbishop of Canterbury as to the absolute necessity of some such limitation of the clause. Undoubtedly what Lord Banbury had said was true, that there were a certain number of maternity homes reputable. The only real question was what form the amendment should take. There was a good deal to be said for the Archbishop's proposal, but the method of trying to effect a safeguard by a definition and by a certificate of other medical practitioners was not wholly satisfactory. The suggestion, of the medical profession who would be guilty of conducting a maternity home of this kind. The number might be very small not be impossible for one black sheep, but it would certainly be, and that was really the only protection which the Archbishop's proposal gave; no doubt they must not be technically in partnership with the medical practitioner himself; but there were all sorts of indirect methods by which evasion could be carried out. The Government therefore thought the object in view would be better achieved by a safeguard of a different kind. Instead of trying to fortify one medical practitioner by of discretion by the supervising authority. The Government proposed that the supervising authority should have absolute discretion in that way, through having local knowledge, he able to protect the public and the women concerned. Only those who got an exemption from the provisions of Part II of the bill would be to the authority to refuse an exemption when it thought fit. That would be the only really efficient safeguard. It might be said that to leave the discretion wholly in the hands of the supervising authority was going too far. The Government agreed with that view, and was providing an appeal in order to prevent any possible injustice following upon this amendment.

Viscount Haldane said that on the whole he preferred the Government amendment, and he thought the House should adopt it.

Lord Merrivale said that the proposal of Lord Salisbury was much more stringent than that of the Archbishop of Canterbury. He supposed that the local supervising authority would not see fit to exempt anyone from the operation of the general law unless it were satisfied that he ought to be so exempted.

The Archbishop of Canterbury said that after what had been said he would withdraw his amendment, provided that he might bring it up again on the report stage if he found it to be necessary.

The Archbishop of Canterbury's amendment was, by leave, withdrawn.

Amendments to Clause 11 were moved by Lord Salisbury providing (1) that any hospital or other premises for the conduct of which a duly qualified medical practitioner resident therein was responsible might be exempted from the provisions of Part II of the Act by the local supervising authority; and (2) that any person who was aggrieved by the refusal of such authority to grant exemption, or by the withdrawal of exemption, might appeal to the Minister of Health, who might give such directions to the local authority as he thought proper.

Viscount Knutsford said that if the bill passed in its present form any hospital or other premises maintained or controlled by a Government department or local authority or by any other body of persons constituted by special Act of Parliament, or incorporated by Royal Charter, would be exempted from registration. Hospitals under a Government department or a local authority needed inspection rather more than others. He once saw a Poor Law infirmary in Great Britain where there were 800 patients, 200 of whom were very seriously ill indeed. There was a resident medical officer who was responsible for the management, and therefore the hospital would be exempted from this Act. There was a filthy syphilis ward, and only one medical officer, who had to do all the post-mortem examinations and attend the delivery of women. She was a girl, 26 years of age, holding her first appointment. When he exposed this case he was called a liar. The city fathers denied that such a thing ever existed, but he was glad to say that they had to admit it in the end and the conditions were altered. That was an instance where inspection by the supervising authority would have done infinite good. So far as the voluntary hospitals were concerned, the more they were inspected the more those who were responsible for them would be pleased. He hoped the Government would agree to take out the provision exempting these institutions from registration and inspection.

The Marquess of Salisbury said that Lord Knutsford would like to see all hospitals brought within the restrictive provisions of the bill. That was a view which, coming from him, was bound to be treated with very great respect, but his (Lord Salisbury's) impression was that the great body of hospitals did not quite share the noble lord's opinion. What the Government had to consider was how far it could carry exemption safely, and the clause, together with the amendments, had been drawn so as to cover the ground as well as possible.

Lord Salisbury's amendments were agreed to and Clause 11 was added to the bill.

The bill passed through Committee and was reported to the House.

Foot-and-Mouth Disease.

In answer to General Clifton Brown and other members, on June 3rd, Mr. Guinness (Minister of Agriculture) said that thirteen cases of foot-and-mouth disease, recently confirmed in South-West Scotland and Cumberland, had occurred in or were attributed to imported carcasses of pigs. Steps had been taken for disinfection of persons who had handled these carcasses, of the bacon factories, of railway and other vehicles which had been in contact with them, and, where practicable, of the ships in which they had been conveyed. An Order had been issued prohibiting the landing of any part of a carcass of cattle, sheep, pigs, or goats from the continent of Europe except fully-cured bacon and ham, lard, other cooked or preserved meat, and treated hides. Carcasses could be highly infective, though no definite lesions could be detected. Therefore inspection of carcasses, either before shipment or on arrival, would not protect against the risk of introducing the disease to this country. The new regulations would be maintained till they could be relaxed without danger to the British farmer. The Government's technical advisers were satisfied beyond a shadow of doubt that recent outbreaks at Carlisle and at Newcastle-on-Tyne were due to imported carcasses of pigs. The use of hay and straw from the Continent as fodder or litter for animals was prohibited. When used as packing material it must be kept from contact with animals and destroyed when no longer required for that purpose. There was no definite evidence of other vegetable products having caused outbreaks of foot-and-mouth disease in this country, and he did not propose to prohibit the importation of any such products. There was much greater danger from the direct infectivity of a diseased carcass than from the purely secondary infectivity of vegetable matter which could only be a mechanical carrier.

In the House of Lords on the same day Lord Strachie congratulated the Ministry of Agriculture on having forbidden the importation of swine, and said the general belief among farmers was that the disease was introduced not only by swine but by largely used in feeding animals. It was significant that there had been no outbreak during the war. Lord Bledisloe (Parliamentary Secretary for Agriculture) prefaced his reply with an expression of regret for the death of Sir Stewart Stockman (Chief Veterinary Officer of the Ministry of Agriculture) and of Sir William

Leishman (Chairman of the Foot-and-Mouth Disease Research Committee). Lord Bledisloe said that in the Carlisle outbreak the probability was that the germs of the disease were contained in washings from a bacon factory which were carried to a sewage farm and that cattle on that farm took the disease through grazing on tainted grass. The incubation period of the disease was considerable, and it was more easily communicable when incubating than when the lesions were to be found on the imported animals. A question had arisen on the importation of meat and of meat offals from the Argentine, but meat offals from that country were so treated as to make them innocuous so far as foot-and-mouth disease was concerned. The whole matter was being examined most meticulously by the Ministry of Agriculture. Lord Haldane said Sir William Leishman had rendered immense service to the army by his researches. Though head of the committee on foot-and-mouth disease, Sir William had not been able to give his whole time to that research. He had been appointed by the late Government when an announcement had just been made that in Germany the bacillus of the disease had been identified. Lord Haldane remarked that they now required as chairman of the committee someone who could give his whole time. If possible the first bacteriologist in the country should take the chair. It was no use appointing an administrator. He was not at all sure that the germ had really been identified, but if it could be and if the proper antitoxin could be discovered, it would be possible to treat infected animals. It would then be possible also to treat articles in such a way that there would be no chance of the disease spreading. Answering the Earl of Stair, Lord Bledisloe said that last year and in the early part of this year an unprecedented number of young pigs had been imported into this country from Holland and Belgium to be consumed as fresh meat.

The Bethlem Hospital Bill.

The Bethlem Hospital Bill, which has already passed the House of Lords, was read a second time in the House of Commons on May 19th. The House ordered that it be an instruction to the Committee on the bill that it have power to insert therein such provisions as may be necessary for the purpose of confirming the agreement entered into between the governors of the hospital and Viscount Rothermere with respect to Bethlem Hospital and for the vesting of the hospital site or part thereof in the London County Council as an open space.

Stamp Duties on Secret Remedies.

On June 7th the House of Commons began the consideration of the Finance Bill in Committee, Mr. James Hope being in the chair. Clause 2 enacts that the additional excise duties imposed by the Finance Act (No. 2), 1915, on medicines liable to duty shall continue to be charged until August 1st, 1927.

Captain W. Benn asked the Financial Secretary of the Treasury to look into this clause, which dealt with matters going back to the seventeenth century. It would be much simpler, from the point of view of the taxpayer, if the Treasury would produce a clause showing what would be levied, instead of referring in the clause to another Act, and then, by that, to another Act; and so on back nearly to 1600.

Mr. McNeill (Financial Secretary to the Treasury) said that when Captain Benn raised this matter last year his predecessor gave an undertaking that it would be considered before the introduction of the present Finance Bill, with a view to a codification of the various old statutes. After consideration it had been decided that codification by itself would be useless. What was needed was a drastic revision of the statutes. That, however, had not been possible before the introduction of the present Finance Bill, but it was intended in the near future to appoint an inter-departmental committee to consider exactly what ought to be done in order to get rid of the superfluity of old and obsolete statutes dealing with particular specifics. There was one particular specific in the schedule called the "elixir of longevity" which had remained in the schedule to the statute of 1812. He understood that the elixir was no longer efficacious, and that showed that mere codification would not meet the case. He hoped that before this time next year something would have been done to remedy the present state of things in this respect.

The clause was carried.

General Medical Council.—On June 7th Mr. Forrest asked the Vice-Chamberlain of the Household, as representing the Lord President of the Council, whether the Crown nominee on the General Medical Council would make any annual report to the Government on its proceedings; and whether, in that case, the document would be published. Major Hennessy (the Vice-Chamberlain) in reply said the hon. member appeared to be under some misapprehension. The meetings of the General Medical Council were open to the public and were reported in the daily press and professional journals. The official minutes of the proceedings were published and were supplied to the Privy Council, and were also available to the public. Mr. Hore-Belisha asked whether Mr. Hilton Young would answer questions in the House of Commons concerning the General Medical Council. Major Hennessy replied that he could not answer that without notice.

Medical Inspection of Emigrants.—On June 7th Sir Burton Chadwick told Mr. Day that he was not aware of any complaint regarding the present method of examination of emigrants on board ship. If the hon. member had any suggestions to make, however, he would see that they were considered.

Notes in Brief.

The Royal Commission on Lunacy hopes to present its report before the end of next month.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

At a congregation held on June 5th the following medical degrees were conferred:

M.B., B.Chir.—S. M. Milner, D. Aserman.
M.B.—R. F. Guymer.

UNIVERSITY OF LONDON.

The following have been appointed teachers of the University in the subjects and at the institutions indicated:

University College.—Mr. Max E. Delafield (hygiene and public health), Mr. F. R. Winton (pharmacology).
London School of Hygiene and Tropical Medicine.—Mr. J. T. Duncan (bacteriology).

Sir Cooper Perry, M.D., F.R.C.P., has been elected chairman of the Architectural Committee for 1926-27.

Applications for grants from the Thomas Smythe Hughes Medical Research Fund, allocated for assisting medical research, must be received not later than June 15th. Further particulars can be obtained on application to the Academic Registrar.

The following candidates have been approved at the examinations indicated:

THIRD M.B., B.S.—"H.Kath."
*A. Byrne-Quinn, *J. J. Low, *Mary C. Luff, *J. H. Simmons, *Jean Walker (University me.
E. C. Archer, E. Bacon, R. T. Bannister, J. M. Barnard, O. E. Beare, H. C. Beccle, J. G. Y. Bell, J. S. Bonzecky, S. Berman, F. A. Bevan, O. P. Bowers, Margery G. Blackie, J. R. Blazé, Anna M. V. Bonhote, H. C. Boyde, Lucy J. Burnett, Olive K. Burnett, L. W. Cann, Elizabeth J. Carpenter, W. N. Chapman, F. W. Charman, Enid Clarke, Violet H. Comber, L. N. R. Comty, Victoria M. Crosse, Evelyn J. Curtis, P. E. J. Cuttings, Gweneth M. Daniel, D. J. Davies, T. D. Deighton, M. De Lacey, Alma Downes-Shaw, G. E. Ellis, H. G. Escourt, W. G. Evans, Christabel S. Eyre, Rachel D. Fox, D. B. Fraser, E. D. Garrett, Winifred M. Gibson, J. F. E. Gillam, Edith L. Gould, Agnes H. S. Gray, F. H. K. Green, C. S. Halliwell, Helen M. Harris, Lella M. Hawkeye, T. R. Hill, Katherine M. Hirst, Janet K. Holgate, Ruth T. Hurdard, K. M. N. Isaacs, A. D. W. Jones, R. H. Knight, G. L. S. Kohnstam, Leemsmith, S. Lerner, L. O. Lindsay, M. Lyons, D. C. McIntosh, J. H.

N. Moulson, Margaret I. Neal, Gr. Olive, J. O. Oliver, J. Parrish, H. L. Peake, J. Pearce, N. R. Pooler, Dorothy E. Pratt, L. Reuvig, G. H. Roberts, Victoria A. Roberts,

Josephine I. Terry, B. M. Tracey, H. Treisman, Kathleen C. Vost, L. B. Ward, Hilda M. Weber, Janet Welch, H. V. Wolls, W. S. Whimster, Dablia Whithorne, Gwendolen I. Wilkins, Katharine G. L. Williams, Ada R. Winter, Dorothy E. Wright, J. C. Young.

* Honours. † Distinguished in Medicine.
‡ Distinguished in Surgery. § Distinguished in Pathology.
¶ Distinguished in Midwifery.

Group I.—Florence A. Adam, S. C. Bakke, Kathleen Blako, J. W. Bottoms, Edith D. Boyle, Alison M. Clark, F. J. T. Foeander, Dora J. Fox, Eliza C. A. Fristedt, B. M. C. Gilsenan, Minnie Gosden, C. H. Hampshire, Catherine M. Hext, D. P. Holmes, M. R. Jones, M. C. Lavin, S. Levy, N. W. Mackeith, Evelyn T. D. MacLagan, Evelyn M. Pakeman, W. E. Parry, G. E. G. Peirce, Agnes M. Ramsbotham, J. W. Schabert, E. F. Stead, Edith A. Straker, Sylvia Sworn, F. W. Ta'Bois, Edith M. Webb, H. F. Wilson. **Group II.**—J. R. Beagley, W. R. W. Bonner Morgan, Rose A. Carter, Evangeline A. Olark, A. C. Counsell, B. R. Crossley, Muriel Davies, J. O. G. Dickinson, J. D. Durand, D. C. Fairbairn, O. F. Farndon, M. Fishman, S. C. Gawne, S. A. Grant, J. I. Griffiths, F. D. H. Hocking, D. E. Huskisson, F. H. K. Knight, Elsie Lyon, Margaret B. MacDonald, L. J. McGregor, I. McPherson, Mary A. Marshall, G. A. Martin, Grace E. Milzen, G. A. H. Norman, B. Phillips, H. J. Powell, Muriel A. Pugh, J. E. C. Rouse, D. J. L. Routh, L. H. Savin, S. T. Seccombe, W. D. Sheldrake, Mary Stirk, S. V. Strong, O. G. Tippet, J. R. Tree, Elizabeth M. Whishaw, J. T. Wybourn.

DIPLOMA IN PSYCHOLOGICAL MEDICINE (with Special Knowledge of Psychiatry).—D. E. Cameron, E. C. T. Emerson, C. O. Perera, J. S. I. Skottowe, R. Thompson.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Subjects of Prizes.

The subject for the Jacksonian Prize for 1926 is "The pathology, diagnosis, and treatment of abscess of the brain," and for 1927 "The pathology, diagnosis, and treatment of bronchiectasis and abscess of the lung." Dissertations for the prize for 1926 must be delivered at the College by 4 p.m. on Friday, December 31st, 1926, and for the 1927 prize by 1 p.m. on Saturday, December 31st, 1927.

The next award for the Cartwright Prize will be for the five years ending December 31st, 1930. The prize, which consists of a medal executed in bronze and an honorarium of £85, will be awarded to the author of the best essay written in English on "The etiology, pathology, and treatment of chronic general periodontitis (pyorrhoea alveolaris)." It is open to persons engaged in the study or practice of dental surgery and possessing qualifications capable of registration under the Medical Acts of the United Kingdom. Essays must be received by the Secretary of the College not later than 4 p.m. on December 31st, 1930.

Further particulars can be obtained on application to the Secretary of the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C.2.

Medical News.

PROFESSOR JOHANNES FIBIGER of Copenhagen, in recognition of his eminent services to cancer research, was entertained by the medical staff of the Cancer Hospital, London, to dinner at the Langham Hotel, on Monday Inst. The chair was taken by Mr. Ernest Miles, F.R.C.S., senior surgeon to the hospital. Among those present were Lord Dawson of Penn, Sir Humphry Rolleston, Sir John Bland-Sutton, Sir Frederick Andrewes, Sir Walter Fletcher, Professor Muir of Glasgow, Dr. H. H. Dale, Professor Bulloch, and Professor Dean of Cambridge.

THE last of the series of lectures on pathological research in its relation to medicine arranged for the summer session by the Institute of Pathology and Research, St. Mary's Hospital, Paddington, W.2, will be given by Mr. J. E. Barnard, F.R.S., on Thursday, June 17th, at 5 p.m., the subject being the microscopy of filterable viruses. The lecture is open to medical practitioners and to all students in medical schools without fee.

AMONG the provisions of the Criminal Justice Act, 1925, which came into force on June 1st, are those extending to twelve months the period within which prosecutions for giving false information for insertion in the birth or death register may be undertaken, and increasing the maximum penalty on summary conviction of such offences from £10 to £50. The Registrar-General considers it important to secure a full public appreciation of the seriousness of such offences and the grave and far-reaching consequences which they may involve.

THE inaugural meeting of the Welsh Branch of the Central Committee for the Care of Cripples will be held at Carnegie House, 117, Piccadilly, London, on Thursday, July 1st. Lord Kenyon, Pro-Chancellor of the University of Wales, will take the chair at 5.30 p.m., and Sir Robert Jones, Bt., will deliver an address on the solution of the problem of crippleddom in Wales by means of a national organization. On the following morning a visit will be paid to the Heritago Craft Schools, Chailey, Sussex, when Mrs. Kimmels will explain the scheme in operation there. Dr. Llewellyn Williams and the Honorary Secretary, Sir John Lynn-Thomas, K.B.E., F.R.C.S., will meet the delegates at 9 a.m. on July 2nd, at 117, Piccadilly, when charabancs will be waiting to carry them to Chailey.

THE sanatorium erected at the Bermondsey Tuberculosis Dispensary will be opened by the Mayor of Bermondsey to-day (Saturday, June 12th), at 3 p.m., when Professor Leonard Hill, F.R.S., will give an address on sunlight and open air.

THE Fellowship of Medicine has arranged two clinical demonstrations on Wednesday, June 16th. Mr. Greeves will give a demonstration in ophthalmology at the Royal London Ophthalmic Hospital, City Road, E.C., at noon, and at 2 p.m. Mr. Sidney Boyd will give a surgical demonstration at the Hampstead General Hospital, Haverstock Hill, N.W. From July 5th to 17th the National Hospital for Diseases of the Heart will hold an intensive course. Beginning on the same date there will be an afternoon course at the Hospital for Diseases of the Skin, Blackfriars. Instruction will be given in the out-patient department, and venereal clinics will be held twice a week. The City of London Maternity Hospital hopes to begin a week's special course in obstetrics on July 5th. There will be a fortnight's special course of demonstrations, at 3 p.m., at the Royal Eye Hospital from July 12th to 24th. There will be an intensive course at the Prince of Wales's General Hospital, Tottenham, N., from July 19th to 31st, in medicine, surgery, and the specialties. Clinics will be held throughout the day in the various departments of the hospital and there will also be demonstrations on fevers and mental diseases. From July 19th to August 14th the West End Hospital for Nervous Diseases will hold a late afternoon course (5 o'clock) in neurology. Copies of all syllabuses and of the general course programme may be had on application to the Secretary of the Fellowship of Medicine, who will also supply copies of the *Post-Graduate Medical Journal*.

THE University of London Club, founded in 1914 for members of the University, has recently been reconstructed, and holders of certain diplomas granted by the University of London and its colleges, graduates of other universities, and holders of certain professional qualifications will in future be eligible. The chairman and committee will give an At Home on June 22nd, at 8.30 p.m., to meet the Chancellor of the University and members of the Senate. The Club House is at 21, Gower Street, W.C.1.

THE Public Health Department of the Essex County Council has issued invitations to a meeting at River Plate House, 7, Flinsbury Circus, London, E.C., at 3 p.m., on Friday, June 18th, to hear an address by Sir Robert Jones, K.B.E., F.R.C.S., on the cripple problem.

THE coming-of-age of the University of Sheffield will be celebrated on July 1st and 2nd, when the Chancellor, the Marquess of Crewe, K.G., will unveil the University war memorial, and a number of honorary degrees will be conferred.

AT a meeting of the Society of Antiquaries of London on June 3rd Drs. T. A. Bowes, J. D. Rolleston, and R. A. Young were elected Fellows.

A MEETING of the Biochemical Society will be held in the Wellcome Physiological Laboratories, Langley Court, Beckenham, to-day (Saturday, June 12th). The various departments of the laboratories and the stables and grounds will be visited from 11.45 a.m. to 1.30 p.m. Papers will be read during the afternoon, beginning at 2.30.

THE prizes at the London Hospital Medical College and Dental School will be distributed in the College Library on Monday, June 28th, at 3 p.m., by Mr. Neville Chamberlain, Minister of Health.

PRIZES and certificates won by the students of the London School of Medicine for Women will be distributed by Sir John Ferguson, K.B.E., on Friday, June 25th, at 3.30 p.m. Lady Barrett, C.B.E., M.D., M.S., dean of the school, will be in the chair.

Dr. NORMAN TATTERSALL, who has been for the past fourteen years tuberculosis physician for the Mid-Glamorgan area of the Welsh National Memorial Association, has been appointed tuberculosis officer to the city of Leeds. On May 22nd, at Bridgend, Glamorgan, he was the guest of a number of his medical friends at a dinner at which a bureau and an illuminated address were presented to him.

THE Wellcome Historical Medical Museum, 54a, Wigmore Street, W.1, was partially reopened on June 1st. It can be visited by members of the medical profession, chemists, pharmacists, nurses, and research workers generally from 9 a.m. to 6 p.m. on week-days, except Saturdays, when it is closed at 1 p.m.

THE reports received by the Colonial Office on the recent outbreak of sleeping sickness in the Ulupa district of Tanganyika show that an area of 10,000 square miles was involved. Its population, however, is sparse, averaging only about one per square mile; 3,000 natives were removed to fly-free areas; approximately 300 cases of the sickness were found, and 90 deaths were ascribed to it. Treatment by "Bayer 205" and trypanamide proved effective. Although the infection is widely spread, it has not attained epidemic proportions. The total number of deaths among natives recorded in 1925 was 161. No European died. A distinct branch of the medical department of the Government is being organized to deal with sleeping sickness, and during the past year six medical men have been exclusively employed on such investigations.

A NEW Order (1926, No. 535/S.24), dealing with factories and workshops in Scotland in which herring curing is carried on, came into force on June 1st, and contains regulations for the provision of adequate washing and first-aid accommodation. The circular containing details of this Order may be obtained from H.M. Stationery Office, price 1d. net.

FOR those who wish to take a holiday abroad various new opportunities are offered. Thus the Italian State Tourist Department, 12, Waterloo Place, S.W., is organizing a trip for British doctors to Italian health resorts, details of which were given in the *BRITISH MEDICAL JOURNAL* of April 17th (p. 728). A correspondent, who writes to us from Cortina d'Ampezzo in the Dolomites, praises highly the bathing equipment, the comfort, and the beauty of the surrounding scenery, at Meran, one of the resorts included in the tour. He mentions also the mud baths of Badgastein. Those who suffer from skin disease and a spirit of adventure may try the sulphur springs of Fasvalis in North Lithuania. It is said that the use of these baths was greatly interfered with during the war, because the German occupants would not allow patients to travel freely to the spot! But the baths were reopened in 1922, and the equipment is being improved. Finally, the P.L.M. railway has arranged a motor "Tour du Mont Blanc," which begins on July 10th. Starting from Chamonix, and passing through the Petit St. Bernard, Courmayeur, and the Great St. Bernard, the tourist can circle completely round Mont Blanc, through France, Italy, and Switzerland, in two days.

Dr. SERGE VORONOFF of Paris has offered a prize of 10,000 francs and a consolation prize of 5,000 francs for the best work on excessive and deficient action of the endocrine glands. Candidates must be members of a Latin race and possess a "Latin mentality."

THE Belgian National League for Combating Tuberculosis recently celebrated the twenty-sixth anniversary of its foundation under the presidency of Dr. Dewey, who has held office for twenty-five years.

AN international congress for combating the improper use of narcotics will be held at Philadelphia from July 5th to 10th.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

REFERRED PAIN.

DR. J. N. DEACON (East Molesey) writes in reply to "Y. T.": *Symptoms and their Interpretations*, by the late Sir James Mackenzie, deals with this subject.

DR. J. E. SHARPLEY (Kirkton Lindsey) writes in reply to "Y. T.": *Pain: Its Origin, Conduction, Perception, and Diagnostic Significance*, by R. J. Behan, M.D. (New York and London: D. Appleton and Co., 1914), is a comprehensive work containing many references; an excellent index to referred and reflected pain.

INCOME TAX.

"J." is one of four partners, and by agreement with the other three has insured himself against sickness; the inspector refuses to allow the deduction of the premiums in computing the firm's profits.

"*." In our opinion the premiums paid by "J." in regard of the future risk of sickness cannot in strictness be deducted as expenses incurred in earning the profits assessed. On the other hand, we are clear that any sums payable under the policy in the event of "J.'s" sickness are not taxable. We suggest that if his inspector will give him an assurance on the latter point he might drop his contention that the premiums should be allowed to him.

"N. G." and his partner gave up a dental practice in London at January 31st, 1926, and have since started a new practice elsewhere in medical radiology and electrology. They hold appointments at a hospital in London, and since January "N. G.'s" partner has seen private patients there.

"*." We assume that "N. G." can show that the dental practice was definitely given up—for example, by sale or mere discontinuance. On that assumption the partners are liable for the year ended April 5th, 1926, on (1) ten-twelfths of the average profits of that practice plus (2) their actual earnings for the two months, February and March, 1926. For the year ending April 5th, 1927, they will be liable on (1) their actual profits in the new practice for the first twelve months (or for the less period if the practice was started after April 5th, 1926) plus (2) the amount of their earnings from the hospital appointment and the casual dental patients whom they have retained. The expense of travelling to London to see the patients there seems to us to arise from the removal to set up a practice elsewhere rather than from the nature of the work, but there is a chance that the inspector would allow it.

LETTERS, NOTES, ETC.

THE ACTION OF DRUGS ON PLANTS.

SIR JAGADIS BOSE returned to the Royal Society of Medicine on June 2nd to deliver another "occasional lecture" on the action of alkaloids and other substances on the pulse of the plant and of the animal. The lecture and the experiments were largely a repetition of what he gave before the society in December,

1923, reported in these columns at the time. He began by drawing attention to the similarities between the plant and the animal in respect of contractile tissue and what he called in both cases nervous reactions; and described his own attempts to obtain an exact record of the responses to stimuli in the mimosa and other sensitive plants. The heart of a plant, he said, was not easy to discover, but it was affected, in the same way as the animal heart, by the administration of minute quantities of certain drugs in the way of stimulus and depression. There were substances which stopped the heart at contraction and others which stopped it at diastole, and it was possible to inflict what appeared to be a mortal blow upon the plant's heart with one drug and almost immediately to revive it with another which acted as an antidote. The sap of the plant, as the conveyor of nutrient material, corresponded to the blood of the animal, and he contested the theory that the movement of the sap was not physiological, but due to some unknown physical cause. To get a record of the mechanical pulsation of, say, the desmodium or any plant was difficult because the arteries of a plant were buried deeply in its interior, and the dilatation and contraction, compared with those of the animal, were extremely feeble, but the task was not hopeless. It needed a hand of infinitely more delicacy than the human hand to feel the plant's pulse, but with the help of an electric probe and a galvanometer he had succeeded in recording pulsations. He produced a plant which, on a dull day of London June, had been restoring to vitality, right up to the moment of the experiment by a prolonged bath of artificial sunlight, and on this he brought to hear in turn a whole battery of stimulants and depressants, poisons and their antidotes, administering to the plant a small amount of each, to illustrate the plant's alternate failure and revival. The attention of the audience was directed to the movement of a slit of light on the screen; when it moved in one direction it signified that the plant, under the almost immediate action of, say, potassium bromide was dying, and when it moved in the other direction that it had revived under the influence of a cardiac stimulant. He repeated this experiment with many substances, including small doses of cobra venom, which on plants and on small animals (though the animals did not figure in the demonstration) had an effect quite surprising in its violence.

A TRIBUTE TO SIR THOMAS BROWNE.

THOSE members of the medical profession to whom Sir Thomas Browne of Norwich, the author of *Religio Medici*, is still a lively inspiration and an "inexhaustible store of entertainment," may be interested in a copy of the second edition (published 1650) of his *Pseudodoxia Epidemica: or, Enquiries into Received Tenets and Commonly Presumed Truths*, which is to be sold by auction at Hodgson's Rooms, Chancery Lane, this afternoon (Friday, June 11th). On the flyleaf of this volume is a manuscript note, written in a fine hand, as follows: "FRANCES LE GROS: THIS BOOKE GIVEN MEE BY THE WORTHY AUTHOUR MY HONOR'D FREINDE, when I was one of his family and most happy in beinge so: 1650." It was to Thomas Le Gros, of Croxtwick, that Browne dedicated a few years later his *Hydriotaphia*; doubtless he was a relative of the Frances to whom Browne gave this copy of the *Pseudodoxia*. Further still, the volume contains the bookplate of Sir William Trumbull (1639-1716), who is known to have travelled in 1664-65 in company with Edward, the eldest son of Sir Thomas Browne. In the same sale are a considerable number of old medical books, none of them of really surpassing interest or rarity: the best is an English translation of Alexis of Piedmont in three parts (1562-63-66), printed in London; and another worth mentioning is a French treatise on sterility, miscarriage, obstetrics, and gynecology, by L. Bourgeois (1609), midwife to the Queen of France.

MEDICAL GOLF.

THE summer meeting of the Shropshire Medical Golf Association was held on the Church Stretton course on Sunday, May 30th. The course was in excellent order, but a very strong wind prevailed throughout the day.

The Captain's Prize, presented by Dr. Richardson (Grinshill), for which there were twenty-eight entries, was won by Dr. T. R. Elliott. Leading scores were:

Dr. T. R. Elliott...	82	-	7	=	75
Mr. W. S. Edmond...	97	-	20	=	77
Dr. I. B. Richardson...	97	-	12	=	78
Dr. J. Wheatley...	97	-	18	=	79
Dr. G. Laurence...	95	-	14	=	81
Dr. A. V. Mackenzie...	90	-	8	=	82
Dr. R. H. Urwick...	92	-	10	=	82
Mr. A. Lavelle...	97	-	15	=	82
Dr. J. A. Ireland...	93	-	10	=	83
Dr. H. G. Beckett...	96	-	13	=	83

The foursomes competition was won by Mr. A. Lavelle and Dr. Glynn Pigott = 4 down, Dr. J. Wheatley and Dr. T. R. Elliott = 7 down, Dr. Richardson and Dr. H. G. Beckett = 8 down.

The next meeting has been fixed for October 10th at the Wrekin Golf Club, Wellington.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 38, 39, 42, and 43 of our advertisement columns; and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 215.

A Chadwick Lecture ON HEREDITY IN RELATION TO MENTAL DISEASE AND MENTAL DEFICIENCY.*

DELIVERED AT THE UNIVERSITY OF LIVERPOOL

BY

THE LATE SIR FREDERICK MOTT, K.B.E., M.D.,
LL.D., F.R.S., F.R.C.P.

The subject of this lecture is an important question to the ratepayer and the race. It can only be answered by a careful consideration and comparison of published statistics, carefully recorded pedigrees, and an accumulation of facts obtained by systematic investigations regarding mental deficiency and insanity, registered and unregistered, in the past and present.

If insanity and mental deficiency be on the increase, as a superficial glance at the rapid rate of increase of registered cases during the past thirty years would indicate, the causes for the increase should be apparent in the answers to the two questions: (1) Have the conditions required for certification undergone any change; has the standard of sanity and mental efficiency been raised so that a larger number of individuals are admitted and detained in asylums? The corollary to this is the rapid increase of provision for housing and maintaining persons of insane and defective mind. (2) If there be a rapid increase of insanity and mental deficiency among the population, as the increase of certified insane and mental defectives, with increased provision, appears to show, what are the causes of this increase?

On the one hand, the eugenists would associate it with the tendency of modern civilization to interfere with natural selection and survival of the fittest, whereby, in the struggle for existence, poor types are weeded out; and to them (the eugenists) the inborn factor is paramount. On the other hand, the social reformer would associate the increase with drink, syphilis, and infectious diseases. As an example I would cite the recent epidemics of lethargic encephalitis, in which the moral sense of children and young adolescents is affected. Poverty, overcrowded dwellings, and all that this entails in improper upbringing, especially in our large towns and cities, must tend to mental and bodily defect. It is the old question of the relative importance of nature and nurture, in which is involved the great problem of heredity and the transmission of acquired characters. The eugenists will allow that good raw material, likewise bad raw material, may be found in all classes, and that there is abundance of good raw material spoiled by bad upbringing and bad conditions of environment. The social reformer should exercise discrimination and recognize the fundamental teaching of heredity that like tends to beget like, and that the most he can do by his efforts is to prevent good raw material being spoiled, and bad raw material being made worse. Undoubtedly education, sanitation, the feeding of the mother and offspring—in fact, child welfare—can, by providing a healthy body, develop and improve such potential mental energy and bodily conditions as the individual possesses. But if there is an inborn failure of mentality, either in psycho-physical energy, educability, or moral sense, then there must be an innate predisposition to some form of mental deficiency. Or if there be a lack of balance and control of the innate potentialities of mind, there will be a tendency towards the development of

insanity at the critical periods of life when the sex instincts matures and wanes.

The increase of registered insanity may be partly explained by a diminution of unregistered insanity as asylum accommodation has increased. Large numbers of this class of patient with chronic incurable mental disease have been admitted and detained for life in asylums. I need only refer to facts regarding accumulation, prior to the war, of 20,000 registered lunatics in the London County Council asylums. Of these, more than 10,000 had been there for ten years, and over 4,000 had been there for twenty years or more. The sheltered conditions under which the inhabitants of asylums lived was doubtless the means of increasing their length of life. During the war, however, there was a great increase of the death rate of the insane owing to low vital resistance, due to an insufficiency of animal fat in the food, and overcrowding, owing to many of the mental hospitals being used for war hospitals, thereby increasing greatly the liability to infectious diseases, especially to influenza, to pulmonary complaints, and to tuberculosis and dysentery.

The fact that a person died in an asylum does not necessarily show that he or she was suffering from a mental disease capable of hereditary transmission. For there are many cases of organic brain disease, such as general paralysis, arterio-sclerosis, and other conditions such as senile decay, which do not indicate hereditary transmission. This necessarily vitiates the value of statistical data and, to a less degree, pedigrees; for, very often, the only information that can be obtained is that the patient's parent or grandparent died in an asylum. There are a great number of cases which are not certified or sent to asylums which are more likely to transmit a neuropathic or psychopathic disposition than many of those who have been certified as insane.

In the past the legal conception of insanity has outweighed the medical conception. Nevertheless, it is primarily a medical question, and it is being recognized by the public that it is undesirable to send acute recoverable cases into asylums, without a chance of their being treated upon hospital lines in special institutions for that purpose. It must be recognized, however, that the great percentage of persons who are sent to asylums suffer with a form of mental disease which is transmissible; for it was found in the London asylums that 28 per cent. of recoverable cases relapsed within five years, and that 12 per cent. returned within one year. This periodic insanity is especially liable to be transmitted, either in an atypical form, or, more often, as dementia praecox in the next generation.

PREMISES OF MIND IN RELATION TO BODY.

Before considering the accumulated facts bearing upon heredity in relation to mental disease and mental deficiency it is desirable to lay down certain premises. The first is: What is mind? There can be no mind without memory; there can be no memory without body. All psychic processes are dependent upon physiological processes occurring in the body. The furniture of the mind is the memory store of our experiences and the bonds that unite them. The avenues of our experience are the senses which continually tell us of the existence of our body, its desires and aversions in relation to the world around, and how these desires and aversions, necessary for the preservation of the individual and the preservation of the species, may be effected by voluntary effort and judgement of value based upon our own experience or the experience of others. The dictum of Aristotle, "*Nihil in intellectu quod non fuerit prius in sensu*," would be more correct if "*et in motu*" were added; for every idea, every thought, tends to activation, either motor or glandular. The store of experience, then, depends upon the whole of the nervous system, but it also depends upon the circulating blood carrying oxygen by the arteries to the capillaries and there removing and carrying away by the veins carbonic acid and other products arising from the functional activity of all the tissues of the body, including the brain. If the blood carrying oxygen to the brain be cut off for a few seconds, unconsciousness occurs, and while this lasts it ceases to be a receptor of sensory impressions—therefore for a brief

* In his introductory remarks in this, the first of a course of Chadwick Lectures, Sir Frederick Mott spoke of the great pioneer work in sanitary science of Chadwick, in whose honour these lectures were given. He was the first to call attention to the necessity of legislation for systems of water supply and drainage in our cities and large towns. This he did in a report in 1842 of the sanitary condition of the labouring population of Great Britain. Sir Frederick Mott also called attention to the fact that most of his work on heredity was done at the Claybury Laboratory of the London County Council. Sir William Collins, one of the trustees, was the originator of the investigation of the causes of insanity by the London County Council and was Chairman of the Council when the laboratory was established; the lecturer took this opportunity of expressing his acknowledgement of the great service Sir William Collins had rendered to psychological medicine.

time there is no memory of the events happening in the world around; and for that period of time memory is not being furnished. The same happens in concussion and sleep. The quantity and quality of the furniture of the mind depends first upon the innate-hereditary dispositions dependent upon species (*Homo sapiens*), sex, race, and familial ancestry. The brain is the material basis of mind; it acts as a receptor of sensations pouring in from the world around or from the body itself. Physiology and medical science have taught us that psycho-physical energy is dependent upon biochemical substances circulating in the blood, and that absence of one of these internal secretions or derangement of the normal balance can seriously affect bodily and mental processes. The truth of this statement is best exemplified in the case of the internal secretion of the thyroid gland. In districts of Switzerland and Central North America iodine is deficient in the water and the soil, and there myxoedema and cretinism are very prevalent. It has been found that cretinous idiocy is due to an absence of thyroid secretion; there is stunted growth of the body and arrest of development of the brain. If thyroid gland be administered to infants suffering with cretinous idiocy, the growth of the body is promoted, the brain grows, and the mind develops, in virtue of its being able to act as a receptor and store of experiences. In districts where there is a subminimal deficiency of iodine, the prevalence of goitre, myxoedema, and cretinism has been enormously reduced by adding iodine in the form of sodium iodide in the salt. This is supplied by the Government, or small amounts are added to the drinking water. The effect upon the prevalence of this disease has been extraordinary.

The cerebrum, so far as we can judge from the cranial capacity, has not increased in size during the last twenty thousand years, nor improved in its capacity of storing experiences. Man has so developed as to be able to make continually enormous progressive advances in culture and control of the forces of Nature by the invention of articulate and graphic language by which the great social heritage of mankind has been built up in successive ages of civilization, whereby everybody who has a normal healthy body, especially a healthy brain, can fashion his mental furniture not only out of his own actual life experiences, but by abstraction from the collective experiences and judgements of past and present civilizations.

The three springs from which all the streams and rivers of mental activity have their source are: the primal instincts of self-preservation, preservation of the species, and the social instinct. Even the most complex and refined feelings and conduct of cultured people, when analysed, can be shown to have their vital urge—*elan vital*—deep down and unconscious in one of these instinctive forces.

The social instinct occurs only in some animals—for example, the bee, the ant, the dog—and the result is more intelligence and more unselfishness. Man has become what he now is by the progressive development of this social instinct. Man has had two languages for intercommunication—gestural language (the language of the emotions) and articulate symbolic intercommunication; also by beliefs, symbolic rites and ceremonies, traditions, customs, and usages directly or indirectly associated with the sex instinct and the preservation of the species, and indirectly and collectively connected with the preservation of the individual. There is an instinctive dread of loneliness, there is an instinctive moral sense—that is, a tendency to a sense of right and wrong—common to all human beings, and there is an inborn aesthetic sense in some favoured human beings, even shown in prehistoric times by the artistic efforts of man.

HEREDITY.

The life of the individual begins at conception when the male and female germ cells unite, each bearing the characters of the species, sex, race, and familial ancestry. The latent potentialities of body and mind constitute the raw material of inheritance out of which the furniture of the mind will be fashioned. The raw material of mental inheritance consists of psycho-physical energy, emotivity, educability, moral and aesthetic sense, and highest control.

The nearest approach to identity of mind and body in two individuals is, as Galton showed, in similar twins; there is identity because they are both derived from a single fertilized ovum, whereas dissimilar twins are derived from two separate fertilized ova. Galton found that similar twins brought up in different environments remained identical in bodily condition and mental disposition; whereas dissimilar twins brought up in the same environment remained dissimilar in bodily condition and mental disposition. Observations and calculations made by Professor Starch tend to show that from 60 to 70 per cent. of mental character and disposition is due to heredity and only 10 to 40 per cent. to environment and upbringing. Inborn characters are fixed and preorganized. What is the latent factor in the fertilized ovum which enables it to extract food and force from the maternal blood during the successive stages of pre-natal growth and development? A repetitive cell division to form organs and tissues with specific differentiated function occurs. By a vital harmonious interaction of the organs and tissues with differentiated functions a social organization of cells is built up on a definite plan of the species. The circulating blood and lymph and the nervous system integrate the functions of these differentiated structures and bring the whole into harmonious interrelation. The well-being and life of the individual from the time of conception onwards depends upon biochemical and biophysical processes in which oxygen is an essential agent. If time be altogether disregarded, heredity may, like habit, be conceived to correspond to memory and based—as Hering, Samuel Butler, and Laycock assumed—on one and the same dynamic principle. This theory has been elaborated by Semon in his work on the Mneme. The mnemonic principle is, that when living matter is excited by a stimulus it is altered dynamically, for when the stimulus has ceased the evidence of excitability is no longer observable and the organic living matter returns to rest; but that a dynamic alteration in the living matter has occurred is shown by the fact that a weak stimulus of the same nature suffices to provoke a revivescence of the same reaction in the living matter. Now if two stimuli simultaneously or successively excite living matter either of the two stimuli or successive stimuli will suffice to effect a revivescence of the whole simultaneous or successive reactions. The progressive development of the embryo from the fertilized ovum may be explained upon the mnemonic principle of an orderly sequence of similar repetitive stimuli proceeding generation after generation in the process of evolution. There has been established a preorganized mechanism in the fertilized ovum of man by which the embryonic cells in the course of their successive phases of development are able under favourable dynamic and circulatory conditions to extract from the maternal blood the materials necessary for building up all the tissues of the body upon an ancestral plan of species, sex, race, and familial pattern. "Like tends to beget like" is a well accepted truism from the time of Lucretius.

An inquiry which was carried out for me by Miss Agnes Kelley in the parish of Bethnal Green showed that like tends to beget like.

This inquiry was made with the object of comparing the heredity and social conditions of a certain number of insane, mentally defective, and normal persons. Sixty cases were taken in each group. The first group was of adult patients in the London County Council asylums; the second of high-grade mental defectives; the third of normal children from the elementary schools. The last two groups were at schools in different districts of Bethnal Green. Every care was taken to make as full and complete a family and social history as possible, and pedigree charts were constructed. The report was published in Part II, Annual Report of the Board of Control, 1915, and the following is a very brief summary of the results of this inquiry.

Insanity was very much more prevalent in the pedigrees of insane persons than in those of mental defectives—namely, in the proportion of 50 per cent. as against 25 per cent. of the defective cases. Conversely, mental deficiency was more apparent than insanity in the family histories of the defective children; while the charts of the normal school children only showed insanity and mental deficiency in a very small percentage of cases.

Good trades and high wages were rare in the mentally defective group. Though there were a few exceptions, the general type of employment was poor, and 75 per cent. of the fathers were casuals and unskilled workers.

There was a corresponding dead level of poverty in the home conditions of these cases, and the incapable mother was very

conspicuous in this group. In few of the asylum cases, and among still fewer of the mental defectives, could the home conditions be described as good, while one-third of the homes in each of these two groups were classed as "homes in which the food was quite inadequate, the clothing very poor, and bare necessities were lacking." The normal group showed a decided improvement in industrial conditions and in the care of home and children, and there were very few cases of intense poverty or neglect. There was, further, a very striking contrast in the dependence on parish and charitable assistance among the families of the normal group on the one hand, and of the insane and mentally defective groups on the other. The normals not only applied less often to the parish, but they were also less well known to charitable agencies.

It is a well known fact that a general durability of all the organs and tissues of the body, manifested by longevity, is inherited. This general durability implies not only functional harmonious interrelation of organs and tissues, but a generalized vitality of the body manifested by a psycho-physical energy and capacity of resistance to disease and recuperation from the effects of bodily injury and disease.

Conversely, a study of heredity shows that the life of the individual *ab initio* may be deficient, inasmuch as the fertilized ovum from the start has inherited a lack of durability or *vis propria*; it may be of the whole body or of some special organ or structure. The cerebrum, which from an evolutionary and developmental point of view is the last to come and is the most complex and refined in structure, is the first to go.

All the physico-chemical processes upon which mental activity depends take place in the thin layer of grey matter which covers the surface of the brain. These countless thousands of millions of cells which constitute the anatomical substance are developed from a relatively small number of cells of the original neural blastema by continuous repetitive divisions upon an ancestral plan of species, sex, race, and familial ancestry, and the result is a convoluted pattern first of the species, then of sex, then of race, and lastly of family. An arrest of development in the number of cells, so that we have a small ill formed brain with a defective convoluted pattern, will cause idiocy or imbecility according to the amount of arrest of development. The superficial extent of the cortex if spread out would be found in these cases enormously diminished as compared with a normal brain, and the dendrites are incompletely developed. They are, therefore, incapable of functioning. Proportional to the failure of development will there be a failure of capacity for mental processes—*amentia*. Mental deficiency is proportional to the defect of development of the organ of mind.

In dementia not due to heredity but to invasion of the brain by the spirochaete of syphilis there is progressive destruction of the normal developed brain by the poison generated by the multiplication of the specific organism, and the loss of mind is proportional to the degree of destruction.

A lack of psycho-physical energy may be transmitted in the male or female germ cells, causing an innate hereditary deficient *vis propria* which may lead to death at any period, pre-natal or post-natal. This is true hereditary deficiency and must be distinguished from congenital conditions affecting the growing embryo prior to birth. Often the two conditions are combined. There may be a lack of vital force (*vis propria*) on account of age of parents—namely, immaturity or senility at the time of conception. The question arises, Can exhausting conditions cause a lack of vital force of the male germ cells? Lead poisoning seems to be able to do this. There is evidence to show that lead poisoning in males whose occupation exposes them continuously to its influence leads to death of the embryo and abortion. It is conceivable that sexual excess, especially of the male, may greatly increase the chance of an immature sperm cell fertilizing the ovum. Nature seemingly has provided against this happening by storing the seed in vesicles, thereby permitting time for the healthy vigorous spermatozoa to grow and the weak to lose their vitality and die, thus permitting a process of survival of the fittest. But if there is continuous stimulation of the reproductive glands, the vesicles will only contain immature sperm cells with a lack of *vis propria* similar to those of the old man.

Lack of *vis propria* affecting the psycho-physical energy of the offspring is more likely to arise in the male germ cell than in the female germ cell because an extensive active process of cell-reproduction only occurs in the female after fertilization of the ovum and growth of the developing embryo, otherwise there is nothing like the amount of cell reproduction there is in the male.

The observations of Kyrle, which I can confirm, show that a large percentage of male infants and children that die of marasmus or tuberculosis have testes in which the embryonic cells of the spermatic tubules show no signs of development beyond the embryonic stage present at birth. This may be explained by an inherent lack of *vis propria* in the most important tissue of the body, and consequently a low power of general resistance to disease. A lack of *vis propria* may also be manifested in the highest evolutionary level of the brain with inability to complete its development; or there may be a premature failure of durability which shows itself after birth by various grades of mental deficiency and dementia *præcocissima*. In such cases an arrest of growth of the branching processes of the neurones, which are the anatomical correlation for higher mental processes, may be found.

Various forms of mental deficiency and mental disorder occur in primitive races similar to those occurring in civilized races, but the symptoms are coloured by the beliefs, social usages, and customs. Natural selection and the struggle for existence tend to eliminate the unfit more in primitive races than among civilized people, where pity and altruism are a part of culture. There is a tendency to end or mend a degenerate stock by the law of anticipation, whereby the offspring of insane parents who become insane do so at an earlier age, and in a more intense form, so that they are segregated and procreation is prevented. Not only is there a tendency for insanity to occur in the offspring of insane parents at an early age in adolescence, but there is a lack of vital urge, shown in a regressive atrophy of the sexual organs, especially in males. This leads directly to a lack of procreative power and indirectly to an absence of desire for the opposite sex. In females the sexual act, as compared with males, is passive, and therefore many cases of dementia *præcox* marry and have one or more children. But the stress of this normal physiological condition is sufficient to bring on the mental disease. The sex instinct is a great source of psycho-physical energy, and coexistent with a lack of this energy is a change in the behaviour of the male. He is brooding, introspective, and his mind is engaged in fantasy rather than reality.

A study of 4,000 cards of relatives in the London County Council asylums and a large number of carefully recorded pedigrees has shown that certain types of insanity are very liable to hereditary transmission. They are: (1) involutional melancholia, (2) manic depressive insanity, and (3) dementia *præcox*. Involutional melancholia in a grandparent may be followed, in the next generation, by manic depressive insanity, or dementia *præcox* in the third generation. A frequent sign of hereditary transmission was the existence of two, three, four, or five members of the same co-fraternity affected with dementia *præcox*, manic depressive insanity, or imbecility.

Eugenists would consider heredity the main cause of insanity and mental deficiency, and would affirm that the State should adopt means to prevent procreation by feeble stocks either by segregation or sterilization. But I do not propose to discuss this very debatable question of sterilization of the mental defective, such as the higher grade imbecile or the moral imbecile, which are found in all grades of society. Before any such proposal could be the subject of legislation much more information is required regarding heredity in relation to mental deficiency and the influence of education and social reforms. It must be remembered that social reformers, at any rate, are able to point to the fact that a larger number of people are living to old age with improved conditions of environment, and if there is a smaller birth rate there is a proportionally lower infantile death rate. Truth appears to me to be with both schools of thought. But, it may be asked, Would it not be wiser to spend the ratepayers' money in the preservation of good types and not waste money in trying to teach mental defectives who are uneducable; each of

whom costs three times as much as a normal child to educate? I do not infer that they must be left without any endeavour being made to develop such aptitudes as they possess. They have neither initiative nor creative ability; they do not possess the imitative faculty necessary for storing up in memory words and numbers, much less of utilizing them for various processes of abstract thought and reason. Now the association of the eye and hand appears before speech in the developing infant and in the process of evolution, therefore simple manual operations can be more easily taught by imitation than can book knowledge. It is reasonable to suppose that a certain degree of skill can be acquired in handicraft by imitation, whereas abstract symbolic thought and reason by means of words and numbers, except in the most simple way, cannot be acquired by the mentally deficient, owing to arrest of development of neural structures and function of the latest highest evolutionary level of the brain. The most successful colonies for mental defectives are those where manual occupational education and treatment are best carried out. Manual occupation has an uplifting effect on these poor children, for it affords a certain satisfaction to them to know that they are not so inferior to normal children as book learning, of which they are incapable, makes them feel. Successful occupation, emulation, and reward, moreover, engender self-respect and a sense of well-being. Rhythmic movements, singing and dancing, also are easily acquired by imitation for similar reasons, and produce a sense of well-being and a joy in life. Especially is it desirable to place mental defectives in colonies at an early age before the sex instinct matures, for owing to the mental deficiency there is a lack of control of the animal passions; they are unable to sublimate the vital urge along healthy lines.

The high-grade imbecile and the moral imbecile are found in all grades of society, and it may be difficult to find sufficient grounds for compulsory segregation till adolescence or until repeated delinquencies lead to a proper inquiry into his or her mentality. With the idiot and low-grade imbecile there is not this difficulty, and they are either infertile or are cut off in early life by disease or neglect, if not placed under care in an institution; whereas the higher grade imbecile, especially of the female sex, is fertile, and very liable to be the mother of a large illegitimate family of children, many or most of whom are weak-minded. In large cities and towns immoral imbecile women sooner or later, however, suffer with venereal disease, and this leads to sterilization and abortion or to the birth of dead children.

In rural districts the migration to the cities and large towns for higher wages has led to a steady and progressive deterioration of the mentality of the population. This is shown by the fact that although there is less drink consumed in rural populations than in industrial and maritime, yet there is, *pro rata*, a higher percentage of registered mental deficiency and insanity. This is a strong argument in favour of encouraging legislation which will lead to an increasing number of a better type of men and women being able to remain on the land and obtain a decent living. A policy which brought this about could not fail to be an important factor in the betterment of the race. Moreover, such a policy would be of great national economic value, inasmuch as the more land that was under prosperous cultivation the less would the nation expend in imports of food. The time has come when the nation must recognize the necessity of regaining a mentally and physically capable rural population with a higher standard of living and a higher birth rate of children potentially sound in mind and body. The Bible says that men do not gather grapes of thorns or figs of thistles. Neither can we expect to have a mentally efficient rural population under present conditions.

The dominions take elaborate measures to prevent mentally deficient emigrants arriving and settling in their country. They prefer to have those that are able to work on the land, so that this is another reason why, unless something is done to improve the conditions of our workers on the land, a steady further deterioration of the race must ensue.

A Post-Graduate Lecture ON HAEMORRHAGE ABOUT AND AFTER THE MENOPAUSE.

DELIVERED AT THE MANCHESTER ROYAL INFIRMARY ON
MARCH 16TH, 1926,

BY

WILLIAM FLETCHER SHAW, M.D.,
PROFESSOR OF OBSTETRICS AND GYNAECOLOGY, VICTORIA UNIVERSITY;
GYNAECOLOGICAL SURGEON, ROYAL INFIRMARY; AND SURGEON
FOR WOMEN, ST. MARY'S HOSPITALS, MANCHESTER.

Excessive or irregular haemorrhage about the menopause and haemorrhage after the menopause are among the commonest symptoms which make women seek medical advice. The symptoms are produced by many different pathological conditions, but this must never allow us to treat the condition lightly, or forget in any case that malignant disease of the uterus is one of the most frequent and by far the most important cause of this symptom.

I have chosen this subject for the particular purpose of emphasizing this fact, and what I wish to be remembered of this lecture can be epitomized in one sentence: "Excessive or irregular haemorrhage about the menopause and any haemorrhage after the menopause should always make us suspicious of malignant disease of the uterus, and we are never justified, in any circumstances, in treating these symptoms without making a vaginal examination, and, in the case of haemorrhage after the menopause, where vaginal examination reveals no growth in the cervix, without curetting the uterus to eliminate the possibility of malignant disease of the body." We all know this, we were taught it as students, and in the majority of instances we act up to it; but there are odd cases which escape, and these are those the consulting gynaecologist so frequently sees.

I do not think anyone but a gynaecologist realizes how many cases come for advice when the disease is past all hope of cure. Of course, in the majority of instances the fault lies with the patient herself; there is an ineradicable belief among women that haemorrhage at that time is quite normal; little attention, therefore, is paid to it, and the difficulty is to make this knowledge general among women without unduly scaring them.

Although the majority of cases brought too late for any hope of cure are thus accounted for, there are nevertheless a very large number who are kept under medical supervision for long periods without an examination being made, and when finally this is carried out the time for useful intervention is past.

Of all the cases of carcinoma of the cervix who consult me in private or in hospital I find I am able to perform a complete Wertheim's hysterectomy in only about one-third, and yet if these cases come early very good results are obtained; taking all my cases together, the earliest with the least favourable, and not making any allowance for death from intercurrent disease or operation mortality, I find that of all I operated upon more than five years ago there are alive and well at the present time 33 per cent. If only we could get all these cases in the earlier stage the curability would be much greater.

Operative treatment of malignant disease of the body of the uterus gives much better results than in the same disease in the cervix, and, moreover, the disease does not so readily invade other structures; still, in this situation as in all others, the earlier the disease is recognized the better is the chance of its total eradication.

It is a simple and easy matter to suggest and carry out an examination upon a complete stranger, especially where she has consulted a gynaecologist for the special purpose, but quite another matter when the patient is a personal friend or acquaintance, as she so often is to the general practitioner; and so, when first consulted about this symptom, quite naturally the practitioner is inclined to temporize, and hope that the cause may be one of the many simple ones and not the one he fears. In this way much valuable time is frequently lost, and it is necessary in the

interests of the patient that this diffidence be put on one side at the first consultation, and a determination made not to treat this symptom until the possibility of malignant disease has been definitely eliminated.

MENORRHAGIA AND METRORRHAGIA ABOUT THE MENOPAUSE.

Carcinoma of the cervix is a very common disease about the menopause, though it may occur at almost any age, and I have seen it as early as 22 and 24 years of age respectively. It is much more common in parous uteri, and is especially liable to commence in lacerations of the cervix. Usually the diagnosis is easy, as a friable area is found on the cervix, and the examination is followed by free haemorrhage. This sign alone should make us very suspicious of malignant disease of the cervix, as should a history of haemorrhage after coitus. The only type which presents any difficulty in diagnosis is that where the growth commences in the cervical canal and exposes only a tiny area of friable surface at the external os. In any doubt the patient should be examined under anaesthesia and a piece of the cervix excised for microscopical examination; but this is rarely necessary.

Erosion of the cervix consists of a slightly raised velvety red area extending on to the vaginal surface of the cervix from the external os. Haemorrhage is readily produced by the examining finger, and so this condition is that most likely to be mistaken for carcinoma of the cervix; firm scraping on the area with the finger generally settles the diagnosis, as the erosion extends only a few cells deep and the subjacent tissue is firm and resilient, whereas in carcinoma of the cervix the friable tissue extends much deeper, and it is usually possible to dig out a fairly deep ulcer with the finger. In a case of doubt it is necessary to examine the patient under anaesthesia and curette the cervix, or even, rarely, to excise a piece of the cervix for microscopical examination. Erosion is not a primary pathological lesion, nor has it any symptoms, but is itself merely the result of some irritating discharge, usually from the interior of the uterus, and curettage of this organ usually cures the condition.

Physiological Atrophy of Muscle.—As a uterus approaches the menopause the blood supply diminishes and the muscle atrophies; normally these changes run concurrently, so that the diminishing muscular tissue is able to exercise the same control over the diminishing blood supply as it did in full vigorous life. If, however, the atrophy of the muscle outstrips the diminution of the blood supply the same control cannot be exercised and menorrhagia occurs. It is the knowledge that this physiological change may explain the onset of haemorrhage which hurls our suspicion, and examination of the patient is often deferred in the hope that this will prove the cause of the symptoms. The only treatment is the administration of pituitrin, ergot, or hydrastis—drugs which will stimulate the weakening muscle to greater effort—but it is necessary again to emphasize the fact that these drugs must never be administered without a vaginal examination being made to eliminate any possibility of carcinoma of the cervix being the cause of the trouble.

Subinvolution.—If involution does not progress normally during the puerperium the uterus is left enlarged and hard, but regular in outline and mobile, and usually gives rise to menorrhagia during all subsequent menstrual periods, but frequently menstruation is quite normal for some years, and then, as the patient approaches the menopause, menorrhagia commences and becomes worse and worse until she is compelled to seek medical advice. At first sight it seems curious that haemorrhage at the menopause should be caused by a lesion produced during a puerperium, possibly many years previously, and that menstruation during the interval should have been quite normal. The explanation is simple. During involution two main changes take place: the excessive muscular tissue is absorbed, and the large blood vessels are replaced by small ones. This change in the blood vessels is one of the most interesting processes in the human body. Instead of the old vessel merely shrinking in size, new vessels are formed within the old one, and at the same time the elastic and fibrous tissues in the old vessel walls swell up, soften, and lose their staining

properties. In normal involution the old vessel wall is absorbed completely, leaving the new vessel to function in the involuted uterus. If involution is not complete portions of the old vessel wall remain, and the internal elastic layer of the vessel will remain permanently surrounding the new vessel; the less complete the involution the larger the amount of elastic tissue surrounding the new vessels. The increased bulk of a subinvolved uterus is due to want of absorption of the muscle fibres, and so this uterus can exert a greater muscular control over the vessels, but to counteract this the vessels are surrounded by varying amounts of elastic tissue. If the elastic tissue is in preponderance the patient will have menorrhagia from the confinement; if the elastic tissue only equals the extra contractile power of the uterine muscle menstruation will be normal until the menopause is approached; then the muscle atrophies, and even though the blood supply diminishes in normal amount the relationship between the two is upset, the muscle has to exert its effect on the

mass of inert elastic tissue, and so menorrhagia commences. The only cure of subinvolution is another pregnancy with a normal puerperium; but in these cases with late onset of the symptoms this is usually impossible. Pituitrin, ergot, or hydrastis will frequently diminish the amount of haemorrhage by stimulating the weakening muscle to fresh exertions; if this fails, curettage followed by these drugs is usually successful. If this also fails, it is necessary, in a few cases, to stop the haemorrhage by x rays, radium, or hysterectomy; the latter is more generally useful, as there are frequently other complications—matted appendages, prolapse, etc.—which can be cured at the same time.

Chronic Metritis.—This term is frequently used clinically to include subinvolution or any bleeding uterus which is enlarged, hard, and regular in shape; but in a strict pathological sense it means a uterus in which much of the muscular tissue has been destroyed by inflammation and replaced by fibrous tissue; this condition, by weakening the action of the muscular tissue, allows haemorrhage to occur, especially as the uterus approaches the menopause. Chronic metritis and subinvolution often occur in the same uterus. The only treatment is to administer pituitrin, ergot, or hydrastis, curette, and finally, if these fail, hysterectomy or radium.

Polypus.—Either mucous or fibroid polypi frequently produce haemorrhage at this time. The diagnosis is easy, as the polypus can usually be felt by the examining finger. Occasionally a fibroid polypus is entirely within the cavity of the uterus, and we can then do little more than suspect its presence from the fact that the uterus is a little enlarged and possibly the cervical canal somewhat dilated. Examination under anaesthesia and dilatation of the cervical canal allows a definite diagnosis to be made and at the same time the polypus to be removed.

HAEMORRHAGE AFTER THE MENOPAUSE.

Carcinoma of the cervix is one of the commonest causes of haemorrhage after the menopause. The diagnosis and treatment is the same as before the menopause.

Carcinoma of the body of the uterus is not nearly so common as carcinoma of the cervix, and does not occur before the menopause, although in some cases the period of amenorrhoea is only very short. There are no physical signs of this disease except a slight enlargement of the body of the uterus, and a definite diagnosis can only be made with the curette, when the material removed is usually so characteristic that a definite diagnosis can be made without waiting for a microscopical examination, and so hysterectomy can be completed under the one anaesthetic. Fortunately, simple panhysterectomy gives as good results as the extensive Wertheim's hysterectomy, and the mortality is much less. If examination of the cervix in haemorrhage after the menopause does not reveal any growth, curettage must always be undertaken to complete the diagnosis.

Senile endometritis is, fortunately, a very common condition. The atrophic endometrium is readily attacked by organisms from the vagina, becomes inflamed, and produces haemorrhage. Curettage completes the diagnosis, as the endometrium is always thin, quite unlike the thick

cheesy material in carcinoma of the body, and at the same time the curettage cures the condition. Senile endometritis is a definite inflammation, and the microscope reveals much small-celled infiltration.

Mucous Polypi.—An atrophic tissue like the endometrium after the menopause would not be expected to produce polypi, but it does so not at all infrequently, especially in the cervix, and I have seen at least half a dozen cases in the last six months. The polypi can usually be detected protruding from the external os, and curettage usually reveals no others in the body of the uterus. Curettage cures the condition.

CONCLUSION.

These are the commonest causes of haemorrhage about and after the menopause, though a number of others, like carcinoma of the vagina, do occasionally occur, but so rarely that we need not keep them constantly in our minds.

The one point we must constantly keep before us is the frequency of malignant disease as a cause of haemorrhage, and the fact that haemorrhage is usually the only early symptom of this disease, and so we must always consider any of these cases as likely to be malignant until we have proved the haemorrhage to be due to some other cause. If we will only do this these malignant cases will be detected much earlier and a far larger number cured of this dread disease.

COMPRESSION OF NERVE FIBRES.

BY

JOHN S. B. STOPFORD, M.D.,

PROFESSOR OF ANATOMY AND DEAN OF THE MEDICAL SCHOOL,
THE UNIVERSITY OF MANCHESTER.

COMPRESSION OF PERIPHERAL NERVES.

DURING a study of the lesions of peripheral nerves caused by missiles of war observations were made which indicated the possibility in certain circumstances of being able to diagnose compression of a peripheral nerve. The earlier investigations¹ led me to the conclusion that in a case of progressive compression of a nerve, uncomplicated by division of any fibres or serious intraneural changes, three stages could often be recognized.

1. The earliest sign generally found was increasing weakness of the muscles innervated by the affected nerve, demonstrating a loss of conduction in the efferent fibres, which was commonly associated with pain of a neuralgic character radiating along the course of the nerve and induced by movement or stretching of the nerve trunk.

2. The appearance of objective sensory disturbances which exhibited a characteristic type of dissociation. In uncomplicated examples of compression, hypalgesia and thermo-hypaesthesia progressing to analgesia and thermo-anaesthesia have been found to occur almost constantly before any definite tactile anaesthesia, even to the lightest possible tactile stimulus, could be recognized. During the appearance of analgesia the tactile sensibility diminishes and not uncommonly disappears. The development of analgesia in the fullness of the development of the nerve. By this time complete paralysis of all the muscles supplied by the nerve distal to the site of compression is to be expected.

3. The development of tactile anaesthesia, which remains less in extent than the analgesia and thermo-anaesthesia, unless the compression proceeds to complete physiological division and causes an absolute obstruction to the transmission of all impulses.

A knowledge of these three stages in the development of complete strangulation of a nerve, in conjunction with the study of a carefully elicited history, makes it possible to diagnose correctly a large proportion of examples of uncomplicated compression of some part of the peripheral nervous system. In my experience, such complications as partial division or the occurrence of intraneural fibrosis very commonly render diagnosis much more difficult and uncertain. The characteristic manifestations of compression are well illustrated by patients suffering from compression of the lower trunk of the brachial plexus by a cervical or first dorsal rib, and in a study of its production by the latter cause² it was found that in nine out of ten patients the objective sensory disturbance was

distinctive; further observations since the publication of that paper have confirmed this. The dissociated sensory loss is undoubtedly the most striking and the most helpful sign, and possesses the clinical advantages of being rapidly and easily demonstrated and not readily confused with any other neurological condition excepting possibly syringomyelia, an error which ought to be avoided without difficulty. It is important to mention that quite frequently patients are unaware of any sensory loss, and are surprised at the analgesia and thermo-anaesthesia which clinical examination reveals.

COMPRESSION OF THE SPINAL CORD.

During recent years my attention has been directed to the frequent appearance of a similar dissociation of sensation as a result of compression of the spinal cord by such lesions as extramedullary tumours, and this observation has proved on several occasions of considerable diagnostic value. The first occasion on which I noticed this was about eight years ago when investigating a patient suffering from fracture dislocation of the cervical spine and subsequent compression of the spinal cord. The man merely suffered from weakness of the muscles, altered reflexes, and hypalgesia and thermo-hypaesthesia below the level of the lesion, and after relief of the compression all these manifestations almost completely disappeared. Recently I was permitted to examine at the Manchester Royal Infirmary a patient who illustrated particularly well the manifestations of uncomplicated compression of the spinal cord, and exhibited undoubted resemblances to the observations made upon patients suffering from compression of a peripheral nerve. I am obliged to my colleague, Dr. E. Bosdin Leech, under whose care the patient was, not only for the opportunity of making several examinations, but also for permission to publish a brief report of the most significant features.

A man, aged 44, previously very robust and healthy, began to suffer from pain in the region of the shoulder about December, 1924. The pain often travelled down the trunk, especially on the right side, and after a time became very severe, attacks of exceedingly sharp pain occurring frequently and persisting for many hours at a time. He then suffered from stiffness of both legs and attacks of "pins and needles," extending from the level of the umbilicus down the front and back of both lower limbs. The stiffness was succeeded by progressive weakness of both legs until, at the time of his admission to hospital in November, 1925, he was unable to walk without assistance. Shortly before admission to hospital he also complained of difficulty in beginning the act of micturition, but he was able to pass urine normally once he had started the stream.

On examination there was no absolute paralysis of any of the muscle groups of the lower limbs, but very profound paresis and marked spasticity was obvious. The deep reflexes of both legs were greatly exaggerated, and there was an extensor plantar response and ankle clonus on both sides. On testing sensation it was found that there existed, as high as the level of the nipples, complete analgesia and almost complete thermal anaesthesia, although the patient was not aware of any objective sensory disturbance. No defect of any other form of sensation could be discovered, although carefully tested.

A provisional diagnosis of extramedullary spinal tumour at the level of the fifth dorsal segment was made and an injection of lipiodol made by Mr. H. H. Rayner, F.R.C.S., for confirmatory purposes. An x-ray examination after the injection demonstrated the presence of an absolute obstruction at the vertebral level suggested by the clinical investigation.

At the operation, performed by Mr. Rayner, it was found that the spinal cord was compressed by a tumour lying between the dura and bones. The tumour was exerting direct pressure upon the cord both posteriorly and laterally, but had not at any point penetrated the membranes. Microscopic examination of a piece of the tumour, made by Dr. G. E. Loveday, showed it to be an angioma.

A similar dissociated sensory disturbance has been seen in so many cases of spinal compression that I have come to regard it as a valuable aid to diagnosis, and it is primarily for this purpose that the report of this patient has been recorded, since it demonstrates unusually clearly the clinical manifestations of the progress of the compression, and bears rather a startling likeness to what has been found in similar circumstances in the peripheral nervous system. In a recent paper on extradural spinal tumours Stookey³ regards it as possible that the tracts in the white matter are more vulnerable to pressure gradually applied to the cord than the grey matter, and it is interesting to notice that in two of five cases of cervical extradural tumours he mentions that "early evidence of

disturbance in the pyramidal and spino-thalamic tracts was found." It is necessary, however, to point out that later in the paper it is stated that the tumour in one of these cases, a small pointed chondroma, was placed in such a position that it could compress a small circumscribed area of cord in the region of the left spino-thalamic tract, and that in this case the sensory disturbances were confined to the right side.

From personal observation it appears that uncomplicated compression of the spinal cord is commonly manifested by the following symptoms and signs, which as a rule present themselves in the order given:

1. Pain of a severe character, commonly described as of a "burning" or "tearing" nature, in the lower limbs and trunk below the level of the lesion. This may or may not be accompanied by pain in the distribution of the spinal nerves arising at the site of compression and produced by pressure on, or irritation of, nerve roots. In a few cases pain is absent, and the initial symptom is weakness of the legs.

2. Weakness and stiffness of the lower limbs and alteration of reflexes.

3. Objective sensory disturbances below the point of compression, at first affecting conduction in the spino-thalamic tract, but later affecting elements of sensation dependent upon other sensory tracts.

4. Bladder symptoms, accompanied in the limbs by more profound loss of voluntary power and movement and more profound and complete sensory loss.

It is not easy to offer any explanation for the occurrence of this dissociation of sensation, found often in compression of a peripheral nerve or of the spinal cord, as it is difficult to perceive any reason why the fibres conducting impulses concerned with pain and temperature should be more vulnerable than the others. In the case of compression of a peripheral nerve the effect must be upon the peripheral sensory neurones which have their cell station in the posterior root ganglion, whilst in compression of the spinal cord the mechanical effect of the lesion must be exerted upon the secondary sensory neurones, which for the pain and thermal paths have their cell station in the grey matter of the cord. It has been possible to follow the results of release from compression in a large proportion of the examples seen in the peripheral nervous system, and from the rapidity with which recovery of sensation appears in the earlier cases it seems improbable that actual degeneration had occurred during the early stages of the manifestation of the dissociated sensory loss. If the compression persists for some time before it is relieved it seems likely that degeneration subsequently occurs, but from the extremely rapid recovery in the earlier cases (within twenty-four hours of release in a few instances) it does not seem possible to conclude that degeneration of the fibres concerned with pain and thermal sensations is a necessity for the production of the characteristic sensory dissociation. It has not been possible to keep under observation a sufficient number of spinal cases after relief of the compression to express a definite opinion about the possibility of recovery from the objective sensory loss. In early cases where there has been only hypalgesia and thermal hypaesthesia, recovery, as far as one can determine by the customary clinical tests, has occurred. Nevertheless, it is very doubtful if recovery of sensation ever succeeds the establishment of complete analgesia and thermal anaesthesia, and this suggests the early development of degeneration, since there is no possibility of the fibres in the spinal cord undergoing regeneration.

When the analgesia was first observed in compression of peripheral nerves I was attracted for an explanation to the work of Ranson,⁴ which suggested that the afferent fibres concerned with protopathic sensibility are non-medullated, but subsequent researches have failed to support Ranson's view, and there appears to be no reason for believing that the protopathic fibres differ in structure from other sensory fibres.

SUMMARY.

Attention is directed to the frequent occurrence in spinal compression of a dissociated sensory loss, similar to that previously described as a result of compression of peripheral nerves.

Since the first indications of this characteristic sensory disturbance may be discovered at a fairly early stage in

the development of the compression and before the onset of profound paralytic symptoms, they may be regarded as a valuable aid to diagnosis. This often renders it possible to undertake the relief of compression before it has caused irreparable damage to the spinal cord.

In the present state of knowledge it is not possible to advance any explanation of the occurrence of this dissociation, but there is evidence which suggests that hypalgesia and thermo-hypaesthesia may appear before actual degeneration of fibres has occurred in either the peripheral nervous system or the spinal cord.

THE EFFICACY AND STANDARDIZATION OF HAEMOSTATICS.

BY

J. W. PICKERING, D.Sc.,

LECTURER ON HAEMATOTOLOGY,
AND

A. HEMINGWAY, M.B., Ch.B., M.Sc.,

DEMONSTRATOR OF PHYSIOLOGY,
KING'S COLLEGE, LONDON.

DURING the last two decades the use of organic extracts and of haemostatic serums in the arrest of obstinate haemorrhage has gained some prominence in medical practice, but no unanimity exists as to the value of the preparations in use. On the one hand, the claims of the makers of haemostatics are supported by a considerable amount of clinical evidence; on the other hand, the results of laboratory experiments by different observers are contradictory, the same preparations being described by some as active and by others as inactive (cf. ¹⁻⁴); whilst one well known haemostatic has been included amongst the nostrums described in *The Propaganda for Reform in Pharmacy* (1922).

The work here summarized was undertaken to ascertain the causes of these discrepancies and to devise, if possible, simple and reliable methods of standardization of those haemostatics which decrease haemorrhage by increasing the coagulability of blood.

Previous Experiments.

An examination of the experimental methods used in testing the efficacy of haemostatics reveals the causes of the varying results obtained by different observers, and shows that the conditions imposed differ radically from those existing in blood escaping from wounds. This is apparent from the following summaries of the methods employed.

1. The blood is kept fluid by the addition of either soluble oxalates or citrates which remove or immobilize the calcium ions of the plasma. The haemostatic is then added and coagulant action is noted when present. Blood under these conditions only clots on the addition of thrombin, and this technique merely indicates either the presence or absence of that coagulant. As calcium ions are essential for spontaneous clotting conditions are introduced which are never present either in normal or pathological bloods.

2. A variant of this technique is commonly used by the manufacturers of haemostatics in the standardization of their products. The speed of the clotting of blood after oxalation and recalcification at room temperatures is compared with that of blood similarly treated to which the haemostatic to be tested has been added. The efficacy of the haemostatic is estimated by any increase in the speed of clotting following its addition. Several errors are inherent in this procedure. The acts of oxalation and recalcification modify the stability of the plasma, so that its coagulability differs markedly from that of normal

blood,⁵ whilst the texture of the clots formed depends both on the speed of recalcification and on the temperature of the reaction.⁶ The consistency of blood clots is as important a factor in the arrest of haemorrhage as is the speed of clotting, since loose clots provide but slight resistance to the escape of blood and are readily broken up when bleeding is rapid. The value of this method is also strictly limited. Solutions of both oxalates and citrates partially inhibit the coagulant action of free cephalin,⁷ which is the active constituent of the large group of haemostatics known as "thromboplastins."

3. Blood kept fluid by the action of "peptone" has been used as a test fluid for appraising the activity of coagulants containing cephalin,⁸ but this method is not generally applicable, as some substances which provoke clotting in "peptonized" blood have little or no action on pure blood.

4. Three other methods of standardization were introduced by Hanzlik.^{2, 3} In his earlier work the preparations to be tested were dissolved in sodium citrate and were allowed to flow rapidly over the denervated pad of a dog's foot which had been cut down to below the papillary layer. The amount of blood escaping in a given time was gauged colorimetrically, and coagulant action was thus appraised. Tested by this method most of the newer haemostatics gave negative results, and were accordingly condemned as worthless. The favourable clinical reports were dismissed as examples of the inexplicable cessation of haemorrhage which sometimes occurs spontaneously. Later Hanzlik³ recognized that the use of citrates was a source of error, and he substituted normal saline as a diluent, again applying continuous irrigation. The efficacy of various haemostatics in the treatment of inaccessible haemorrhage was estimated by observing variations in the amount of blood issuing from a wound after their intravenous injection. In these experiments the wound was continuously irrigated with normal saline. In both groups of experiments either cessation or reduction of haemorrhage was frequently followed by a recurrence of bleeding. It was therefore concluded that the coagulant action of haemostatics is both variable and incomplete. Several circumstances contributed to these results. Continuous irrigation disturbs and dislodges clots, and thus favours a recurrence of bleeding. Although local vaso-constriction of the arterioles was prevented, alterations in the general blood pressure and changes in the tone of the capillaries of the wounded area were not estimated; consequently there were variations in the amount of escaping blood. The amount of tissue coagulant exuding from the cut tissue was not controlled, and in those experiments in which a haemostatic was injected intravenously and the wound continuously irrigated with normal saline uniformity of the dilution of the escaping blood was not assured. Nevertheless, experiments open to these objections have been used as the basis of statements intended to be authoritative.

Essentials in the Standardization of Coagulant Haemostatics.

The essential conditions for the accurate standardization of haemostatics may be summarized as follows: (1) No substance which acts either chemically or physically on blood, other than the haemostatic, should be present. (2) No substance should be removed from the blood. (3) The blood should be uncontaminated by tissue juices. (4) The blood should remain fluid sufficiently long to observe the effect of the haemostatic. In addition, the action of the haemostatic should be studied in different concentrations and at different temperatures, as these conditions modify its efficacy.

The Methods Employed.

Advantage was taken of the fact that blood shed through a paraffined cannula into a vessel completely coated with paraffin wax remains fluid at room temperature (17° C.) for at least an hour, provided the animal has not suffered severe haemorrhage. Blood under similar conditions remains fluid for thirteen to fifteen minutes at 37.5° C. Fluidity is thus preserved sufficiently to test the coagulant action of any haemostatic under the conditions previously named. Cat's blood was used, as it reacts more constantly to coagulants than that of the dog or rabbit. The animals were anaesthetized with a mixture of chloroform and ether.

In the standardization of the local action of haemostatics 10 to 12 c.cm. of blood was shed from an artery into a paraffined vessel through a paraffined cannula. By means of paraffined pipettes 1 c.cm. of blood was immediately transferred to each of a series of paraffined vessels containing 0.25 c.cm. of the haemostatic to be tested in the dilutions recorded in Table I, isotonic sodium chloride being used as a diluent. The speeds of clotting were then observed at 17° C. and at 37.5° C.

The efficacy of haemostatics when administered internally was tested as follows: 1 c.cm. of blood was shed through a paraffined cannula into a paraffined vessel, and was used as control blood. The haemostatic was then administered, and after an appropriate interval 1 c.cm. of blood was shed through another paraffined cannula inserted into another artery. The time of completion of clotting of this blood was observed at 17° C. and at 37.5° C. By "time of completion of clotting" is understood the time occupied in the conversion of the whole of the blood into a gel. The results given in Tables I and II are representative of 400 experiments. Fresh preparations of the haemostatics were used.

Results.

The haemostatics which precipitate blood plasma, such as ferric chloride and alum, have a low efficacy, as the coagula are loose in texture and permit the escape of blood from damaged vessels. The clots produced by the haemostatics named in Tables I and II are firm in texture and contract normally. They are thus efficient in the arrest of bleeding.

TABLE I.—Time of Completion of Clotting after the Addition of 0.25 c.cm. of various Haemostatics to 1 c.cm. of Pure Blood at 17° C. and 37.5° C.

Name of Haemostatic.	Source of Haemostatic.	Temperature.	Time for Completion of Clotting at Dilutions Stated.				
			Full Strength.	Half Strength.	Quarter Strength.	Eighth Strength.	Sixteenth Strength.
			min. sec.	min. sec.	min. sec.	min. sec.	min. sec.
Coagulen (Ciba)	Blood platelets	17° C. 37.5° C.	14 12 3 40	14 55 3 20	12 50 3 40	12 10 4 10	12 0 3 20
Thromboplastin (Armour)	Brain tissue	17° C. 37.5° C.	4 0 2 0	4 0 2 15	4 45 1 35	5 35 1 40	6 45 1 35
Thromboplastin (Ledele)	Brain tissue	17° C. 37.5° C.	2 5 1 0	2 15 1 5	2 20 1 0	2 50 1 0	2 40 1 35
Thromboplastin (Squibb)	Brain tissue	17° C. 37.5° C.	3 0 2 10	3 15 2 0	3 40 2 0	3 30 1 55	3 45 1 53
Cephalin (Armour), 3% solution ...	Crude cephalin	17° C. 37.5° C.	47 0 4 50	41 48 5 45	26 50 5 45	23 0 6 25	23 50 5 10
Protogulin	Thrombin	17° C. 37.5° C.	1 20 0 15	1 40 0 45	1 10 0 50	1 45 1 40	2 10 1 10
Hemoplastin (Parke, Davis) ...	Serum of ox and horse	17° C. 37.5° C.	19 30 8 10	19 30 8 25	16 10 4 57	15 0 4 48	15 0 3 25
Fibrinogen (Merrell)	Lung extract	17° C. 37.5° C.	8 5 2 35	8 30 3 0	9 17 3 30	10 33 4 0	13 50 4 55

TABLE II.—Times of Completion of Clotting of Pure Blood shed into Paraffined Vessels after the Internal Administration of the Haemostatics Named.

Name of Haemostatic.	Amount Administered.	Mode of Administration.	Dose in Man Recommended by Makers.	Time of Completion of Clotting at 17° C.	Time of Completion of Clotting at 37.5° C.
				min. sec.	min. sec.
Coagulen (Ciba)	1.25 c.cm. of a 3% solution	Intravenous	10 to 20 c.cm. of a 3% solution	24 0	10 55
Fibrogen (Merrell)	0.5 c.cm.	Intramuscular	3 c.cm. orally followed by 1 c.cm. subcutaneously for each 75 lb. of body weight	9 20	5 20
Thromboplastin hypodermic (Squibb)...	2.5 c.cm.	Intravenous	10 to 20 c.cm. every 24 to 48 hours	20 10	8 5
Thromboplastin hypodermic (Squibb)...	7.5 c.cm.	Intravenous		19 0	7 20
Hemoplastin (Parke, Davis)	0.25 c.cm.	Intravenous	2 c.cm. either intravenously or subcutaneously; in severe cases 5 c.cm.	11 0	8 0
Sodium citrate... ..	5 c.cm. of a 10% solution	Intramuscular	30 c.cm. of 10% solution intramuscularly	17 30	5 40

Note.—Hypercoagulability is evident in a few minutes after intravenous injection (two to three minutes). In intramuscular injection the results are naturally slower. In the experiment recorded with fibrogen (Merrell) the blood was shed three hours after injection, in that with sodium citrate one hour after injection.

Conclusions.

Each of the newer haemostatics accelerated the clotting of pure blood *in vitro*. Table I shows that preparations which appear inefficient at room temperature (17° C.) are active coagulants at body temperature. The standardization of haemostatics by reactions at room temperature is therefore undesirable. It also follows that coagulant haemostatics should be applied locally at body temperature and the wound should not be allowed to cool.

The application of a haemostatic by continuous irrigation is inadvisable, as the clots formed are disturbed by the moving liquid and complete clotting of the escaping blood is thus hindered. The use of a hot bandage (37° to 40° C.) soaked in the haemostatic avoids disturbance of the clots whilst providing a temperature at or near the optimum for haemostatic action. This practice is also useful when the haemostatic is administered internally when haemorrhage continues from an accessible wound.

Of the preparations investigated only those mentioned in Table II are used internally. They do not produce either a severe fall in blood pressure or intravascular clotting in the cat when administered by the routes and in the concentrations named. The experimental results thus agree with the clinical observations. Periodicity is evident in the coagulant action of some of the preparations, the lower dilutions being more active than the higher. These results correspond with those shown in the experiments of Waksman⁷ on the coagulant action of cephalin. The greater activity at lower dilutions may account for the sudden cessation of bleeding which sometimes occurs when initial haemostatic action is small.

The increased coagulability of the blood after the intra-

venous injection of small amounts of sodium citrate is not described, as it is established both experimentally⁸ and by numerous clinical observations.^{10 11 12}

Summary.

1. A method of standardizing the coagulant action of haemostatics is described.
2. Those haemostatics which precipitate blood plasmas are ineffective.
3. All the haemostatics named in Tables I and II are effective coagulants when the temperature of the blood is maintained at 37.5° C. Some are also effective at room temperature.
4. Stress is laid on the maintenance of the temperature of the wound at 37.5° C. in the use of haemostatics.
5. The experimental results recorded in this paper agree with the clinical observations on the efficacy of the haemostatics investigated, but are at variance with the findings of those investigators who have employed blood kept fluid by either oxalates or citrates.

ACUTE DUODENAL OBSTRUCTION DUE TO NEO-NATAL VOLVULUS.

BY

ALFREDA H. BAKER, M.B., B.Ch.,

RESEARCH FELLOW,

AND

VIOLET MIZEN, M.B., B.S.,

HOUSE-SURGEON.

(From the Obstetrical and Gynaecological Unit, Royal Free Hospital.)

We think this case may be of interest as illustrating one of the congenital causes of vomiting in infants dealt with by Dr. H. C. Cameron in his Lumleian Lectures, which were published in the *BRITISH MEDICAL JOURNAL*.

J. W. B., a male infant, born in the obstetrical unit of the Royal Free Hospital on July 23rd, 1925, after a normal pregnancy and delivery, was healthy, weighing 8 lb. 1 oz., at birth. Breast-fed, his progress was in every way normal for the first six days of life, and on the seventh day his weight was 8 lb. 6½ oz. On this day he began to vomit at irregular intervals after feeds, sometimes immediately, sometimes after a lapse of ten to thirty minutes. For three days he was given mercury and chalk 1/8 grain twice daily, and his food was changed successively to diluted breast milk, to Nestlé's milk (one part in twelve), to albumin water and brandy, and, finally, to normal saline.

On the second day of illness the vomit contained much bile, and on the third day vomiting became projectile. On the fifth day visible peristalsis of the stomach was observed. The abdomen was seaphoid, and at no time could any tumour be felt.

At first the stools were normal milk stools, but on the twelfth day of life (fifth day of illness) two stools were passed, consisting apparently of pure meconium. All later stools consisted of mucus only, tinged green. On two occasions the stomach was washed out with sodium-bicarbonate; the fluid returned contained large quantities of bile.

The diagnosis of low duodenal obstruction was made and the question of operation considered. The general condition of the infant, however, contraindicated operative measures. The child gradually grew weaker, and on the evening of the eighth day the temperature rose suddenly to 104° F., death occurring on the tenth day of illness.

Throughout the illness the baby at no time showed any sign of pain or shock suggestive of acute abdominal lesion. From the seventh day of life, when his weight was 5½ oz. above birth weight, he lost weight progressively, until at death, on the eighteenth day, he was 2 lb. 9 oz. below birth weight.

Post-mortem Examination.

On opening the abdomen the much dilated stomach and first and second parts of the duodenum presented; they formed one continuous distended cavity, the stomach passing from the pylorus to the left and upwards, to press on the left lobe of the liver. The coils of small intestine were collapsed and purplish-black. Gangrene of the small intestine had begun, and there was a very

fetid odour. The caecum lay on the left side of the abdomen, with a retrocaecal appendix. The tense ascending colon passed from left to right across the fourth part of the duodenum, under cover of coils of ileum. The transverse colon lay coiled under the dilated stomach on the left side. The descending and pelvic colons and the rectum were normally situated and attached.

Between the pylorus and the splenic flexure of the colon there was no direct attachment of the intestines to the posterior abdominal wall. The duodenum had a mesentery. There was acute torsion of the third part of the duodenum, and round this point as axis, there had been a volvulus of the entire gut distal to the third part of the duodenum and proximal to the middle of the transverse colon. The superior mesenteric artery was twisted spirally round the third and fourth parts of the duodenum. The presence of the artery, together with the acute torsion, effectually obstructed the lumen of the gut at this part. The vascular lumen was apparently also partially, or completely, obstructed.

The torsion of the duodenum was readily undone by twisting the mass of intestine from left to right, through an angle of 180 degrees. The duodenum was then seen as a straight tube

Diagram of position of viscera at birth. A volvulus of 180 degrees occurred, secondary to this condition, the caecum passing forward and to the left in front of the duodenum. The superior mesenteric artery was carried across the third part of the duodenum. A=Superior mesenteric artery, B=Duodeno-jejunal flexure, C=Transverse colon.

with a much thickened muscular wall, running straight down the abdomen; the birth condition had apparently been re-established, any further reduction producing a torsion in the opposite direction. The caecum now lay directly to the right of the duodeno-jejunal flexure. The main loop of small intestine between the duodeno-jejunal and ilco-caecal junctions passed from left to right, the returning limb of the loop (ileum) crossing to join the caecum directly in front of the duodenum.

The ascending colon passed round behind the duodenum through an arc of three-quarters of a circle; there was an acute bend, and then the transverse colon passed upwards and to the left, to lie under the stomach, as described above. The knuckle of bowel caused by the bend was tightly bound down on the left of the duodenum to the upper surface

of the mesentery of the ileum. The ascending colon was also adherent to the root of the mesentery as it passed behind the duodenum. The rest of the gut had a free mesenteric attachment.

The mesentery was drawn tightly round the third part of the duodenum, drawing with it the superior mesenteric artery, which thus passed successively downwards behind the duodenum, forwards round the right side of the duodenum between the duodenum and ascending colon, then transversely across the duodenum, passing into the mesentery of the ileum. A large branch of the artery passed obliquely downwards, crossing anterior to the duodenum, and then behind the duodeno-jejunal flexure, to supply the jejunum. This artery appeared to cause partial obstruction to the duodenal lumen. The lumen of the colon was obstructed by the acute flexure at the junction of ascending and transverse colons. The caecum and ascending colon contained faeces of a normal yellow colour. The ascending colon was tense and smooth.

The specimen suggests a primary malrotation in a direction the reverse of the normal, bringing the colon behind the duodenum, this rotation being arrested, at the stage where the ileum had passed forward across the duodenum, by the firm adhesion of the transverse colon to the mesentery of the ileum. Any further rotation could only occur by torsion of the duodenum and volvulus. After birth the irregular peristalsis induced by the obstruction at the duodeno-jejunal flexure, and more especially at the junction of the ascending and transverse colons, determined the occurrence of the volvulus, which carried the caecum through an angle of 180 degrees across the duodenum to the left, twisted the superior mesenteric artery tightly across the third part of the duodenum, and thus produced acute duodenal obstruction.

Our thanks are due to Professor McIlroy and to Mr. Norbry for permission to publish the case.

A CASE OF EMBOLECTOMY.

BY

SIR CHARLES GORDON-WATSON, K.B.E., C.M.G.,
F.R.C.S.,

SURGEON TO ST. BARTHOLOMEW'S HOSPITAL.

MR. GEOFFREY JEFFERSON is to be heartily congratulated on the successful case of embolectomy recorded in the *BRITISH MEDICAL JOURNAL* of November 28th, 1925. In a leading article in the same issue some comments are made (to which I shall refer later) on a case upon which I operated in 1911; the details of this were published in a clinical lecture on post-operative embolism of the femoral artery in the *Clinical Journal* of December 10th, 1913.

The publication of Mr. Jefferson's case has stimulated me to record a case on which I operated in 1914 at St. Bartholomew's Hospital, and which I should probably have published before but for the war.

A married woman, aged 27, was admitted to the maternity ward at St. Bartholomew's, under Dr. Barris, on March 2nd, 1914. She was suffering from mitral stenosis, and had severe albuminuria with oedema of both legs. On March 4th she was delivered with forceps. On the following day marked dilatation of the heart was noted, followed by dyspnoea. During the morning of March 13th sudden acute pain was felt in the right foot below the knee, and no pulsation could be felt in the leg below the groin.

I saw the patient about five hours after the onset of symptoms. She was desperately ill, with feeble pulse and severe dyspnoea. The right limb was somewhat mottled below the knee, cold and insensitive. No femoral pulse could be felt. I exposed the common femoral artery under local anaesthesia, the patient being propped up in the sitting position as she was unable to lie down. I removed an embolus from the bifurcation of the artery with some recent thrombus from above, passing a probe up the artery until blood flowed. The artery was closed with fine vaselined silk, and pulsation was restored to the limb immediately after the operation. Shortly after the patient was returned to bed it was noted that pulsation in the femoral could not be obtained. The patient died the same evening, about three hours later. Before death pulsation was absent from both femorals.

Post-mortem examination showed that thrombosis had occurred in the right common femoral artery up to the bifurcation of the aorta and down to the junction of the external and internal iliacs on the left side. Mitral stenosis, bilateral pleural effusion, and chronic interstitial nephritis were also found.

It is doubtful if this patient would have recovered in any circumstances in view of the severe kidney and heart disease, but the rapid and extensive thrombosis above the embolism showed that the operation was performed too late. It seems probable that after the embolus had been removed the probe passed through and did not dislodge to any extent the thrombus, which possibly was even then extending up to the bifurcation of the aorta. So feeble was the action of the heart that the channel was soon blocked up again—a block which before death occurred extended to the left common iliac.

This case emphasizes the importance of early operation if any benefit is to accrue.

In the case which I published in 1913 (operation in 1911), referred to in the *BRITISH MEDICAL JOURNAL* of November 28th, 1925, an embolus occurred in the common femoral artery a fortnight after laryngectomy for carcinoma. At the operation the embolus became dislodged when the artery was lifted up in the wound in order to apply a Crile clamp before arteriotomy, and was checked at the bifurcation of the popliteal. I did not expose the popliteal but awaited events. Gangrene occurred below the knee. I subsequently amputated just above the condyles, and the patient made a good recovery.

It has been argued (*BRITISH MEDICAL JOURNAL*, November 28th, 1925, p. 1018) that the lower end of the popliteal should then have been exposed and the clot removed, a procedure which may present considerable difficulties. In the *Clinical Journal* I argued that immediate massage or pétrissage, as described and advocated by M. Paul Claisse (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, June 10th, 1910, p. 766) in reporting a successful case, might have been

successful in breaking up the embolus at the time of lodgement and before thrombosis had occurred. I still think that this might have succeeded and ought to have been tried. Such an opportunity of breaking up an embolus at the instant of formation, before thrombosis had commenced, is not very likely to occur again. In this case no serious thrombosis had occurred above the femoral bifurcation, as femoral pulsation was restored after dislodgement of the embolus, and remained intact down to the knee.

Massage, by the breaking up of a peripheral embolus, deserves more attention than it has met with, especially in the aged.

ACUTE SUFFOCATIVE PULMONARY OEDEMA.

PREVIOUS references to acute suffocative pulmonary oedema seem to indicate that this condition is less rare than was previously thought. The etiology is uncertain, but the notes and reports recently received throw a little light on this problem which has an important bearing on treatment. Hitherto such remedies as atropine, strychnine, and pituitary extract have been prescribed for the relief of symptoms in the absence of a clear conception of the underlying cause. Disturbance of the vasomotor mechanism of the lungs was suggested by Dr. F. B. Julian (April 17th, p. 697), while Dr. M. Cohen (March 20th, p. 528) ascribes the occurrence of the symptoms to a sudden transient relative failure of the left ventricle.

I.—ASSOCIATION WITH CARDIAC DISEASE.

Acute suffocative oedema of the lungs is an event so serious and so far from being a rarity that I may perhaps be allowed to give my conclusions, based on a series of cases from 1921 to 1925, which I studied in some detail. The one factor common to all is an advanced degree of cardio-vascular sclerosis. Valvular disease was present in some, but not in others; in all of them there was just prior to the attack or had been at some time evidence of auricular fibrillation. The onset is sudden in patients previously comfortable, or at any rate not distressed by their arrhythmia, and in no case was there peripheral oedema. During the attack the patient is only partially conscious and may have no recollection next day of any measures taken during the attack. With one of my series I had several opportunities of examining the chest very early in an attack, and the picture presented to the mind by auscultation is that of an attack of asthma without the lengthening of the expiratory phase; the oedema process creeps over the lung lobule by lobule, and with the extension the distress increases steadily. I have not in any of my cases been able to make out increase in the diameter of the heart over what it had been the day before. As to treatment, all my cases responded to hypodermic administration of atropine, with or without morphine, but in some resection is necessary in addition.

I think the routine treatment for the cases with free expectoration should be 1/50 grain of atropine followed at once by resection to about 20 oz.; as the attack subsides a further dose of 1/100 grain of atropine should be given with at least 1/4 grain of morphine to ensure sleep and give the neurones time to recover.

I have used adrenaline and also amyl nitrite, and found them without appreciable effect. The events are intensely dramatic, and the patient, who at 10 p.m. was moribund, at 10 a.m. next day may be enjoying his ordinary breakfast without an added sound in his lungs and without recollection of the events of the night before.

The pathology seems to be some vasomotor derangement. It certainly is not heart failure in the ordinary sense, for in one of my patients the attacks lessened and ceased as the ordinary signs of muscle failure appeared, and in the last few weeks of her life she was free from the attacks, though she had the peripheral oedema and other signs of progressive heart failure.

The late Sir James Mackenzie in a private communication said he had done autopsies on several of these cases without being able to discover the actual cause of death: that the dilatation of right heart theory was not true—enormous dilatation was common enough but never in

association with this peculiar oedema; that he had little doubt it was a vasomotor phenomenon and not explicable on a mechanical basis, but that he had never found or known of any sensible explanation, experimental or otherwise.

It seems that we must wait on the physiologists to enlighten our darkness by further experimental work directed to this particular subject, which may also help to elucidate angina pectoris.

Stafford.

A. E. HODDER, M.B.

Of the cases cited in the JOURNAL of April 17th (p. 696) and by Dr. Cohen, March 20th (p. 528), no fewer than eight out of the eleven were the subjects of valvular heart disease. Dr. Coleman's fifth case may possibly also have been. The cardiac condition is not mentioned in the remaining two cases.

The known association of auricular fibrillation with mitral stenosis raises the question whether acute suffocative pulmonary oedema may be due to paroxysmal auricular fibrillation.

The following case is significant.

An adult woman was admitted to hospital one evening under my care with an acute abdominal condition; there were abundant moist râles all over the chest. The pulse was so rapid that it was impossible to count it with any accuracy. The patient was in the same distress as is seen in acute suffocative pulmonary oedema. Though she was spitting up frothy mucus it was not pink or abundant. The heart beat did not sound irregular, but it was so fast that it was difficult to estimate the rhythm. Something made me suspect that the auricle was fibrillating, and when the ward sister told me that the patient had previously been in the ward with some heart condition I no longer doubted it. Neither a general anaesthetic nor any operation was admissible; either would have been fatal; 1½ drachms of tincture of digitalis was given at once, and at six-hourly intervals 1/45, 1/30, and 1/15. The result was most gratifying, and next evening a laparotomy was performed under local anaesthesia, and a band which was obstructing the bowel was divided. The patient recovered.

I know that dyspnoea and attacks of nocturnal cardiac dyspnoea occur in patients whose ventricular beat is not so irregular as to suggest auricular fibrillation (I do not speak of the actual attack), but the presence of this condition may be demonstrated by a polygraphic tracing. I would suggest that a very careful investigation of the cardiac condition in all cases of acute suffocative pulmonary oedema may lead to an elucidation of the true nature of this condition. Such cannot, of course, be made during the urgent symptoms, but possibly some of the patients who survive the attack may show evidence of fibrillation in a venous tracing made when the urgent symptoms have subsided.

S. M. HEBBETHWAITE, M.D.Lond., M.R.C.P.

Cheltenham.

The following case of recurrent attacks of acute pulmonary oedema may be of interest.

The patient is a woman, aged 52 years. She has aortic incompetence, signs of which were first observed three years ago. Between her attacks she is very pale; the heart is moderately enlarged, and the systolic blood pressure in the arm is 160 mm. Visible pulsation in the carotid arteries and water-hammer pulse are well marked. There is oedema of the feet, but no signs in the lungs. She is irritable and difficult to manage.

During the past year she has had nine attacks of acute oedema of the lungs, all of a similar character. The interval between the first two was about three months, but they have gradually become more frequent, only a fortnight intervening between the last two attacks. They all occurred (with one exception) between 10 and 12 p.m., and nearly all on Sundays—perhaps brought on by excitement and overeating on these days. The onset is sudden and without any previous warning. On arrival, she is found making efforts to sit up in bed; she is anxious and terrified and appears to be aware of the danger of the attacks. The breathing is rapid and difficult. The face is pale and covered with a cold sweat. The lips and nose are livid. The fingers are cold and clammy. The pulse is feeble, small, and rapid. The temperature is subnormal. There is a profuse pink frothy expectoration and foaming at the mouth. After a short time consciousness is lost. Over the entire chest are heard numerous coarse bubbling râles. The attack lasts about two hours. On one occasion the patient had two attacks in one night, between which she recovered consciousness and lost her distress. On the day following an attack she feels quite well, and has often been found out of bed.

The treatment adopted in each attack consisted of a hypodermic injection of morphine 1/6 grain and atropine 1/100 grain, aromatic spirit of ammonia (1 drachm) by the mouth, and a hot-water bottle to the feet. If there was not much improvement in fifteen minutes the atropine was repeated.

London, N.

M. ROCKFELT, M.B., B.S.Lond.

IN the BRITISH MEDICAL JOURNAL for April 17th I notice some published cases of acute pulmonary oedema. My case was as follows:

A man, aged 60, with high arterial tension and mitral regurgitation, commenced his illness with acute bronchitis; on the second day bubbling râles were audible without a stethoscope, accompanied by considerable dyspnoea.

At 5.30 p.m. on the third day I was called in and found him with marked dyspnoea and cyanosis, drowning in his own secretion, although in the morning his condition was better than on the second day. Diarrhoea was present, and his pulse rate was 136, occasionally irregular. I immediately gave him a hypodermic injection of digitalin 1/100 grain, strychnine 1/64 grain, and atropine sulphate 1/75 grain. In two and a half hours' time he had completely recovered, with a pulse rate of 80. He asked me, in fact, what he might eat.

Kensington, W. E. V. SLAUGHTER, M.R.C.S., L.R.C.P.

II.—OCCURRENCE IN CHILDREN.

THE case of acute pulmonary oedema which Dr. Kenefiek recorded (JOURNAL, January 9th, p. 55) draws attention to a condition which is probably far from uncommon, yet only dealt with casually in textbooks and the medical schools. On January 9th I read in a newspaper an account of an inquest on a child aged 2, who was stated to have died from an acute exacerbation of a latent pneumonia, but, from the description given, I imagine that this was also a case of acute oedema of the lungs. During 1919 and 1920 there were recorded in the columns of the JOURNAL several letters on acute suffocative catarrh—again, presumably, the same condition. Personally I have seen two definite cases, one of which I reported (JOURNAL, February 28th, 1920, p. 293). Both were fatal, but indeed they were moribund almost at the very beginning of the attack. To deal effectually with the condition as Dr. Kenefiek did requires an exceptional combination of circumstances, since the acute cases of the disease are sudden in onset, occur in previously healthy patients, and are rapidly fatal. It must therefore be admitted that acute oedema of the lungs is a disease in which sudden death may occur in the apparently healthy, and which, if from no other point of view than the medico-legal one, warrants adequate consideration by general practitioners. The point I wish to make is that there are probably many cases of less acute or subacute oedema of the lungs in children which are not fatal, which are generally diagnosed as acute bronchitis, and which I certainly hold are non-microbial or non-inflammatory in origin. It is not uncommon to be called to a child who was quite well on the previous day or even on the same morning, and yet has suddenly developed a severe cold. Examination reveals some difficulty in breathing, and may be some degree of cyanosis, while loud crepitant sounds are heard all over the chest, both back and front. A diagnosis of a very acute bronchitis is made, treatment prescribed, and a guarded prognosis given. On the next day, however, the patient is found quite well and perhaps playing. I do not now regard such a case as acute bronchitis, but as subacute oedema of the lungs, which, in my opinion, is essentially anaphylactic in origin. The mother cannot tell how the child caught the chill, but may state that the patient on a day or two previously had eaten something unsuitable.

The diagnosis is made by the history, the rapidity of onset, and the absence of pyrexia. The only other disease which somewhat resembles it is acute diphtheritic laryngitis, but a careful examination will distinguish between the two conditions. The treatment is an emetic, followed later by a small dose of calomel and the administration of tincture of belladonna. The ordinary expectorant mixtures should not be given.

There is an analogous group of cases which, clinically at any rate, usually come under the category of acute nephritis, and which I view as essentially similar in origin. How often does one see a child with all the physical signs of acute Bright's disease, yet no history is obtained of any previous chill or acute infection, and in the course of a week or so the patient is quite well. No trace of albumin is found in the urine, whereas at the onset the urine was loaded with albumin and perhaps contained blood. In some of the recorded cases of acute oedema of the lungs

the abundant frothy expectoration was albuminous and accompanied by blood.

The study of acute pulmonary oedema is eminently one for the general practitioner who has the opportunity of seeing and treating it from the beginning. I do not think there is a more dramatic calamity than an acute case of this condition. I have been informed that Zola, somewhere in one of his books, describes a case; if any reader can supply the reference I should be very grateful.

STEWART McNAUGHTON,
Monkwearmouth Hospital, Sunderland. M.D.Ed., D.P.H.Camb.

III.—FATAL TYPE.

THE series of cases of this condition published in the JOURNAL of April 17th demonstrates, not the value of any particular line of treatment, but the fact that one type of the disease will recover in spite of the adoption of the classical heroic methods or of other methods of an empirical nature. I wish to counteract the unjustifiable optimism engendered by the recording of successful cases, and to point out that there is a type in which no treatment is of avail, as death occurs before aid can be summoned.

My personal experience extends to three cases; in one of them, occurring during the course of status epilepticus, the subcutaneous injection of camphor in olive oil resulted in subsidence of the oedema of the lungs; in the other two the result was not so happy. The first of these fatal cases was in a woman, aged 60, who was brought into hospital dead, with the typical pinkish froth issuing from her lips and lying on the front of her blouse; she had felt faint, gone into a shop, and horrified the shopkeeper by suddenly expectorating an enormous quantity of frothy fluid and dying within thirty seconds. The next case was in an old man with what at autopsy proved to be syphilitic aortitis and coronary disease; his death was no less dramatic. He had been in hospital for about six hours, and was fairly comfortable in spite of his failing heart and cardiac oedema of the lungs of a slight degree; suddenly he sat up in bed, called a nurse, jumped out of bed with foam issuing from his mouth copiously, and fell dead before he could reach a chair three yards away.

For the less acute type I would suggest that the rational treatment is the immediate subcutaneous injection of 1 c.cm. of pituitrin to reduce the pressure in the pulmonary circulation, atropine sulphate 1/30 grain to reduce the pulmonary oedema, with the knowledge that its action will not develop for about twenty minutes; phlebotomy to the extent of a pint from the external jugular vein; and oxygen if it can be administered through the froth issuing from the upper respiratory tract.

Birmingham. ERNEST BULMER, M.D., M.R.C.P.

IV.—DRY CUPPING: RECOVERY.

MAY I add my experience with reference to the cases of acute pulmonary oedema reported in the JOURNAL?

In March, 1925, at 2 a.m. I was called to see a lady, aged 65, a visitor at a hotel. On first observation the patient appeared to be in *extremis*. She was deeply cyanosed, speechless, and orthopnoeic. There was some coughing, with frothy mucus, and a hurried physical examination revealed dullness with moist sounds, but no heart murmurs. The pulse was very feeble; the temperature was normal.

A hypodermic of caffeine was administered, and the patient was dry-cupped extensively over the front and back of the chest. For this purpose a miscellaneous assortment of glasses were requisitioned, such as champagne, wine, and ordinary tumblers. The result was not picturesque, but the almost instantaneous relief afforded was striking and remarkable.

This lady has been a visitor again this year, and in the interval has remained well.

In this case I should certainly not think of administering antimony tartrate, as recommended by one of your correspondents; such treatment, in my opinion, is open to serious criticism.

Cairo. T. GERALD GARRY, M.D.

We may note here that in the *Journal of Physiology* for March (vol. lxi, No. 1, p. 98) there is a paper by R. K. Lambert and H. Gremels from the Instituto of Physiology, University College, London, relating some

experiments on the factors concerned in the production of pulmonary oedema. By means of the heart-lung preparation, the use of saline injections, and estimating the extent of effusion into the lung tissues by measuring the increase of electrical conductivity the course of the development of pulmonary oedema was followed. It was possible to rule out such factors as the rise of pulmonary pressure, the dissociation of the outputs of the ventricles, and affirm that the real cause of oedema lay in the changes which occur in the endothelium of the capillaries. This experimental conclusion seems to be in agreement with the results derived from clinical observation.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

SCURVY SIMULATING ACUTE INTUSSUSCEPTION.

The following case, being one of scurvy in a somewhat atypical form, presents certain features of interest.

A male child, aged 2½ years, had for three weeks been peevish and shown a disinclination for food. Two hours previously the child had vomited, and had suffered spasms of abdominal pain recurring every twenty minutes. Streaks of blood had been passed twice with normal motions. He was fat and slightly pale, but otherwise healthy in appearance. Abdominal pains of a colicky nature were obviously present. Physical examination revealed nothing abnormal, but the temperature was 101°.

Rectal examination showed no abnormality, and urine was normal. The symptoms of abdominal colic with passage of blood in a healthy-looking boy baby led to a tentative diagnosis of intussusception. It was decided to wait a few hours, however. Six hours later a very marked purpuric eruption was present over the abdomen and buttocks. This was followed within an hour by a large boggy swelling over the right side of the head and orbit. Shortly afterwards a similar tender swelling occurred over the lower end of the left femur. The gums were not affected. Scurvy was diagnosed and antiscorbutic treatment instituted. Within twelve hours the rash faded, and within forty-eight hours a great reduction in the size of the swelling occurred. Inquiry into the previous feeding of the child showed that there had been a vitamin deficiency in the foodstuffs given.

The chief points of interest in this case are: (1) that the child is older than is usual for this disease; (2) haemorrhage from the bowel is not a very common symptom in scurvy, and in this case made the clinical picture approximate to that of acute intussusception; (3) the purpuric rash, taken in conjunction with the abdominal pain, simulated Henoch's purpura, and it was not until the large haemorrhages occurred elsewhere that this diagnosis was abandoned.

ROBERT R. FOOTE, M.R.C.S., L.R.C.P. Lond.

Maidenhead.

A CLINICAL OBSERVATION BEARING UPON THE CORTICAL LOCALIZATION OF VISION.

The visual centre is situated in the cerebral cortex; around the calcarine fissure, on the mesial aspect of the occipital lobe. Each occipital centre corresponds to the homolateral half of each retina and to the contralateral half of each visual field. Hence destruction of one occipital cortex results in loss of the field of vision on the opposite side—homonymous hemianopia. The calcarine fissure divides the half-vision centre into an upper and a lower part, which correspond to the upper and lower quadrants of the related half-retina. A lesion of one of these parts causes a condition of quadrant hemianopia, a lesion above the fissure resulting in a loss of lower quadrants in the visual fields, a lesion below the fissure, of upper quadrants.

Special reference to the localization of central and peripheral vision has been made by Gordon Holmes in his Montgomery Lectures. From his cases of war injury he drew the conclusion that the macular and perimacular regions of the retinae are represented at or near the occipital poles of the hemispheres, and assumed that the centre for peripheral vision lies in the anterior portion of the visual area. He quotes a case of Riddoch's in support of this latter view. A missile and fragments of bone had inflicted injury on the mesial aspects of the occipital lobes, probably in the anterior portions of the visual centres; there resulted a contraction in the peripheral field of vision of each eye.

The case here put on record is a parallel one.

Trooper S. was thrown from his horse on September 15th, 1915. His head struck a sharp point of rock, which penetrated the skull at a point 5 cm. anterior to theinion, and exactly in the middle line. A gap of 2 cm. diameter was made in the skull, the superior longitudinal sinus was torn across, and fragments of bone were driven between the occipital lobes. A small amount of brain tissue was escaping. The bone fragments were removed,

and the sinus was plugged. The man made an easy recovery, but complained that he seemed to be looking through two tubes. Examination of his visual fields showed extensive and remarkably symmetrical loss in the peripheral portions (see figure). I have seen this man again after an interval of ten years. He had no disability from his injury other than the narrowed vision, which remains unchanged.

KENNETH MACKENZIE, M.D., Ch.M.Ed.,
Auckland, New Zealand. F.R.C.S. Eng.

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

—OXFORD DIVISION.

A MEETING of the Oxford Division was held at the Radcliffe Infirmary on May 26th, when Dr. CHEATLE presided over a gathering of thirty-six members.

Mr. WACSTAFFE related the surgical results of a rather unique motor accident, in which one ear crashed into another (a three-seater) at right angles. The car was not overturned, and no one was thrown out. Two of the three occupants in the second ear, both young women, received fractured pelvis; while the male companion who was on the side distant from the blow escaped injury. The patients were able to walk after two and a half and three and a half months respectively.

Mr. HUGH WHITELOCKE showed a case of a man aged 61, who had had difficulty in swallowing since 1910, gradually becoming worse. In 1918 x-ray examination showed a pharyngeal pouch, and gastrostomy was performed. The question of removal of the diverticulum was discussed. He also showed a woman, aged 51, with a spontaneous fracture of the humerus. Malignant disease as a cause appeared to be excluded, but it was uncertain whether the break resulted from a simple cyst, a blood cyst, or a condition of fibromatosis.

Mr. BEVERS showed a specimen of the complete sac and ovum in a case of tubal gestation, and also a fine example of a uterine cast from the same patient, whose recovery after operation was uneventful.

Mr. MAX PAGE gave a valuable address on the treatment of some common fractures, illustrated with lantern slides. His paper was subsequently discussed by several members.

ULSTER BRANCH.

THE annual meeting of the Ulster Branch of the British Medical Association was held in the King Edward Memorial Hall of the Royal Victoria Hospital, Belfast, on May 27th; the President, Dr. GAUSSEN (Dunmurry), occupied the chair.

Clinical and Pathological Demonstrations.

The following demonstrations were given:

Professor MACILWAINNE showed three cases of endocarditis—one of specific origin, one rheumatic, and one of subacute endocarditis.

Dr. MORROW showed a case of splenic anaemia, and one of specific enlargement of the liver.

Dr. G. G. LITTLE and Professor THOMSON showed a case of achalasia of the cardia.

Dr. BOYD CAMPBELL showed a case of intermittent claudication improved by removal of the arterial nerves from an inch of the femoral.

Dr. MARSHALL (Ulster Hospital for Children, Belfast) showed some cases of congenital heart disease, including two of patent ductus arteriosus.

Dr. ALLEN (Queen Street Hospital for Sick Children, Belfast) showed some cases of rheumatic endocarditis in various stages, a case of congenital heart disease, probably the patent ductus arteriosus type, and a case of coeliac disease with infantilism.

Dr. TURKINGTON showed a case of syringomyelia with cervical ribs, and a case of functional paraplegia.

Dr. McCaw showed a case of monilethrix of the hair in a woman.

Dr. FOSTER COATES showed a case of dementia praecox, and a case of disseminated sclerosis.

Mr. MITCHELL showed a case of abdomino-sacral excision of the rectum with preservation of the sphincter.

Mr. KIRK showed a case of pyrorectomy, of fibrosarcoma of psoas muscle, of epithelioma of the scalp, and of hypernephroma.

Professor FULLERTON showed a tuberculous kidney with cystograms; a fixation forceps and its use for ureteral calculus; epithelioma of lip, resection and plastic modelling of face; spinal graft; a case of cancer of the breast removed twenty years ago and now showing recurrences in abdomen.

Dr. CHERRY (Coleraine) showed skiagrams of a case of chronic obturator hernia and reported the condition found at operation.

Mr. IRWIN showed a case of Perthes's disease; of congenital coxa vara; of a mongolian child with cleft palate; of dysostosis cleidocranialis; of spastic paraplegia after Stoeffel's operation; of pathological fracture of femur; of transplantation of tendons for claw-hand; three cases of gastric ulcer operated on by Polya's method; of papilloma of renal pelvis.

Mr. CRYMILE showed a case of toxic adenoma of thyroid after operation; he also showed three consecutive cases of partial gastrectomy with retrocolic end-to-side gastro-enterostomy: (1) hour-glass stomach; (2) pyloric stenosis with cardiac lesser curve ulcer; (3) prolonged pylorospasm terminating in pyloric cancer; and the skiagram and specimen of a small gastric ulcer situated at the incisura angularis, treated by wedge resection and isoperistaltic proximal gastro-enterostomy.

Mr. MALCOLM showed a case, with recovery to normal function after five years' treatment for multiple surgical tuberculosis of hip, spine, phalanx, and subcutaneous tissue; a case of angioma of foot simulating caries of bone; two cases illustrating the treatment of dental cyst.

Pathological and Biochemical Demonstrations.

Demonstrations were given as follows:

Professor MACILWAINE, a specimen of an aortic aneurysm. Dr. HOUSTON, a method of demonstrating blood platelets; a coccus isolated from ulcerative colitis and found in four cases of the disease, but not in a fifth; a new method of complement fixation. Professor THOMSON, the kidneys of a fatal case of interstitial nephritis in a boy of 15. Dr. T. A. L. JOHNSON, methods of estimating blood sugar and blood urea. Dr. J. S. CAMPBELL, slides showing phagocytosis of red cells in four cases of pernicious anaemia, and cultures of gonococci. Dr. J. CHERRY (Coleraine), blood smears of two cases of asthma taken during severe paroxysms—one purely spasmodic in a lad of 13 with 12 per cent. of eosinophilia and 67 per cent. of polymorphs, and the other a case of catarrhal asthma in a woman with no eosinophilia and 90 per cent. of polymorphs.

Reports of Societies.

EDINBURGH OBSTETRICAL SOCIETY.

A MEETING of this society was held on May 12th, the President, Dr. R. W. JOHNSTONE, being in the chair.

Concealed Haemorrhage with Placenta Praevia.

Dr. F. J. BROWNE described a case of concealed haemorrhage with placenta praevia. The patient was a primigravida who had completed eight months of her pregnancy and was admitted to hospital on account of vaginal bleeding. Placenta praevia was diagnosed and the vagina was packed. Twelve hours later the pack was removed and external version attempted, but was not persevered with on account of the large amount of old blood clot that was passed. The membranes were therefore ruptured and spontaneous delivery took place three hours later. The placenta was normal in appearance and size, but overlying it was a quantity of fairly old blood clot, which covered practically the entire portion which had been praevia and extended into the upper portion as well. The clot weighed over 12 ounces. A catheter specimen of urine contained a moderate quantity of albumin. Three other cases described by Holland, Williamson, and Swayne were discussed, after which Dr. Browne stated that none were cases of purely unavoidable haemorrhage, and his own case

showed that in some cases of placenta praevia the haemorrhage might be concealed; the concealed haemorrhage, however, might be due to mechanical separation of the portion of the placenta situated in the lower uterine segment, and therefore was unavoidable. Thus placenta praevia could not be excluded in a case of concealed haemorrhage, and some cases of concealed haemorrhage without albuminuria might be accounted for in that way. In all cases described, however, albuminuria was present, and therefore it was justifiable to presume the bleeding to be of toxic origin, and thus bleeding in placenta praevia might sometimes be accidental.

Ante-natal Care.

A communication was read by Dr. W. F. THEODORE HAULTAIN on some practical aspects of ante-natal care, the great importance of such care to mother, child, doctor, and the State being pointed out. In the first place Dr. Haultain disagreed with the relative frequency of the vertex positions as stated in the leading textbooks on the subject. From statistics of 1,000 cases seen within fourteen days of labour at the ante-natal clinic of the Simpson Memorial and Royal Maternity Hospital, Edinburgh, and another 1,000 uncomplicated full-term cases delivered in the labour ward of the same hospital, the relative frequency in round figures was found to be L.O.A. 60 per cent., R.O.A. 30 per cent., R.O.P. 8 per cent., L.O.P. 2 per cent. The figures for primiparae and multiparae were taken separately in each case, but little variation was shown in these two main groups.

TABLE I.—Relative Frequency of Vertex Positions.

	Primiparae.		Multiparae.		Total.	
	Ante-natal. 452 Cases.	At Labour. 477 Cases.	Ante-natal. 548 Cases.	At Labour. 523 Cases.	Ante-natal. 1,000 Cases.	At Labour. 1,000 Cases.
L.O.A.	255=56.4%	304=63.7%	304=55.5%	350=66.9%	55.9%	65.4%
R.O.A.	146=32.3%	129=27.0%	188=34.5%	132=25.3%	33.4%	26.1%
R.O.P.	35=8.0%	40=8.4%	39=7.1%	31=5.9%	7.5%	7.1%
L.O.P.	15=3.3%	4=0.9%	17=3.1%	10=1.9%	3.2%	1.4%

The efficacy of pads as described by Buist in posterior cases was then discussed, and statistics were given of 70 consecutive occipito-posterior cases, which had been treated at the ante-natal clinic during the last two years; 38 of these were primigravidae, and in these the pads proved successful in 33 by substituting an anterior position for the posterior; in multiparae 25 were successful; thus in the whole 70 cases success was obtained in 82.8 per cent. In every case success or failure was judged by the position at labour as well as that found in the clinic after removal of the pads. To achieve success it was stated that (1) the treatment should not be done till the last month of pregnancy, (2) the head must be movable, and (3) castor oil should be taken at night when the pads were in position. No danger could be ascribed by the treatment to either mother or child, and the difficulty of the future labour could not be aggravated by the treatment, which was very simple and would in many cases avoid a tedious and often dangerous labour.

TABLE II.—Application of Pads in Occipito-posterior Positions.

	No. of Cases.	Successful.	Failure.	Per cent. Successful.
Primiparae ...	38	33	5	86.9
Multiparae ...	32	25	7	78.1
Total ...	70	58	12	82.9

The statistics of a consecutive series of cases of external version in breech presentations were then given. In all 28 cases had been so treated in the last one and a half years—12 in primiparae and 16 in multiparae. Among the primiparae version was successful on 9 occasions, and

among the multiparae 14 successes were reported; thus 82.1 per cent. were successful in the total number. Anaesthesia was recommended to aid success in primigravidae, and the manipulation was not advised till the last month of pregnancy. Failure in the primigravidae was attributed to the cases being of the "frank breech" variety, the failure in each case being noted at the time of manipulation, whereas in the multiparae the two failures were caused by a return of the breech presentation after it had been turned.

TABLE III.—*External Version in Breech Presentations.*

	No. of Cases.	Successful.	Failure.	Per cent. Successful.
Primiparae ...	12	9	3	75.0
Multiparae ...	16	14	2	87.5
Total ...	28	23	5	82.1

The technique to be employed in the all-important measurement of the diagonal conjugate was then gone into fully, and it was advised that it should not be taken more than six weeks before full term, for by that time the perineum and soft parts were soft and the promontory of the sacrum could be reached in most cases with comparative ease, whereas earlier in pregnancy it was usually a very difficult procedure. By the estimation at this time, there would still be plenty of time to decide on induction of premature labour if required, and if the pelvis was too small to warrant induction at that time then the case was one for Caesarean section and not induction. With regard to the position of the patient to allow this measurement to be taken with the greatest ease, Dr. Haultain advised the exaggerated left lateral position, the woman flexing herself as much as possible. Extreme gentleness in making the estimation was insisted upon so as to obtain satisfactory results.

In conclusion, Dr. Haultain thought that ante-natal care did not begin early enough, and suggested that patients should be seen after having missed one period; by that means a large number of abortions might be averted, especially those due to a retrodisplacement of the uterus, the bowels could be looked after, and all cases of slight sickness could be treated; thus might hyperemesis gravidarum be practically obliterated. Rarer conditions such as tubal gestation could also be recognized before rupture occurred and the woman's life put in danger.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A MEETING of the Aberdeen Medico-Chirurgical Society was held on May 6th, the President, Dr. J. CROMBIE, in the chair.

Dr. J. CRAIG read a paper on acute rheumatism in childhood. Although, he said, the term "rheumatism" was unfortunate, they could now pick out a definite entity, a disease that worked by successive recrudescences and reinfections and produced clearly defined clinical pictures. The manifestations of the disease were: (1) carditis, when the heart was mainly affected; (2) arthritis, when the joints were affected; (3) chorea, when the brain was affected; and (4) subcutaneous nodules, when the subcutaneous tissues were involved. These four chief phenomena, he went on to say, as might be expected in a general infection, often occurred together, but in the young invasion of the body by this disease was synonymous with invasion of the heart. It was pointed out by Dr. Craig that many series of statistics could be given to show the seriousness of the problem. In 1925, 13.5 per cent. of medical admissions to the Royal Aberdeen Hospital for Sick Children were cases of active rheumatism. These patients occupied beds for long periods, and the strain on the hospital accommodation was very great. Rheumatism was a disease of childhood. It was a little more frequent in girls than in boys, and more common in urban districts and in the artisan and labouring classes. The problem of the exciting cause was still unsolved. In Dr. Craig's opinion the real causal organism had not yet been found. The essential pathology

of the disease was one of focal nodules disseminated in the fibrous structures of the body. In the heart these nodules were found specially about the central fibrous body. Anatomical specimens were exhibited showing this body and its intimate relationship to the valves. Clinically the mitral valve was most frequently affected; but the aortic valve was more frequently involved than clinical examination showed, and rather as a valvulitis than as a simple endocarditis. In all the other parts affected the same nodules could be found. No special type of child was found to be the subject of rheumatism in Aberdeen. The children were often nervous children, but this nervousness might be due to the disease itself. The symptoms were often vague, but the combination of pallor, languor, and wasting was suggestive. A high temperature, though often present at the onset of the active phase, was not a striking symptom. Dr. Craig then dealt with the signs of carditis in some detail, and the significance of an accentuated second pulmonic sound, of the so-called reduplication of the second sound at the apex, and of mitral diastolic murmurs. In Dr. Craig's opinion the charting of the pulse rate was far more important than charting the temperature. Subcutaneous nodules were found to be not uncommon in Aberdeen—five out of thirty-six cases showed them. All the cases with nodules had marked involvement of the heart, and these nodules must be searched for, as they caused no pain and no symptoms. Tonsillitis was common in Dr. Craig's cases, but the role of the tonsil in rheumatism was somewhat difficult to define. Treatment should be centred on saving the heart, rest and patience being most useful in this connexion. The length of the period of rest in bed should certainly be at least six months. A home for treating the cases during convalescence was required, as accommodation for long periods could not be found in the hospitals. The child should be kept at rest so long as the pulse rate was falling and had not reached normal. The return to normal life should be gradual, and at each progressive stage the effect of graduated exercise on the heart and pulse rate should be noted. In most cases, in Dr. Craig's opinion, removal of the tonsils and adenoids was necessary; but the removal had little effect on the rheumatism itself. The use of salicylates in treatment was discussed; and Dr. Craig was of opinion that their usefulness was somewhat overrated.

In a discussion which followed Dr. WILLIAM BROWN, Professor ASHLEY MACINTOSH, Professor R. G. McKERRON, Dr. CHURCHIE, Dr. A. G. ANDERSON, and Dr. SOUPER took part.

THE RELATION OF THE BLOOD FLOW THROUGH THE KIDNEY TO URINE EXCRETION.

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland on April 16th, the President, Dr. C. M. WEST, in the chair, Professor J. M. O'CONNOR demonstrated Indian ink injections of the living kidney blood vessels, and read a paper on the blood flow through the kidney and its relation to urine formation. Professor O'Connor said that by diverting the blood of the left kidney down the vena cava into a reservoir while the blood pressure was maintained by a reserve of blood in a compensation tube connected with the aorta, the blood flow through the kidney at constant arterial pressure could be examined. On closing the compensation tube the flow with falling pressure could be determined. If the blood flow was compared with the prevailing pressures there was found with falling pressures a kink or kinks in the graph indicating increases or decreases in the blood flow. These kinks occurred at various levels of blood pressure and of blood flow, and were in the one animal relatively the same at all levels. A similar kink could be produced by diminishing the pressure in the renal artery by a clamp on the abdominal aorta, while the pressure was maintained constant in the rest of the body by a carotid artery connected with the compensation tube. Similar alterations in flow either positive or negative resulted from the injection of diuretics. These results were in keeping with the suggestion that the flow of blood through the kidney was regulated by a compression of the glomeruli by the secretion pressure of the urine. Experiments in which the

kidney vessels were injected with Indian ink showed in agreement with the theory that the relative number of glomeruli uninjected or only partly injected corresponded with the kink on the graph of blood pressure and blood flow.

The PRESIDENT said that until he had heard Professor O'Connor's paper he had not been aware of any opening of the glomeruli, and he did not see why destruction of the capsule should block up the vessels of the glomeruli. Referring to the injection and non-injection of glomeruli, he asked if Professor O'Connor allowed the injection to flow for any length of time first, and to continue flowing till the kidney got black, or if the injection just flowed through the kidney vein. He himself did not see why the blood should flow through every vessel of the kidney simultaneously.

Dr. W. A. TAYLOR asked if Professor O'Connor had ever tried to determine the amount of blood flow through the kidney in a given time, and to calculate from this the relation between the time and the amount of the blood flow through the kidney. He believed this flow was very great.

Dr. F. H. MOORE asked if Professor O'Connor had found the urine altered in any way after he had performed his experiments; if, for example, when the vessels were clamped and the blood flow altered, there was any albumin in the urine. Referring to nephritis, he said that he thought more investigation of the physiology of this disease was required. Oscar Clotts of Montreal, in referring to the altered circulation of the blood in a nephritic kidney as compared with that in an ordinary kidney, had said that in nephritis the kidney was altogether different from the original healthy kidney. Dr. Moore believed that rabbits suffered from chronic interstitial nephritis in their old age, and the study of these animals might throw some light on Professor O'Connor's theory, especially in relation to nephritis.

Dr. L. G. GUNN asked if, when Professor O'Connor was experimenting on one kidney, the second kidney was left alone, and said that sometimes the secretion of one kidney stopped altogether for a time, but that then the other kidney acted very vigorously. After nephrectomy it was quite common for patients to get pronounced attacks of polyuria, without any apparent reason at all.

Professor O'Connor, replying, said that the kidney was almost stony-hard, and this hardness varied according to the activity of the kidney. If the kidney was secreting well it was specially hard. When an injection was given it always came out through the renal vein. The blood flow through the kidney was very great; the maximum flow in a rabbit's kidney was 6 c.cm. of blood a minute. Cutting the kidney nerves caused vaso-constriction, which gradually passed off, but sometimes the constriction was so great that no urine flowed for a considerable time. The second kidney was hardly ever touched, but was nearly always left alone. It was commonly thought that the greater the amount of urine passed the better the kidney was working; but from his experiments he did not think it was so. He believed that as often as not, when the flow was small, the kidney was doing just as much work as when the flow was big.

THE CURE OF HERNIA.

At a meeting of the Brighton and Sussex Medico-Chirurgical Society held on June 3rd, the President, Dr. E. RIVAZ HUNT, in the chair, Mr. M. FITZMAURICE-KELLY read a paper on the cure of hernia.

In reviewing the progress made in the last quarter of a century, Mr. Fitzmaurice-Kelly remarked that the title of his paper represented an ideal, but that they were now substantially nearer to attaining it. One of the chief factors in the causation of recurrences, wound sepsis, was now to all intents and purposes abolished. Discussing the sacular theory of Hamilton Russell, he expressed the opinion that though it accounted for many cases, it was not as universally true as its advocates claimed, and that, from the practical point of view, while there were many cases in which the sac was the cause of the hernia, and its removal was sufficient to effect a cure, there were many in which there was damage, either primary or secondary, to the abdominal walls, which called for some measures of plastic repair. Discussing the methods advocated, Mr.

Fitzmaurice-Kelly thought that any method which sought to displace muscles by sutures was foredoomed to failure, and that such stitches did more harm than good. For a time the method of filigree implantation had many advocates, and in many cases of ventral and umbilical hernia had given good results; in large inguinal hernia the results were less certain, and any recurrence was very difficult to deal with. Further, the occurrence of wound infection was not uncommon, and was fatal to success. Transplantation of patches of fibrous tissue was introduced to deal with cases, such as direct inguinal and ventral hernias, in which there was a defect of the abdominal wall to fill. The immediate results were good, but many recurrences were reported, owing, it was said, to the absorption of the transplant. But this conclusion was traversed by Gallie of Toronto, who showed by careful experiments that the union of the transplant to the edge of the defect was the weak spot. To meet this he devised the method of using his fibrous tissue transplants in strips, in the form of living sutures, thereby fixing them immovably to the margins of the defect to be filled. The application of this method to many varieties of hernia, especially to recurrences and to cases not amenable to other methods of operation, was described, and Mr. Fitzmaurice-Kelly claimed that since its introduction a large number of patients previously regarded as hopeless could now be cured, and that in all cases in which the removal of the sac was insufficient it was the method of choice. Particularly was this the case in old patients with direct hernias, and in this connexion the use of spinal analgesia, and the consequent immunity from lung complications, was insisted upon.

The PRESIDENT asked whether it was necessary for the patient to lie up for a longer period after the living suture operation than after the more usual methods.

Mr. GEOFFREY BATE said he had originally been rather sceptical, but was now a convert to the method. He asked if any trouble was experienced with the wound in the thigh, and thought that many patients might object to such a large incision apart from the hernia wound.

Mr. H. N. FLETCHER mentioned Souttar's method of silk implantation. In umbilical hernia he had had very good results with Mayo's method of overlapping the aponeurosis. While the living suture method was probably the best for large ventral hernias, many of the slighter cases could be cured by layer-to-layer suture. He emphatically agreed as to the importance of spinal analgesia in preventing post-operative lung complications.

Mr. FITZMAURICE-KELLY, in reply, said that Gallie's researches showed that vascularization of the graft was complete in three weeks, and there was no reason in these cases for a prolonged convalescence. He had had no symptoms referable to the thigh incision in any of his cases; in most, it was easy to suture the gap in the fascia, but when three or more lengths had been taken the gap had been left open without any disability resulting. With regard to Mayo's operation for umbilical hernia, and many other of the older methods, it was certain that good results had been achieved. But all along the line the difference between the best surgery and the second best was represented by a small but constant percentage, and any method which gave a prospect of definite improvement in results should be adopted. Gallie's results, in over a hundred cases (mostly relapsed or rejected as unsuitable by others), so far showed no relapses, and this was a great advance on the results of any other method in similar cases. While not denying that the filigree method and Souttar's method had rendered service, he thought the method of living sutures was sounder in principle and better in practice, and should supersede them.

TYPES OF MENTAL DISEASE.

A MEETING of the Devon and Exeter Medico-Chirurgical Society was held on May 20th at the Devon County Mental Hospital; in the absence of Dr. R. Worthington the chair was taken by Mr. J. M. ACKLAND.

Dr. R. EAGER, medical superintendent of the hospital, showed cases illustrating some of the types of mental disease. The mental deficient type was exemplified by a man, aged 37, who was an imbecile of the "savant" type,

his specialty being the hymn-book. The titles and numbering of the hymns had been memorized by him from cover to cover so far as could be judged by the several tests put to him by the meeting. As an introduction to the manic depressive psychotic class of case, Dr. Eager gave a short explanation of the term defining the condition, and deprecated the loose nomenclature often associated with the melancholic form of the affection. There were two distinct phases for consideration in the manic depressive psychosis. The first was the melancholic phase, of which the chief feature was depression, as indicated by the abject misery in the face, by the general tendency to flexion throughout the muscular system (as evidenced by the bending of the trunk forwards with the chin sunk on the chest, knees flexed), and by retardation of thought. Two middle-aged men were shown in illustration of this phase. In each case the gait was typical, the general appearance miserable, and a very prominent detail was the difficulty in arousing them from absolute silence. In one of the cases there was difficulty in feeding. In contrast to these types, patients were shown of the manic phase, one of whom, a man aged 36, had been recently admitted in the acute stage; although his state was still critical he had made some progress with the continuous warm bath treatment. Four patients—a woman and three men, aged 40 to 65—were also shown, illustrating the milder and more chronic stage where volubility and a braced-up extensor carriage were the common features, with a mental condition varying from mild elation to considerable exaltation. Dr. Eager pointed out the physical wear and tear involved in this phase, whereas in the melancholic phase there was conservation of energy. Passing to consider dementia praecox, Dr. Eager emphasized the potency of hereditary influences in this condition and its occurrence in adolescence, at the threshold perhaps of a promising professional career. There was then a reversion to infantile habits; introspection, a "shut-in mentality," and a lack of concentration were predominating features. The facial aspect denoted surprise as contrasted with the misery depicted on the face of the melancholic type of depressive psychosis. Delusions occurred of the pseudo-type without a "reason basis"; the emotional reactions were indifferent, there were no interests, no anxieties, and no fears. The patients were imitative in action and in speech, and in attitude might show cataleptic phases, katatonia, antics, and mannerisms. Among other cases shown were a youth, who was an example of the "antic" class, and performed somersaults so continuously that a bald patch had appeared over his occiput; and a young bank clerk in whom micrographia and the habit of copying from books in his minute neat handwriting were the outstanding features.

Malarial Treatment of General Paralysis.

Dr. BAINBRIDGE gave a short account of general paralysis of the insane, and of his recent experience of the malarial treatment. The salient points in this disease were the long latent period and the earlier signs which so often appeared to be trivial. There might be a slight diplopia, a slight ptosis, or a transitory fit. As time went on pyrexial attacks might occur, and with coarse tremors, altered reflexes, Rombergism, and slurring speech the diagnosis soon left little to doubt if it had not been already established by an examination of the cerebro-spinal fluid. Dr. Bainbridge briefly touched on the various mental states associated with the disease—namely, the melancholic, paratoid, and the excitable. He urged the importance of carefully choosing patients for malaria treatment, and of not accepting as a cure what might prove to be only temporary improvement. He then showed cases in which malaria treatment had been employed.

Dr. J. W. MURDOCH demonstrated the following cerebro-spinal fluid tests: Lange's colloidal gold test and the Kalkas colloidal paraffin test, both showing the type of reaction found in general paralysis, and the Nonne-Apel (globulin) reaction. Slides were also shown illustrating the fourth ventricle with the well marked "frothing" or cat's tongue appearance in this disease; the cerebral cortex from a case of general paralysis of the insane with proliferation of glial cells and fibres, and degeneration of cortical cells; and a smear showing *Spirochæta pallida*.

Reviews.

TUBERCULIN: ITS VALUES DEFENDED AND EXPLAINED.

THE title of Dr. CAMAC WILKINSON's book, *The Principles of Immunity in Tuberculosis*,¹ has an academic quality that may possibly fail to invite the practical clinician. It is well therefore to state at the outset that, whether the doctrine which the author proposes is or is not accepted, the purpose of its presentation is a therapeutic one. The argument leads to measures of treatment and to methods of prevention, and full recognition is given to the claim that it is by success in these directions and not by ingenious speculations that the validity of the statements advanced can be effectively justified. The book, in a word, presents a scheme for the prevention and treatment of tuberculosis, and more particularly of pulmonary tuberculosis; and this scheme in essence is the use of tuberculin as a diagnostic and therapeutic agent and the establishment of tuberculin dispensaries for the thorough training of practitioners in the administration of this agent. It is an essential part of Dr. Wilkinson's case that such training is an indispensable condition of success and that only by prolonged and practical experience can the wise use of tuberculin be attained. So long ago as 1908 he wrote, "tuberculin is an invaluable and indispensable agent in the diagnosis of early tuberculosis"; and again, "pulmonary tuberculosis can be cured with certainty by tuberculin." After eighteen years of further experience he maintains and emphasizes these positions, and to explain and justify his faith is the purpose of the present volume. A very different verdict has been pronounced and is widely accepted. Dr. Wilkinson challenges this verdict on the basis of his personal observations, and the weight to be given to these must be a matter of individual judgement. What we have to do here is not to appraise the claim, but briefly to describe it.

The following are some of the principal propositions that Dr. Wilkinson sets out to establish: Infection by tubercle is a frequent occurrence in the early years of childhood; the usual avenue of invasion is the respiratory tract; the event may be unattended by any suggestive clinical disturbance, though evidences of pleurisy may sometimes be detected; the primary lesion tends to heal and may completely disappear, but bacilli travel from it to infect the neighbouring lymphatic glands; occasionally resistance here is ineffective and a generalized tuberculosis follows; for the most part, however, the invasion is controlled and localized after a process of struggle between the tissue cells and the attacking bacilli; this struggle may be indicated by fever and other evidences of toxæmia, but not necessarily by physical signs of pulmonary disease; a successful resistance—and this is a frequent experience—confers on the patient a large measure of immunity and protects him from reinfection in later life; the immunity, however, may fail in face of a mass reinfection, and this is the natural history of the ordinary case of chronic pulmonary phthisis; such a condition is not an early or primary manifestation of tubercle, but is, on the contrary, a late development in a patient in whom the first infection occurred in earlier years.

In accordance with these statements it follows that early mild infection with tubercle proves for most people a valuable protective influence, and, but for it, acute tuberculosis at various ages would be a common experience. The immunity is ample against what may be called the ordinary risks of infection, but it may break down in presence of a mass infection, and in such circumstances chronic pulmonary tuberculosis is established. Thus there arrives a new source of potential infection in the community, with the chance, or rather with the certainty, that the vicious and miserable circle will be repeated in other individuals.

It is common ground to all the authorities that protection from mass infection is of the highest importance, for immunity, however established, never reaches a level at

¹ *The Principles of Immunity in Tuberculosis*. By W. Camac Wilkinson. B.A. Syd., M.D. Lond., F.R.C.P. London: Nisbet and Co., Ltd. 1925. (Demy 8vo, pp. viii + 141. 10s. 6d. net.)

which such infection can be confidently and surely defied. Dr. Wilkinson by no means neglects this aspect of the question—indeed, he emphasizes it. But he wishes to start both prophylactic and therapeutic activities at a much earlier stage, and he asserts this to be possible. His claim is that by the use of tuberculin a pulmonary infection can be recognized before the arrival either of physical signs in the chest or of bacilli in the sputa; that by the same agent, in doses gradually increased to relatively large amounts, the tissue resistance to the invading organisms can be stimulated and carried to success; and that, consequently, the development of what he regards as a late event—namely, chronic pulmonary tuberculosis—can be prevented; and this alike to the advantage of the individual patient and the protection of the community. Further, Dr. Wilkinson affirms that the use of tuberculin in proper doses as a diagnostic agent is entirely free from danger and that in a non-infected person it produces neither a reaction nor other form of disturbance; that treatment by tuberculin in many cases allows the patient to attend to his ordinary calling and has therefore a decided economic advantage; and that even in advanced cases of open pulmonary tuberculosis it may free the sputa from tubercle bacilli, and in this way lessen opportunities for mass infection.

Naturally, in view of all these confident propositions the question arises: If tuberculin is of such high value, why, after so many years, is it so little used? Or rather, Why is it feared and condemned? Dr. Wilkinson will find many authorities who will agree that slight infections in early life have a protective value against non-massive infections in later years; but he ploughs for the most part a lonely furrow when he advocates tuberculin in the fashion he here proposes. Not that he is dismayed on this account. On the contrary, his answer is his own personal experience and the contention that his critics have not satisfied the conditions that he defines; and he warns the practitioner against the use of tuberculin, whether for diagnosis or treatment, unless he has had "three months' training, notably at a tuberculin dispensary." Dr. Wilkinson has made some converts, and he is resolute in his endeavour to make more. But he insists that the way is a hard one and that only those who follow it can be trusted as safe guides. He is evidently fully assured of the soundness of his position, and his book has the interest which belongs to the able and vigorous statement of a strongly held conviction.

TESTS FOR HEPATIC EFFICIENCY.

FULLY recognizing the difficulties of estimating the efficiency of the liver by tests, FIESSINGER and WALTER have reviewed this rather burning subject in a monograph, *L'exploration fonctionnelle du foie et l'insuffisance hépatique*,² which, while written in a philosophic vein, provides an up-to-date account of the now numerous methods of testing the various functions of the liver. The authors give useful references to the literature, especially of their countrymen, who have done so much in advancing new conceptions of this subject.

The monograph is divided into three parts: A summary of the physiology of the external and internal secretions, which occupies about one-fifth of the whole text, appropriately precedes the detailed descriptions of the tests for these functions; this section is the largest of the three. The functions of the liver, beginning with the external secretion of bile, are then taken seriatim, and the tests applicable discussed and their limitations indicated; among the tests for the glycogenic function the authors' honey test is briefly mentioned. The concluding part deals with the clinical aspects of hepatic insufficiency which may be complete, and then presents a uniform picture, or partial, due to disorder of one or some only of the numerous functions of the liver cells, with the result that very varying syndromes may be produced. These minor degrees of hepatic insufficiency are very common and readily induced by osmotic factors and by various poisons, and have been

specially investigated by Fiessinger, who insisted on the fragility of the liver cells. The commonest sign of moderate and chronic hepatic insufficiency is wasting, which is seen not only late but early in the course of cirrhosis.

The monograph closes with a chapter on the treatment of hepatic insufficiency, in which the use of waters, as at Vichy, Vals-les-Bains, Pougues, and Le Boulou, finds a place. In this open-minded treatise there is no attempt to insist on the value of laboratory tests at the expense of the information to be obtained from ordinary clinical examination.

MALARIA AND THE ENGINEER.

A SERIOUS responsibility rests upon engineers of the public works departments in the various colonies in that, after consultation with the health officer, on their shoulders is laid the burden of dealing with one of the gravest of the health problems of the empire—namely, malaria. This burden will be vastly lightened by Mr. HOME's book on *The Engineer and the Prevention of Malaria*.³ Too often works entailing enormous expense are undertaken on general lines of antimalarial campaigns without sufficient regard to the nature of the problem as presented in some special locality. Mosquitos differ in their habits and habitat; the growth of trees may screen a district from invasion, and the removal of them consequently make matters worse; drainage of large sites may be performed without producing eradication of the pest; in short, in many tropical countries money has been wasted owing to the measures undertaken being of the nature of trial and error instead of being the outcome of reasoned discussion of the particular local problem at issue.

Mr. Home's work is based upon wide experience of the question on the Central American coast, in the West Indies, in West Africa, Egypt, and Syria, and is of an eminently practical nature. After brief introductory accounts of the economic loss due to malaria (in which might be included the equally great financial loss from erroneous and ill considered antimalarial measures), and of the vectors of the disease, there follows an interesting summary of different schemes. The large question of low-land drainage is next taken up, and the methods applicable to salt marshes, lagoons, mangrove coasts, rice fields, river marshes, townships, and so on, and the special advantages of different systems in varying conditions. Hill drainage is next dealt with, and then the question of oiling, the use of larvicides, and the biological means of combating the mosquito. There is an excellent chapter on houses and quarters, their site, aspect, and construction.

Duo credit is given to other workers, and the illustrations throughout are very clear and really explanatory of the points they are designed to represent. There are remarkably few misprints; in fact we have only noted two—the specific name of *Stegomyia* in the footnote on page 14, and an extra syllable given to Mr. MacGregor on page 22.

There are four appendixes to the book, all of a most practical character. The first, by Lieut.-Colonel MacArthur, D.S.O., M.D., is on mosquito netting, a subject which should by now be well known to medical workers in the tropics from his writings in the *Journal of the Royal Army Medical Corps*. This is a matter on which knowledge has been, and is even now, hazy. The kind of netting to use, the reasons for the size of mesh to be employed, and the correct way of measuring and ordering it are all dealt with. The next two sections, from the pen of Dr. A. P. Buxton, now Director of the Department of Entomology at the London School of Hygiene and Tropical Medicine, are concerned with applied entomology in relation to mosquitos and houseflies. The importance of a knowledge of the meaning of the pH values of waters and of the way to estimate them is by no means a mere academic question in the breeding of insects; the last section of the appendix explains this matter very clearly, though briefly.

To sum up: This is a book which every public works engineer in the tropics should read and keep for future

² *L'exploration fonctionnelle du foie et l'insuffisance hépatique*. Par Noé Fiessinger et Henry Walter. Paris: Masson et Cie. 1925. (Med. 8vo, pp. 267, 5 figures. 30 fr.)

³ *The Engineer and the Prevention of Malaria*. By Henry Home, M.Inst.C.E. London: Chapman and Hall, Ltd. 1926. (Fanny 8vo, pp. x + 176; 43 figures. 3s. 6d. net.)

reference, and every medical officer in charge of a district would reap advantage from it, in that from his medical investigations he would be on firm ground in discussing the relative values of possible measures suggested for dealing with the particular combination of factors presented in his own area.

STRUMPELL'S "PATHOLOGY AND THERAPEUTICS."

A work which has reached its twenty-fifth edition¹ in forty-three years and has been translated into eight languages does not call for review in the ordinary acceptance of the term. The continued demand for it is sufficient proof of its usefulness. The death of Professor STRUMPELL early in 1925 necessitated another being entrusted with the present issue, and the choice of Professor CARL SEYFARTH was a happy one in that his association with the original author, as assistant, has led to the retention of the general plan of the work. Throughout, the clinical aspect of disease is constantly borne in mind and the correlation of symptoms, as far as is possible, with the underlying pathological conditions is never lost sight of. These are points which the student wishes to know, and which the physician should always visualize if his treatment is to be on rational lines and not purely empirical.

No book of so large a size as this—the two volumes before us contain 1,847 pages—can be quite up to date at the time of publication, but we notice the omission of certain matters which have been long enough before the medical world to be included in a work so recently revised as this. Thus, in the section on small-pox and varioloid in the first volume, no mention is made of alastrim, though epidemics have occurred in various parts of the world during the last five or six years; the value of the Schick test is now sufficiently established to warrant inclusion; the use of antidyenteric serum in toxic cases, especially of infection by the Shiga-Krusc organism, is not discussed at all; van den Bergh's test is not mentioned; the causal organism of Weil's disease is said to be a spirochaete, and the differences between spirochaetae and leptospirae are passed over, and there are other ways of diagnosing the disease than by injection of the patient's blood into a guinea-pig; trichinosis in pigs is not contracted by eating the faeces of trichinosed man; *Ankylostoma duodenale* is described, but the equally if not more common hookworm, *Necator americanus*, is not even mentioned. *Taenia nana* is said to be exclusively a parasite of man, and we have found no reference to the work of the last two or three years on the identity of this with the *Hymenolepis fraterna* of rats and mice. The sections dealing with tropical diseases, if they are to be judged by the standard of the rest of the work, would have been better omitted altogether. It is not possible to deal at all adequately with eleven important diseases in thirteen pages. Some tropical conditions—malaria and dysentery, for example—are not treated in this section, but among the general infective diseases; even there, however, amoebic dysentery is all too summarily dismissed, especially as amoebiasis is assuming increasing importance in Europe; its causation, symptoms, diagnosis, pathology, and treatment are all disposed of in a couple of pages.

The second volume is concerned chiefly with diseases of the kidney, the blood, and the nervous system. The last subject is treated under four main headings—the peripheral nerves, the spinal cord, the medulla oblongata, and the brain. These articles fill 574 pages.

The work seems to have been carefully revised, the coloured plates are excellent, misprints are few, the print and paper are good. There is an index filling fifty pages at the end of the second volume; it would be a great advantage if there were one also to the first. It is a matter for regret that the price of German books is maintained at a level which is almost prohibitive for the practitioner.

¹ *Lehrbuch der Speziellen Pathologie und Therapie der inneren Krankheiten für Studierende und Aerzte.* Von Professor Dr. Med. Adolf Strümpell. Fünfundzwanzigste völlig neu bearbeitete Auflage von Professor Dr. Med. et Phil. Carl Seyfarth. Erster Band und Zweite Band. Leipzig: F. O. W. Vogel, 1926. (Sup. roy. 8vo: Bd. I, pp. xi + 872, 194 figures, 10 plates; paper cover M.50, bound M.53. Bd. II, pp. ix + 955,

NOTES ON BOOKS.

Is the new edition of *Instructions for Collectors*, No. 7, *Blood-sucking Flies, Ticks, etc.*,⁵ issued from the British Museum (Natural History). Major AUSTEN has brought his work up to date by incorporating knowledge established so recently as the beginning of the present year. Mosquitoes are not included; these are dealt with in a special issue of this series. In the first part are notes on the various blood-sucking flies, their geographical distribution, and the appearance, life-history, and habits of each. Any work written by this author can confidently be expected to be expressed with conciseness, accuracy, and clearness; but the accounts of the habits of these pests are so graphic and realistic that for one who has lived in the tropics the mere reading of them makes him hear again their hum and feel their vicious stings, though he does not suffer from the irritating after-effects. The remainder of the work deals with the collector's outfit and the best ways of collecting, killing, labelling, preserving, and transmitting. The directions are so clear that there is no longer any excuse for the arrival of bruised, broken, mould-covered specimens at the entomologist's laboratory. The illustrations are excellent. In a future edition drawings of some of the larvae might with advantage be included to round off the information imparted by the descriptions.

The third edition of *A Text-Book of Medical Diagnosis*,⁶ by Drs. JAMES M. ANDERS and L. NAPOLEON BOSTON, of which the first edition was reviewed by us nearly fourteen years ago (*JOURNAL*, September 28th, 1912, p. 796), has been brought up to date by inclusion of a large number of new subjects, such as filterable virus, blood pressure, electro-cardiograph, endocrine glands, lipodystrophia progressiva, bronchospirochaetosis, thromboangiitis obliterans, aplastic anaemia, pyorrhoea, fractional gastric analysis, duodenal intubation, estimation of liver function, botulism, basal metabolism, sickle-cell anaemia, trench fever, acute epidemic encephalitis, alastrim, epidemic pleurodynia, and the Bárány test. The general arrangement is excellent and the descriptions are clear, concise, and accurate, so that we have no hesitation in recommending this volume, in spite of its unwieldy size, as a work of reference. The illustrations are good, with the exception of the photographs of the acute exanthemata, which are too blurred to be of any value.

The third edition of *A History of the London Hospital*,⁷ by E. W. MORRIS, house governor since 1903, will be welcomed by all who have a personal interest in hospitals in general and "the London" in particular. We reviewed the first edition at considerable length on October 8th, 1910 (p. 1058); the present edition has been revised and largely rewritten, with the result that its historical value is considerably enhanced. The dramatic difference in the treatment of the sick poor in early days and in the present is brought into vivid relief by the plentiful illustrations scattered through the book. The pleasant style in which the numerous facts are narrated is a marked feature of the volume; the chronology of the hospital and the bibliographical list of bygone members of the hospital staff are particularly valuable. We anticipate that the demand for this really interesting history will be large.

Low's Handbook of the Charities of London, 1926,⁸ gives the objects, dates of formation, offices, and secretaries of over 1,200 charitable institutions. It remains a standard work of reference, particularly notable for its well classified table of contents, and has proved its worth by reaching its ninety-first year of publication.

⁵ *Instructions for Collectors: No. 7. Blood-sucking Flies, Ticks, etc.* By Major E. E. Austen, D.S.O. Fifth edition, revised and enlarged. London: British Museum (Natural History). 1926. (5½ x 8½, pp. 28, 13 figures, 6d.)

⁶ *A Text-Book of Medical Diagnosis.* By James M. Anders, M.D., Ph.D., LL.D., and L. Napoleon Boston, A.M., M.D. Third edition, entirely reset. Philadelphia and London: W. B. Saunders Company, 1926. (Roy. 8vo, pp. iv + 1422; 528 figures, 20 plates. 55s. net.)

⁷ *A History of the London Hospital.* By E. W. Morris. Third edition, revised and largely rewritten. London: E. Arnold and Co. 1925. (Cr. 8vo, pp. xii + 503; illustrated. 7s. 6d. net.)

⁸ *Low's Handbook of the Charities of London, 1926.* Ninety-first year of publication. London: T. A. Newbery. 1926. (Cr. 8vo, pp. lxxi + 157, 1s. 6d. net.)

PREPARATIONS AND APPLIANCES.

An Appliance for Bedridden Patients with Incontinence.

As appliance for ensuring increased comfort to helpless paralysed cases suffering from incontinence of urine has been devised by Messrs. W. B. Hilliard and Sons, of 123, Douglas Street, Glasgow, C.2. It consists of a closely fitting rubber scrotal receiver, a rubber tube with spiral attachment preventing compression, and a hollow metal piece which is thrust through and remains in the mattress and allows the tube to be passed freely through it. The urine is collected below the middle of the bed in a receiver. The appliance is of value in rendering constant changing of the bed linen unnecessary and in relieving the patient's discomfort and the nurse's labour. The price of the complete set, with directions, free by post is 70s.

THE SECOND AUSTRALASIAN MEDICAL CONGRESS.

UNDER THE AUSPICES OF THE BRITISH MEDICAL ASSOCIATION,
DUNEDIN, NEW ZEALAND, FEBRUARY, 1927.

LAST summer we announced that the second session of the Australasian Medical Congress (British Medical Association) will be held in Dunedin, New Zealand, in February, 1927. The scientific proceedings will be conducted in twelve sections, which will meet in the buildings of the medical school, to which important additions are now being made. The President of the congress is Dr. L. E. Barnett, C.M.G., Emeritus Professor of Surgery in the University of Otago. The congress will be opened by Sir Charles Fergusson, Bt., Governor-General, on February 2nd, and will continue until February 9th. A list of the sections was published in our columns of August 29th (p. 392). Further particulars can be obtained from Dr. W. P. Gowland, honorary general secretary, Australasian Medical Congress, Dunedin, New Zealand.

Early this year (January 16th, p. 117) we published an article furnished by the Executive Committee of the congress on the general arrangements and on the opportunities New Zealand affords, especially in its mountain districts, for tours of great interest. The authorities of the congress hope that as many members of the Association at home as can spare the time will attend the congress and visit the numerous beautiful and interesting places to be found in the two islands.

By the courtesy of the High Commissioner we are able to illustrate this article by a sketch map. The North Island is approximately 515 miles long and the South Island 525; the area of the two taken together is a little smaller than that of Great Britain and Ireland. The ordinary route from Dunedin to the North Island is by train to Christchurch, and thence by boat to Wellington. It is possible to go from Dunedin to the North Island by steamship direct; most travellers, however, will prefer the land journey, which will give them an opportunity of making a trip to the Southern Alps, which form the boundary between Westland and Canterbury. From Wellington there is a railway to Auckland and beyond to almost the extreme northern point of the North Island.

The journey from here is, of course, long. There are several routes, each of which presents certain advantages and disadvantages. We are indebted to the White Star Line for the following particulars:

SERVICES TO NEW ZEALAND.

By the White Star and Associated Lines.

Direct Route.—From Southampton, calling at Colon (Panama Canal), to Wellington. Return fares: first class, £175; second class, £122. (Shaw, Savill and Albion Company.) Time, five to five and a half weeks.

By South Africa and Australia.—From Liverpool, via Capetown, Albany, Adelaide, Melbourne, and Sydney. Sydney to New Zealand by intercolonial steamer. (Aberdeen, Blue Funnel, and White Star Joint service.) Return fares: first class, £179; cabin class (White Star steamers only), rates from £128. Time, about eight weeks.

By Canada or United States.—Southampton or Liverpool to New York (or Montreal during summer season). Rail journey through United States, or Canada, to San Francisco or Vancouver (with option of various routes). Steamer from Vancouver, via Honolulu and Suva, to Auckland, or San Francisco, via Papeete and Rarotonga, to Wellington. Return fares: first class £212 10s.; cabin class Atlantic, first class beyond, £188; second class Atlantic, first class beyond, £183. (These fares cover an Atlantic fare of £44 first class, £31 cabin class, and £28 second class.) Meals and sleeping-berth charges extra on the railway portion of the journey. Time, four and a half to five weeks.

Passengers selecting to go out by any of the above routes (excepting only White Star cabin class Australian steamers), and purchasing a return ticket at the rate quoted, can, if they wish, arrange to use the return ticket by any of the other routes above mentioned; the return tickets would also be available by steamers of certain other lines homewards via Australia and the Suez Canal. In the case of such availability being used, the fare would be readjusted to the half return fare of the carrying line, by extra collection or refund. If it is desired to visit other points outside the above routes, the White Star Line (1, Cockspur Street, London, S.W.1) will be pleased to make up itineraries and give advice in accordance with any special requests received.

Similar accommodation by Canada or United States can be arranged by the Canadian Pacific Company (62-65, Charing Cross, S.W.1).

The P. and O. Steam Navigation Company (32, Lime Street, London, E.C.3) has kindly supplied the following particulars:

P. and O. Service by the Cape and Australia.

The P. and O. one class steamers to Australia via the Cape (with through connexions for Dunedin) carry third-class passengers only, including a large number of assisted migrants. The accommodation is excellent of its kind, but naturally the conditions generally are essentially those which would be found in the third class of any steamer. The fares for through tickets to Dunedin via Sydney range from £39 to £55 single, £71 to £100 return, the fare being governed by the size and position of the cabin occupied.

Messrs. Thomas Cook and Son (Berkeley Street, London, W.1) have also expressed their readiness to give information.

New Zealand has been called the paradise of the trout fisher, and the chief places at which this sport can be enjoyed are easily reached. But there are other sorts of fishing, including sea fishing.

We have now received an article by Professors Malcolm and Carmalt-Jones on the development and present condition of medical education in New Zealand.

MEDICAL EDUCATION.

In order, they say, to understand more clearly the present position of affairs, it is necessary to recall briefly the early history of the colony.

Following the visits of Captain Cook towards the end of the eighteenth century, the history of New Zealand for about seventy years consists chiefly of accounts of whaling and trading expeditions, with frequent encounters between the natives and landing parties, and of the missionary efforts of such men as Marsden, Selwyn, Williams, and others. About 1840 the British Government somewhat reluctantly decided to recognize New Zealand as a British colony, and soon afterwards settlements began to be made at Wellington, Nelson, and New Plymouth, in addition to the earlier trading and missionary stations at the Bay of Islands and at Auckland.

About 1850 two important church settlements, in the style of that of the Pilgrim Fathers, were made—in Otago by the Presbyterian Church of Scotland, and in Canterbury by the Church of England. In each of these cases the conditions on which the settlements were founded included the setting aside of a certain amount of public land as an endowment for the purposes of education, including the establishment of universities or colleges.

For ten to fifteen years these were small communities isolated from each other by almost trackless bush and almost fordless rivers, while communication by sea was infrequent and uncertain. But about 1861 the discovery of gold in Otago and in Westland led to a great influx of emigrants, and for a few years Otago was one of the chief gold-producing areas in the world, while, by supplying food

to the increased population, the Canterbury settlement shared in the general prosperity.

When the rush had died down, owing to exhaustion of the more readily worked gold, the agricultural and pastoral value of the new country began to be more fully realized, and a great impetus was given to the settlement of parts of the country that would otherwise have developed but slowly. The main routes for all kinds of traffic to these more remote districts still follow the tracks made by the toiling men and heavy laden pack-horses of those strenuous days, and the small townships have generally started as the lonely "pubs" of the same period.

The University of New Zealand.

It was during the later stages of this prosperity that the University of Otago, the earliest of its kind in New Zealand, was founded. At that time (1869) the separate communities of New Zealand had a large degree of local government under the control of a General Assembly in Wellington. The project of establishing a university at Dunedin roused the jealousy of the older, but at the same time less prosperous, provinces of the North Island, and, although Otago had secured by legislative enactment the right to confer degrees, the conflict ended in the establishment (in 1870) of the University of New Zealand as an examining body, to which Otago University, and subsequently the University Colleges of Canterbury, Victoria (Wellington), and Auckland, were affiliated. The organization corresponds to that of the University of London, and, as in that case, it has been subjected to much adverse criticism, but on the whole it has suited the country and a recent Royal Commission has recommended its continuance, at least until the population in the four centres warrants a separate university in each.

The Otago Medical School, Dunedin.

The one great difficulty is the question of the special schools for medicine, engineering, law, mining, etc. At present the Government cannot afford to maintain a separate medical school in each centre or even in each island, and yet there are facilities for hospital work in all the centres. The only medical school in the dominion, that of Otago, is in Dunedin. This was established about 1876, when a chair of combined anatomy and physiology was set up, with Dr. Millen Coughtrey as the first occupant. It is interesting to note that D. J. Cunningham, afterwards famous as the professor of anatomy in Edinburgh University, was an unsuccessful applicant. He was then a final-year student.

The history of the Otago Medical School, like the development of the embryo, epitomizes to some extent the evolution of medical schools in general. At first only the fundamental sciences, with anatomy and physiology, were taught, and those who worked for the establishment of the school had great difficulty in keeping the project alive. Only two years of the proper medical curriculum could be provided, and the home universities would not recognize the training till the school was more fully established and equipped with teachers and students in attendance, while, on the other hand, it was difficult to induce students to commence study in the expectation that the school would be recognized.

In 1877 Dr. J. H. Scott was appointed professor of anatomy and physiology in succession to Dr. Coughtrey, who had resigned, and for nearly forty years, till his death in 1914, Dr. Scott was the ruling spirit of the school. In little more than a year after his arrival some distinct progress could be noted. The University of Edinburgh, from which Scott had come, recognized a sufficient number of classes to cover two years' work in Otago, and recognition by other British schools followed soon afterwards. In 1883 the University of New Zealand was able to recognize the Otago Medical School as a school capable of giving a complete medical curriculum, and the granting of degrees in medicine naturally followed.

From then onwards the existence of the school has never been in serious danger, although progress was retarded by the financial depression of the years between 1880 and 1890. During this period, and even up to the end of the nineteenth century, owing to the depredations of rabbits

and to the fall in the price of wool, the rentals of the lands set aside by the early pioneers for university education fell to a very low figure. Since then, with the development of the frozen-meat trade and the rise of the dairying industry, and other causes of increased prosperity of the country, the Medical School has been financed more and more by the Government, and is now generally recognized as the National Medical School.

Recent Developments.

From time to time extensions of the original medical buildings have been made. Dr. Scott, in his earlier years, had little more than a small dissecting room, museum, and a cellar for subjects. Extensions took place from time to time, including a new physiology department (under a separate professor) in 1905, extensions to anatomy and physiology in 1914, and a complete new medical block on a site facing the hospital in 1916. These additions, as well as the provision of new chairs and lectureships, have been made possible largely by the generosity of the public of Otago aided by Government subsidies.

At present there is in course of erection, on a site adjoining the block built in 1916, a new block to house the departments of anatomy and physiology, with some provision also for medicine and surgery. The funds for this extension have been promised by the Government, thanks largely to the persevering efforts of the present Dean of Faculty (Sir H. Lindo Ferguson), who succeeded Professor Scott as dean in 1914, and under whose able guidance the school has made remarkable progress in every direction during the last twelve years.

As contrasted with the three professors and the few hospital surgeons and physicians of fifty years ago, the teaching staff now consists of twelve professors, twenty-five lecturers and senior assistants, as well as a number of junior assistants and demonstrators.

There are whole-time professors in anatomy and physiology, and graduates who visit the United Kingdom to continue their studies certainly find themselves at no disadvantage in their training in these subjects. The chair of pathology and that of bacteriology and public health are also whole-time appointments, and their professors are respectively chief pathologist and chief bacteriologist to Dunedin Hospital, where the main clinical instruction is given, so that liaison between the wards and the laboratories is easily maintained.

Public health, as indicated by its inclusion in the title of the professor of bacteriology, receives unusually close study in the undergraduate course, and full recognition is given therein to the importance of preventive medicine, which has, of course, unusual scope in a country still in process of settlement, a point which is very strongly emphasized in all teaching.

Clinical Teaching.

Within the last few years half-time professors of medicine, clinical medicine, and surgery have been appointed, who are by statute members of the staff of the Dunedin Hospital, so that systematic and clinical instruction can be very closely associated and an unusually large amount of time devoted to the latter. In addition, the members of the clinical staff of the hospital who do not hold university chairs are also under an obligation to teach, and classes are detailed to attend them so that the important item of numerically small clinical groups of students can be maintained.

In addition, under a recent arrangement, and through the generosity of the hospital staffs concerned, students may take a part or the whole of their final year's instruction in the hospital of one of the other "centres" of the dominion. In this way a large amount of clinical experience can be gained, and use is made of all that is available, which, though necessarily less than that obtainable in great cities, permits of full instruction in all ordinary hospital practice.

At Dunedin the pathological and bacteriological departments are excellent, the x-ray apparatus is adequate and well served, and a new department is in course of construction. An electro-cardiograph will be established in

the new buildings. Research is in progress on goitre and other subjects of particular interest to New Zealand.

The Congresses of 1896 and 1927.

An Intercolonial Medical Congress was held in Dunedin in 1896, and is still remembered in Australia by some of its participants. Should any of these revisit Dunedin for the Australasian Congress in 1927 they will find that for the University of Otago Medical School the past generation has been one of progress.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.

THE annual meeting of the London and Counties Medical Protection Society, Limited, was held on June 9th, under the chairmanship of the president of the society, Sir JOHN ROSE BRADFORD, P.R.C.P.

The annual report, the adoption of which was moved by the PRESIDENT, stated that the number of applications from members for advice and assistance reached 801 during the year, as compared with 785 in 1924, and 662 in 1923. Satisfactory results were generally obtained without litigation; where litigation had occurred it had been almost wholly successful. The council continued to make provision, by special insurance for an unlimited amount, to defray damages awarded against members, together with costs allowed to the other side, in actions which the society undertook for members and in which a successful result was not achieved. The society bore the whole cost of defending or conducting cases, and it was only in respect of damages and costs which might be awarded against members in unsuccessful cases that this special provision had to be made. There had been a substantial increase in membership during the year, but the council observed with regret that there were still very many practitioners who neglected to avail themselves of the protection afforded at so small a cost. Members were particularly requested to insist upon their partners and assistants becoming members also. The solicitors to the society (Messrs. Le Brasseur and Oakley), in their report, stated that the feature of the year was the importance and weight of certain cases which arose under the Insurance Acts. Members had been supported in a number of appeals and inquiries, and in only one did a member fail to win his appeal. The solicitors remarked, however, that out of three cases in which the society, defending a member on appeal, succeeded in establishing certain technical objections to the procedure of either the Local Insurance Committee or its Medical Service Subcommittee, in only one did the Minister allow any costs to be paid in favour of the member, whereas experience showed that should a member lose an appeal costs were invariably awarded against him.

Sir JOHN ROSE BRADFORD said that there were two things which had often been alluded to before from that chair, and which no doubt would have to be alluded to year after year. One was to impress on all members involved in a dispute of any kind not to take any action on their own account before communicating with the society. Numerous difficulties encountered would be avoided if members would place such matters in the society's hands from the earliest possible moment without taking legal action of any kind themselves. The second thing was to impress upon practitioners in cases of injury—not necessarily obscure injury—the importance of having an x-ray examination made, or, if the patient or his friends refused, of obtaining a statement in writing to that effect. The society was in a very satisfactory financial position. In 1924 it had a deficit on its year's working owing to the quite exceptional expenditure incurred in connexion with one case; but in 1925 the financial position reverted almost to what it was before that large expenditure was undertaken. The total surplus funds of the society for 1925 were £38,319, and for 1923 they were £39,621; there was therefore very little difference, and when it was considered that a sum of £7,000 was expended in that one case he thought it would be admitted that the society had come through very satisfactorily.

On the motion of Dr. C. M. FEGEN, Sir John Rose Bradford was re-elected to the presidency unanimously and with acclamation. Dr. Fegen himself was re-elected

treasurer, and the vice-presidents and members of council retiring by rotation were all re-elected. One new member comes on to the council in the person of Sir William Hale-White. Votes of thanks were accorded to various officers, including the solicitors of the society; with them were coupled the names of the standing counsel, Mr. Neilson, K.C., and Mr. T. Carthen.

TENURE OF PART-TIME MEDICAL OFFICERS OF HEALTH.

SANITARY OFFICERS ORDER, 1926.

THE Sanitary Officers Order, 1926, dated May 27th, which revokes the Sanitary Officers Order, 1922, but continues some of its provisions, relates to the qualifications, duties, and tenure of office of medical officers of health and sanitary inspectors in England and Wales. The Order, which is made by the Minister of Health, does not apply to Scotland. The requirements prescribed may conveniently be noted in the above-mentioned sequence with respect to the two classes of officers named, taking medical officers first.

The medical officer of health of a district or combination of districts for the purpose of the Public Health (London) Act, 1891, or the Public Health Act, 1875, must, under the new Order, as under the Order of 1922, possess a diploma in sanitary science or have had three years' previous experience of the duties of a medical officer of health. This requirement covers all medical officers of health in England and Wales excepting medical officers of counties, who are appointed under the Housing, Town Planning, etc., Act, 1909, by reference to the Local Government Act, 1888. By Article 21 of the Order the Minister of Health reserves the right to dispense with the stipulated qualifications if a small district, for example, should prove unable to obtain a duly qualified officer.

The duties of a medical officer of health, as prescribed in the Order, are to render all services duly laid upon him by statute, order, regulation, by-law, or other instrument; to forward weekly returns of infectious disease to the Minister of Health and duplicates to adjacent medical officers; to submit an annual report to his local authority and copies to the Minister; to send to the Minister one copy of any special report which he may present to his local authority, and to report forthwith to the Minister any case of plague, cholera, or small-pox, or any serious outbreak of disease. Metropolitan medical officers are freed from the weekly returns of infectious disease, and county medical officers from both the weekly and emergency returns.

As regards the tenure of office of medical officers of health, it will be recalled that this question has been much under discussion. The freedom of action of a medical officer who held his appointment at the pleasure of his electors was checked by the insecurity of his tenure. If he did his duty without fear or favour, he might, wittingly or unwittingly, traverse the interests of influential members of his local authority and find himself dismissed from office. Such a position from the outset was clearly indefensible, but distrust of the expert has such deep roots in the English mind that reforms came slowly and were granted with apparent reluctance. Gradually, however, though not without effort, security of tenure has been won for certain medical officers. The new Order seeks to extend it, in a modified form, to certain others. It lays down that a part-time medical officer of a district must be appointed in the first place for a limited term ending on March 31st next ensuing, after which date he will continue to hold office from year to year without further appointment, subject to the right of the local authority to determine the appointment on March 31st in any year by not less than three months' previous notice. This arrangement would appear to offer to the part-time medical officer some kind of defence against the hasty indignation of an unrighteous local authority. So long as the post is on a part-time basis, appointment for a limited term appears to be obligatory; but the local authority may at any time, subject to the concurrence of the Minister, turn a part-time into a whole-time appointment, when the security attaching to a whole-time appointment would presumably accrue to the officer.

The Order provides in the above terms for part-time district medical officers only. It does not concern itself with county, metropolitan, or whole-time district medical officers, who, in general, already enjoy, under statute, a notably higher security. A county medical officer, for example, is appointed without limit of time and is removable by the county council with the consent of the Minister of Health, but not otherwise. A metropolitan medical officer is also appointed without limit of time, and is removable either by or with the consent of the Minister. A whole-time district medical officer is similarly appointed and secured by the Public Health (Officers) Act, 1921, subject to the proviso that a portion of his salary is charged to the Exchequer contribution account. A whole-time medical officer of a county borough is only safeguarded if a portion of his salary is paid out of moneys voted by Parliament before the borough attained county status. Compared with these securities, the tenure of the part-time officer, though strengthened by the Order, is still, comparatively speaking, precarious. It should be added that even high security of tenure in the foregoing instances does not amount to an *ad vitam aut culpam* holding. The Minister presumably might determine the charge of a blameless officer on the ground that his post had become superfluous. But it does imply protection against capricious dismissal, the assumption being that both the Minister and the local authority are not likely to be capricious at the same time. It is therefore a valuable safeguard for all practical purposes.

In the case of sanitary inspectors, the Order requires their qualification to be either a certificate of the Royal Sanitary Institute and Sanitary Inspectors Examination Board, or a certificate of the late Sanitary Inspectors Examination Board, or a certificate issued before January 1st, 1899, by the Sanitary Institute, or, outside London, a certificate of the Royal Sanitary Institute issued before January 1st, 1926. The Order also prescribes the duties of sanitary inspectors in some detail and makes certain provisions for their tenure of office.

THE INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

MEETING AT PISTANY, CZECHO-SLOVAKIA.

The annual meeting of the International Society of Medical Hydrology, presided over by Dr. GUSTAVE MONOP of Vichy, was held at Pistany, Czecho-Slovakia, last April.

Etiology and Treatment of Chronic Rheumatism.

A discussion on this subject was opened by a paper read by Sir WILLIAM WILLECOX. After pointing out that chronic rheumatism is not a local disease, but a local manifestation of a general pathological condition, Sir William said that many years' study of toxicology and clinical medicine had led him to the view that the cause of the disease must be looked for in a poison acting on the body cells. The cardinal principle in toxicology was to search for the focus of production of the toxins, and then to eradicate the cause as far as possible. Chronic rheumatism included (a) forms of arthritis, such as rheumatoid arthritis, arthritis deformans, osteo-arthritis, and chronic villous arthritis; (b) forms of fibrositis—panniculitis, inflammations of fasciae (as in lumbago and myalgia), inflammations of tendons and ligaments (as in stiff neck, Dupuytren's contractures, etc.), inflammations of tendon sheaths, tenosynovitis, bursitis, Heberden's nodes, fibrous nodules in sciatica and brachial neuritis). Such factors as sex, age, race, family history, mental strain, debility, trauma, physical strain, exposure to cold and wet, and living in damp houses could only be regarded as subsidiary predisposing causes. In the great majority of cases "infection" must be regarded as the primary cause. Sir William Willecox held that errors of metabolism in the liver, intestine, or kidney could not occur without some cause of external origin. To regard "faulty metabolism" as an important cause of chronic rheumatism was erroneous. The true explanation of the association of chronic rheumatism with defective function of the organs was that the faulty metabolism was due to an extraneous cause—namely,

the toxæmia of the infection. Most careful search, said Sir William, was required to discover the focus of infection; and when no focus was found it was probable that the investigation had not been sufficiently complete. The author reminded his audience that at the discussion on rheumatoid arthritis at Bath last year there was a consensus of opinion that the origin of this disease was infective. Arguments in favour of the infective origin were: (1) that

ns may give rise to arthritis and from chronic rheumatism—for example, gonococcal, bacillary dysenteric, pneumococcal, typhoidal, streptococcal (as in septicaemia and tonsillitis); (2) that progressive rheumatoid arthritis may follow parturition; (3) that in the great majority at all events of early cases of chronic rheumatism a definite infective origin can be found. In 100 consecutive cases of arthritis and fibrositis under his care, Sir William had traced dental sepsis in 72, intestinal in 13, a tonsillar source in 10, and gonococcal origin in 5. But a very much larger number of cases would be necessary in order to obtain an accurate idea of the true infective origin of chronic rheumatism. Sir William showed x-ray photographs to illustrate various types of focal infection from septic teeth. In tonsillar infections the author laid stress on the tendency of the joint symptoms to improve temporarily, with subsequent recurrence. In these cases also there was a great tendency to effusion into the joints. Infection of the nasal accessory sinuses must be looked for; and it should be remembered that in antral disease radiograms and transillumination were often misleading, and that puncture and bacteriological examination of washings were the only certain tests. Sir William thought that when the mouth or naso-pharynx was affected it could not be long before the intestinal glands became affected, and might carry on the infective process even when the primary focus had been eradicated. In elderly people the intestinal glands might be the primary focus. In 90 per cent. of his cases a definite infection had been found in colon washings, generally of the *Streptococcus viridans* type. Further foci of infection might be found in diverticulitis, the urethra, and the pelvic organs of women.

Sir William Willecox then discussed the association of arthritis or chronic rheumatism with gout, anaemia, hepatic disorders, gastric or duodenal ulcer, appendicitis, cholecystitis, and some skin affections. Tuberculosis he did not regard as an important etiological factor. But "constitution" or "diathesis" seemed to him an important matter. An inherited tendency existed in some families to fibrositis and joint trouble. Arthritis and endocrine disorders were both due, commonly, to infection; and there was strong evidence that diabetes was caused by a chronic toxæmia.

Sir William urged that treatment of chronic rheumatism should aim at the removal, as far as possible, of the infective cause. He did not wish to belittle the immense importance of hydrotherapeutic measures and climatic treatment. In fact, he was an ardent believer in hydrological methods. But treatment should be begun with a "clean slate"; otherwise the improvement from hydrotherapeutic measures would be only temporary, and recurrence was inevitable. He was glad that this was being recognized at spas. In conclusion, Sir William enumerated the therapeutic measures which he had found of most value, and expressed the opinion that vaccine therapy should never be used until the focus of infection had been removed, as far as possible.

In the discussion which followed Sir William Willecox's paper, Drs. Schmidt and Reichart described the use of hyperthermal mud baths at the Pro Patria Hospital. Dr. Schmidt showed the importance of minimal elevations of temperature in rheumatic subjects, and Dr. Reichart demonstrated the technique of heart cooling in thermal treatment, by which daily applications of heat could be borne without fatigue. Dr. Mougeot regarded latent infection in the colon, hepatic insufficiency, and endocrine disorders as important factors in causing rheumatism. Dr. van Breemen described the results of the treatment of rheumatic disorders during the last twenty years at the clinic for physical treatment at Amsterdam. Dr. Kahlmeter spoke of the excellent results from physical treatment in

the institutions in Sweden. Dr. Alison Glover drew attention to the serious nature of the problem in England, and to the occupational and climatic factors in causation.

The meeting was attended by some seventy persons of thirteen nationalities, amongst whom were representatives of the Ministry of Health and of the Swedish Board of Pensions. The members of the society and their friends were guests of the Czecho-Slovakian Government. In the course of the proceedings representatives of Germany were admitted to the society, an international committee on chronic rheumatism was appointed, and national committees were formed for Great Britain, Holland, Sweden, Germany, and Austria. The British committee was stated to be putting forward proposals for the treatment of chronic rheumatism by physical methods at spas and at out-patient clinics in large centres of population. The subjects discussed at the meeting included the use of baths and waters in the treatment of disorders of the liver, glandular insufficiency, and hypertonia. A full report of the meeting will be published in the summer number of the *Archives of Medical Hydrology*.

Nova et Vetera.

SEVENTEENTH CENTURY UROLOGY.

UROLOGY of one kind or another was very much to the fore during the half-century following the restoration of Charles II.

Diuresis was advocated as a cure for many different conditions, and the methods of producing it were equally varied. Dr. Archer, "one of His majestie's physitians," used to sell "Tobacco, prepared for prevention and cure of most diseases, working by Urine and Spitting, being pleasant and safe, approved to purify the Blood and fortify the Vitals, curing Colds, Catarrhs, pains in the limbs, Gout, Dropsy, Scurvy, etc., being two sorts, one at Two shillings per ounce, the other at One shilling." It was to be had "with printed Directions and sealed up to prevent Counterfoits at his house in Winchester Street, the sign of the Golden Ball near Broadstreet, and not elsewhere."

The Great, Famous and most Excellent Nephritick Powder had originally been brought from Germany by an Eminent Merehant. It was "prepared from the Flower, Seed and Leaf of an Herb growing near the Spaw in Germany," perhaps John Taylor's

"mungrill Spaw,
Whose waters (cleare as Chrystall, sweet as Hony),
Cured all diseases (except want of Morny),
Relieved the Palsey, Cramp, or Apoplexie,
Scab, Scurfe, or Seald, or Dropsie, if it vex yee."

The powder had "all the virtues of the said Spaw waters," and "this excellent virtue in addition" that it carried off "all Cold and Crude Humours, which either they or any other Purging Waters" left behind. "It provoked Urine, dissolved and brought away Heat and Gravel, gave Ease in the Gout, Cured the Strangury, and Purged Wind to Admiration. It was made exactly as you would make Coffee, and Sweetened with a little Sugar, and Drank Morning and Evening, 2 or 3 Dishes at the Time." It was guaranteed to "Purge you gently, not hindering your Business," and could be had "in Twelve-penny Papers with the iuventor's Cifer."

Wright's Diuretic, or cleansing, Tincture "Urinarily discharged all the Relicks of the Lues Alamode, or Venereal infection, and chased its Cocomitants, such as the mucous, sanious matter, which, lodg'd in the Reins or Spermatick Parts, caused a sharpness in the Urine or too frequently provoked it." The "Relick" was stated to be "discoverable by the subsequent Symptoms, viz., by a Debility or Weakness of the Back, and a foetid, nauseous and averting Smell of the Urine, with purulent matter residing at the Bottom or flying in it with a variety of Figures." Further, the Tincture effectively carried off "all Relicks of the Venereal Disease after ill managed Cures, not only cleansing the urinary Passages of all Sand, Gravel, Films or Membranous Pellicles, etc., but

after a singular Efficacy invigorating the Reins, restoring them and all their Genital Parts to their Original Tone and Use, though the mischief and decay be of the longest date with an Equal Success in each Sex." The Tincture was obtainable "at ten shillings the bottle of Doctor Wright at his House, the Golden Head, in Bell-Savage Yard on Ludgate Hill."

"The Specifick Virtues of the Opagryical Essenco" were so surprising that they "totally eradicated and expelled all Impurities and Rollets lying in the Kidneys or Urinary Passages and attended with sharp pain, etc., in making water." "Any Person, under such Disasters," might "without any other Advice, Trouble or Confinement, with the greatest Ease, Safety and Seerecy, cure him or herself (its operation being by Urine only) of all such secret Maladies although of long standing." One bottle was usually enough to "perfect the cure" and would be "delivered to any messenger." It kept good in all climates and might be taken in the hottest or the coldest weather. "Thirty drops taken presently after injury was suspected by either sex immediately expelled the Malignity, and infallibly prevented the Consequence thereof." It was to be had of "nono but the Author, at the Queen's Head over against Katherine-street in the Strand at half a guinea the bottle."

Mr. Spooner, at "the Golden Half Moon in Lemon Street, Whyte Chappel," supplied an excellent electuary at 3s. a pot. This quickly cured "the Diabetis, in those that could not hold their water, to a Miracle." It also "wonderfully comforted and strengthened the weakened parts so that the Incontinence of Urine would not return. It was never known to fail."

On the other hand, Dr. Rogers of Fleet Street wished to "satisfy all Persons that the Powder," which he retailed in 5s. packets, "did very lately give immediate relief to a Nobleman of above 80 years of age that had Suppression of Urine for 4 or 5 days and was in extream Torment. Upon taking the Powder he had present Ease and grew perfectly well in a few Days."

Tipping's pleasant Liquor, which dissolved "Stone in the Bladder or Kidnies, bringing it away visibly and giving Ease in the Cholick," could be had "at the further End of Red Lyon Court in Fleet Street, leading to New Street, the first door on the Left Hand up the Steps."

Another "Infallible Cure for the Stone and Gravel, whether in the Reins or Bladder" could be obtained at "Jacob's Coffee House, against the Angel and Crown, Tavern in Threadneedle Street, behind the Royal Exchange, at 3s. 6d. a bottle, with directions." This was a "Chymical Liquor" which

"in the most racking cases gave instant ease, and perfectly freed the Patient from all pain in the back, and this pain so much like the Cholick, dilated the Ureters, made them slippery, so that the small stones and gravel might pass from the Reins, to be voided visibly with the Urine, without Pain. It cleansed the Kidneys, Bladder and all the Urinary Passages from slimy calealeous matter, certainly took off all Heat, pains, and Stoppage of Urine, and absolutely broke and dissolved all large Stones (possible to be dissolved). It also assuredly prevented the Stone in those that were troubled only with Gravel. Indeed for all Disorders of the Reins and Bladder it could not be paralleled."

It seems unfortunate that Sir Thomas Adams, ex-Lord Mayor of London and President of St. Thomas's Hospital, did not try the magic liquor. His biographer states that

"the latter Years of his Life were Years of Pain to him, by reason of that Disease of the Stone in the Bladder, whereof at last he died: a Stone so weighty, that it exceeded 25 Ounces, so grievous that a little before his Death it made him roar, but yet not murmur, GOD graciously supporting him under the Weight, and Sustaining him under the Pain of it; and indeed the Providence of GOD was singularly remarkable, in that having a Stone of so vast a Bigness in his Bladder, his Pain was comparatively so little and his Life so long, for had there not been as it were a Way paved, or rather a Channel cut through the Stone for his Water to pass, the Stoppage of it must of necessity have very much added to his Smart, and lessened his Days."

He died in 1668 at the age of 81, his death "being occasioned by a fall stepping out of his coach, which forced the stone down and stopped the Urinal passages and killed him." The calculus was presented to Cambridge University.

W. K. IRWIN, M.D., F.R.C.S.,
Surgeon to Out-patients, St. Paul's Hospital
for Genito-Urinary Diseases.

British Medical Journal.

SATURDAY, JUNE 19TH, 1926.

BICENTENARY OF THE EDINBURGH MEDICAL FACULTY.

THE two hundredth anniversary of the founding of a Medical Faculty in connexion with the Town's College at Edinburgh was fittingly celebrated last week. The ceremony was a commemoration of the whole university as well as of its medical department, because the institution of medical and other faculties had conferred on the local college two centuries ago the status of a general university. Many important events in medical science and practice have happened during those two hundred years, and not a few of these have happened at Edinburgh. It was pointed out by Sir George Newman in his address at the graduation ceremony that Edinburgh had drawn the inspiration of its teaching from Leyden, where most of the men who founded the Medical Faculty had sat at the feet of Boerhaave about the year 1718. An important fact to recall, however, in this connexion is that the teacher in medicine of Boerhaave himself was that Archibald Pitcairn who went from Edinburgh to Leyden as professor of medicine in 1692, and to whom the founding of the College of Physicians in Edinburgh was largely due. The central event of last week's celebration was the opening of the new surgery department, and especially its research section, by the Secretary for Scotland, Sir John Gilmour, M.P., as is reported more at length at page 1054. The article there printed, together with that which appeared a fortnight ago (p. 959), will, with their illustrations, give a general idea of the plan and purpose of this new department, which all will recognize to be a most important addition to the splendid facilities possessed by the Medical School in Edinburgh.

Sir John Gilmour referred to the fact that the building was in part the gift of America, and that it was a helpful and inspiring thought to realize that on the great main issues of life the two peoples felt they could work hand in hand. In this connexion it may be remembered that the United States owes a debt to the early Faculty of Medicine at Edinburgh, for to Edinburgh in the middle of the eighteenth century came most of the young men of the American colonies who aspired to return home and practise medicine. John Morgan, who was appointed by the American Congress Director-General and Physician in Chief of the American Army in 1775, was an Edinburgh graduate, as was also his successor at Washington's side, William Shippen, junior. Benjamin Rush, another pioneer of American medicine, graduated at Edinburgh in 1768, and took a prominent place in the origin of the United States as one of the signatories of the Declaration of Independence. All these three men had sat at the feet of William Cullen in Edinburgh.

In thinking of the contributions which the Edinburgh Medical School has made to medicine the mind naturally turns specially to the middle of the nineteenth century, the epoch when James Y. Simpson, about the year 1847, was labouring to introduce the practice of anaesthesia in this country against a considerable amount of opposition. About the same time Goodsir advocated the importance of the cell as the controlling centre of nutrition—a doctrine for which Virchow

recorded his indebtedness by dedicating to him his *Cellular Pathologie*. To the same period belongs the discovery of leucocythaemia by John Hughes Bennett, which led to a closer investigation of the diseases to which the blood is liable. To this period also belongs the publication of *Mind and Brain*, by Thomas Laycock (1859), in which the doctrine of unconscious cerebration, that has so greatly developed in recent years, was first adumbrated. Greater, perhaps, than all these in its practical effects was the slightly later development by Lister, during his Edinburgh period from 1869 to 1877, of the principles of antiseptic surgery which had seen the light at Glasgow in the year 1865.

At the opening ceremony Professor Wilkie observed that the past two centuries had seen some remarkable changes and advances in medicine, but none more remarkable than that which had taken place in surgery during the past fifty years; the dread with which the word "operation" was whispered some sixty years ago contrasted strongly with the attitude of the public to-day towards the art of surgery. From the new research department valuable contributions to the development of this art would, it was anticipated, proceed, and a pleasing note was struck when he said it was hoped that members both of the University staff and of the extramural staff would without distinction combine in the attack upon the wall of ignorance. It is true that discoveries are usually not completed either in the place they began or by the man who initiated them—indeed, the practice of antiseptic surgery is a striking illustration of this fact; but there are good grounds to expect that such a department as that opened by the Secretary for Scotland at Edinburgh last week, where research is quietly and systematically fostered without demanding a periodic publication of results, will be of ultimate general benefit to medical and surgical science.

Sir George Newman, in reviewing what had seemed to be the design of the forefathers of the Edinburgh Medical School in regard to medical education, laid down four clear principles which appear to be equally applicable in the future. These were the integration of the several sciences which contribute to medicine; the application of the experimental method, which appears to be the particular feature of this new department; a clear recognition of the important part which medicine can play in social evolution; and finally, and perhaps most important of all, sound clinical study. There is no fear at the present day that research will not receive due encouragement. There is, perhaps, a fear that the study of the individual patient at the bedside may temporarily not receive all the attention that is essential to progress.

THE TECHNIQUE OF RADIUM THERAPY.

RATHER more than a year ago the Committee of the Radium Institute, London, issued a volume entitled *A Clinical Index of Radium Therapy*, and a detailed review was published in our columns (April 4th, 1925, p. 670). The volume, as we remarked at the time, was of the nature of a textbook. It was written by the medical superintendent, Mr. A. E. Hayward Pinch, F.R.C.S., and his assistants, Dr. Philip Gosse and Dr. Oskar Teichman, with the assistance of Dr. R. Douglas Reid (house-surgeon), and to it Dr. J. C. Mottram, director of the pathological laboratory, and Mr. W. L. S. Alton, F.I.C., director of the chemico-physical laboratory, contributed chapters. The first part was concerned with the physics of radium, its

disintegration products and the rays emitted, with the use of applicators, with the local and general reaction, and with the fundamental principles of radium therapy. This was followed by a series of chapters discussing the applications of the rays to diseased conditions. The value of the information given was highly appreciated, as is evidenced by the fact that close on three thousand copies were circulated. The Committee has now published another volume, entitled *A Manual of Technique in Radium Therapy*,¹ which is of the nature of an appendix to the first. It is prepared by the same officers of the institution, with the addition of Dr. Roy Ward, and is copiously illustrated with photographs of the apparatus and accessories, of the building and its equipment, and by radiographic plates prepared by Drs. Coldwell and Allechin.

When radium was first introduced into therapeutics the treatment was conducted almost entirely by external radiation by flat-surface applicators, tube apparatus being only employed for insertion into existing cavities or canals. At the present time much more work is being done with tubes than with flat applicators, and a special "surgery of access" has developed. To meet this change a large and completely equipped theatre, with communicating anaesthetizing and sterilizing rooms, has been constructed on the first floor, and a smaller theatre on the second. During 1925, 327 operations were performed to provide access to various regions, including the nose, mouth, pharynx, larynx, oesophagus, stomach, rectum, breast, bladder, and uterus. The new volume describes in detail the methods used in this surgery of access. As the methods employed at the Radium Institute are the result of long and wide experience, a study of the volume will be of great value to surgeons who may be called upon to undertake these preparatory operations. The use of radon (radium emanation) possesses special advantages in many cases; as a gas it is capable of condensation, and apparatus so charged emits a centrifugal radio-activity of intense degree. The preparation and mode of insertion of these tubes is described and illustrated. As they are small they can be buried in and effectively radiate growths which could not otherwise be treated satisfactorily. The importance of bringing the general health of all patients to as high a standard as possible before radium treatment is commenced is emphasized. Among the preparatory operations which may have to be undertaken are extraction of teeth and removal of diseased bone; tracheotomy, both to enable a prolonged intralaryngeal exposure to be given and as a precautionary measure when treating growths in the inferior pharyngeal, laryngeal, or post-cricoid regions. Gastrostomy may be necessary in carcinoma of the oesophagus; by it the oesophageal spasm is abolished, regurgitation lessened, and the patient's nutrition improved. Again, when there is a growth in the sigmoid flexure or rectum, colostomy may be advisable before radium treatment is commenced; it permits daily irrigation of the lower segment of the bowel with a non-irritating antiseptic solution. In long-standing carcinoma of the bladder with chronic purulent cystitis and intermittent or persistent haematuria, cystotomy is often indicated as a preliminary procedure, especially in male patients; it permits constant and effective irrigation of the bladder and removes offensive and irritating detritus; the growth can also be more accurately radiated. The operation is indicated also

before treating carcinoma of the prostate with radium. The existence of a cystotomy opening makes it possible to insert small radium tubes into the growth from its bladder aspect as well as by the perineal route.

The book ends with some notes on complications and sequelae, and contains much valuable practical advice. It is pointed out that the term "radium burn" is often applied loosely and incorrectly to the simple vesication and ulceration which follow upon unscreened radium exposure; they are, in fact, an essential part of the reaction necessary for correct treatment. The term should be reserved for the few instances in which the exposure and dose have been prolonged and excessive. The ulceration so produced is extreme and attended by severe and persistent pain; repair is always slow and frequently imperfect. Hints are given on the best treatment of such conditions, and Mr. Pinch and his colleagues by producing these two books, and the Committee of the Radium Institute by its liberality in circulating them, have rendered a real service to the profession.

POOR LAW REFORM.

AMONG the matters advanced a step at the meeting of the Council of the Association last week was the action to be taken by the Association consequent on the Government's tentative proposals for the abolition of the Poor Law guardians and the transference of their functions to the councils of counties and county boroughs. The Council endorsed the main idea of these proposals as being in harmony with two principles which the Association has long maintained—namely, that the Poor Law medical services should be entirely separated from other aspects of Poor Law relief, and that the administration of these services, with all other health services, should be unified centrally and locally. The Council also approved such comments as had been made by its special committee on certain details of the proposals.

The reply of the Ministry of Health to these comments was satisfactory, except, unfortunately, with regard to two of them which the Association regards as of very great importance. In the Association's suggestions for the reform of the administration of local health services it is stated to be essential that the local government authority should be advised on all health matters, including those transferred from Poor Law administration or from Insurance Committees, by a statutory health committee on which there should be a minority representation of the medical profession and of other bodies experienced in health matters, the majority of the committee consisting of members of the authority. This arrangement would be similar to that now existing as regards educational matters. The Ministry of Health in its reply states that it is an "essential element in the scheme that resort to co-option by the responsible local authorities should be voluntary on their part, and should not be made compulsory." It is impossible for the Association to remain satisfied with this.

The second point is that the Council has objected to the proposal that county councils should be given a general supervising power over and responsibility for the administration of health services in the hands of all borough and urban district councils within the county. The Association has not the same objection in the case of rural district areas, though even there it would prefer that the health powers of the rural council should be relinquished in favour of the county and not merely supervised by the latter. It is

¹ The Committee of the Institute has authorized the free distribution of the book to members of the medical profession. Copies can be obtained post free on application to the Secretary, Mr. Thomas A. Garner, F.R.C.S., Radium House, 16, Riding House Street, London, W.1.

noteworthy that this objection has been unanimously endorsed by the Association of Municipal Corporations, which has decided to organize opposition thereto. It is not to be expected that populous and important towns, with long experience of the effective management of sanitary and health services, will, merely because they are not county boroughs, consent willingly to have placed over them as a superior authority county councils which are in every case less experienced and in many cases less zealous and efficient than they are. In such cases this would be a retrograde step in health administration. The only question in this regard that ought really to be open to discussion is the population limit which should entitle a town to have full health powers itself or at least to be free from the county supervision. There is, of course, room for differences of opinion upon this point. Many experienced administrators would place the population limit lower, but there is certainly a very strong case for exception being made of those boroughs or urban districts with a population of 75,000 or more; this is the figure of population the Royal Commission on Local Government has already reported as that "which should entitle a town council to propose the constitution of a county borough."

It is evident that on these two points pressure will have to be brought to bear on the Ministry of Health to modify its proposals, and it is not too early for the Association, through its central authorities, its Divisions, and its individual members, to exercise its influence in this direction in the interests of good health administration.

SOLVING THE CRIPPLE PROBLEM.

FROM time to time during the last few years we have drawn attention to the problems connected with the treatment of cripples, and have recorded the work doing and done in the efforts to grapple with them.¹ We have now before us two publications on this subject, the one being the lately issued report of the Central Committee for the Care of Cripples for the years 1924 and 1925,² and the other a report by the Hampshire county medical officer, Dr. R. A. Lyster, to the Elementary Education Subcommittee, which is very largely concerned with the care of orthopaedic cases.³ The Central Committee for the Care of Cripples took its origin from an article by Sir Robert Jones and Mr. G. R. Girdlestone published in the *BRITISH MEDICAL JOURNAL* of October 11th, 1919. Since its formation the committee has worked hard to develop the scheme for the whole of England, and is now extending its work to Wales, Scotland, and Ireland. The Central Committee is now able to record great progress since the issue of the last report (for 1922 and 1923), but makes it clear that much yet remains to be done. "Prevention," it says, "is still incomplete, treatment often still too late, so we still find many cripples too severely handicapped to enter industry without special training." This question of special training has long been under consideration. As the result of discussions held at the Wingfield Hospital, Oxford, to which we referred on December 12th, 1925, a scheme was approved by the Ministry of Labour and started experimentally at the Wingfield Hospital and in Hertfordshire with the intention of bringing together representatives of all the interests concerned. Much can be done in this way to help towards a solution of this difficult problem. The training of orthopaedic nurses for the staffing of ortho-

paedic hospitals and after-care centres was referred to a committee of the British Orthopaedic Association, which has made recommendations, of which the most important is one which lays it down that every orthopaedic nurse should have a full training as well as special orthopaedic teaching. The impression made by the report of the Central Committee is hopeful. General practitioners and specialists seem everywhere to be working well together, and the activities of the Central Committee seem to have aroused none of the jealousies which are apt to arise when attempts are made to co-ordinate so many separate if cognate forces. The one most serious obstacle to progress is the lack of money. The Government, with the pressing need for economy and reduction of expenditure ever in mind, finds itself unable to sanction any fresh expenditure until its necessity is clearly proved. The future in this direction is not bright. Dr. Lyster in his report refers to a former report by him in which he quoted a letter from the Board of Education on the advisability of making local arrangements for the cure and after-care of cripples, and of linking up certain voluntary institutions in the north of the county with those already supported by local authorities in the south and west. Hitherto it appears that the North Hampshire Orthopaedic Clinics, which are staffed by the Voluntary Aid Detachments of the Red Cross, and each of which is run by its own committee, have very efficiently provided for the needs of certain areas, but unfortunately they have got into debt, and a grant of £300 a year from the county funds is recommended to cover the deficit and to help in the formation of three new centres. Lord Major Treloar's Hospital at Alton has hitherto helped to provide treatment for cases from the north of the county, but now asks the county council to provide a capital sum of £2,000 for twelve beds, and to pay at the rate of £78 a year for each occupied bed. The borough of Portsmouth has subscribed £10,000 for the provision of fifty beds to be set aside for its cripples, and has agreed to pay the same annual rate, but the Board of Education will not approve of any capital payment to the hospital. We gather that Portsmouth obtained the £10,000 from voluntary sources, and Dr. Lyster thinks that it should be possible to raise one-fifth of that sum from such sources in the rest of the county and so overcome the present difficulty. An arrangement has been come to for the treatment of cripples living in Bournemouth and its immediate neighbourhood at the Royal Victoria and West Hants Hospital at Boscombe. It thus appears that, provided the money is forthcoming for the provision of twelve more beds at Alton, the needs of the county are in a fair way to satisfaction, and one more blank space in the orthopaedic chart of Great Britain is filled in.

PROFESSOR LEIPER.

AT the annual dinner of the West London Medico-Chirurgical Society on June 11th the gold medal of the society was presented to Professor R. T. Leiper, M.D., D.Sc., F.R.S., of the London School of Hygiene and Tropical Medicine. This medal, founded by Dr. Phineas Abraham in 1910, is given triennially for distinguished services to medical science and heroism in the performance of medical duties. The award to Professor Leiper was for contributions to medical helminthology, especially to preventive medicine. Preventive medicine is a branch too often taken for granted, and the services of those who labour in its interests only slightly recognized. The man who can produce a spectacular cure is much more in the public eye—lay as well as professional; while he who makes possible the prevention of epidemics has too frequently to consider the performance of his duty as his sole reward. The action of the West London Medico-Chirurgical Society

³ Hampshire County Council, Public Health Department.

is accordingly all the more welcome. Professor Leiper follows a number of other distinguished recipients of this medal—Dr. Neisser, Sir Arthur Keith, Dr. T. R. Elliott, and Sir Clifford Allbutt. His own contributions to science may be numbered among the greatest discoveries in medical zoology made during the past decade. His work on the life-histories of the guinea-worm and the African eye-worm is well known; but his elucidation of the difficult problems of the Egyptian bilharzia worms was not only one of the most valuable contributions made to medical science during the war, but was a masterpiece of inductive reasoning and carefully planned and executed work. He has enabled not only the Egyptians, but the British army in Egypt, to prevent, simply yet effectively, infection with the blood flukes, and to avoid the serious consequences which inevitably follow such an infection. In his brief reply Professor Leiper paid a warm tribute to Sir Patrick Manson—a fellow Scot. From the time when he joined the London School of Tropical Medicine in 1905, and for nearly twenty years afterwards, Professor Leiper said he had owed much to Sir Patrick for his advice, encouragement, and, above all, for the opportunities for research afforded him. Manson made opportunities while others waited for them to occur. His influence on tropical medicine has been profound, while his example and precept have made preventive tropical medicine one of the greatest forces in the medical world. The task Manson set is not yet completed—it had scarcely been commenced at his death; but if the spirit of Manson continues in those ancillary sciences which serve medicine even greater triumphs would be accomplished. We may agree with Professor Leiper that the ancillary medical sciences have deserved well of their mistress. By honouring Professor Leiper the West London Medico-Chirurgical Society has honoured them, and, through them, itself.

ILLUMINATION PROBLEMS.

THE Department of Scientific and Industrial Research has recently appointed a research committee on illuminating engineering. The members include Sir J. Herbert Parsons, F.R.C.S., F.R.S., and two representatives of the Medical Research Council (Mr. D. R. Wilson and Dr. H. Hartridge). The other members represent the National Physical Laboratory, the Office of Works, the Illuminating Engineering Society, the electrical and gas industries, and architecture. The work to which the committee has set itself concerns some fundamental problems in illumination. The nature of these problems was described in a paper read before the Illuminating Engineering Society on June 1st by Mr. J. W. T. Walsh, the representative of the National Physical Laboratory on the committee. The first involved a thorough investigation of the problems of glare, and the committee was working in close touch with the committee on the physiology of vision recently appointed by the Medical Research Council. One of the most urgent aspects of this matter concerned street lighting. Knowledge of the variables which entered into the problem was extremely limited; it was not possible to say, for instance, whether glare was reduced or increased by halving the intensity of a source and at the same time halving its distance from the object aimed at. The second fundamental problem, undertaken at the suggestion of the Home Office, concerned the relation between the degree of illumination and ease and accuracy in the performance of fine work. Here the committee was working in association with the Fatigue Research Board of the Medical Research Council, and printing was chosen as a convenient process for study, and the active co-operation of the Joint Industrial Council of the printing trade secured. A complete account of this work, with recommendations, would, Mr. Walsh said, shortly be available. The third fundamental investigation

concerned the effect of windows on the natural lighting of rooms, a subject long neglected by most illuminating engineers. An extended series of investigations had been put in hand on the effect of the size and height of windows, the transmission value of different types of commercial glass, and the character of interior decoration. In addition to these fundamental researches the committee is tackling certain small special problems. One of these relates to the efficiency of an enamelled iron reflector widely used for direct lighting in industrial and other premises; another concerns the design of picture galleries so as to obviate reflections in the picture glass of objects in the gallery. We understand that part of the new wing of the Tate Gallery will afford opportunities for an interesting experiment in overcoming this drawback to the pleasure of picture exhibitions. Another problem is the effect of colour and distribution on the degree of illumination required for comfortable work. Other questions are the effect of a flickering illumination on ease of working, and the brightness of illumination fittings. The earlier reports from the committee will be concerned with these relatively minor investigations, but the fundamental researches are proceeding, though solutions of them are not to be expected within a short time.

ASEPTIC RESECTION OF THE COLON.

ALTHOUGH the small bowel readily lends itself to plastic surgery, and every kind of excision, exclusion, or anastomosis can nearly always be performed with the practical certainty of success, the same procedures in the large bowel are followed by infection, faecal fistula, or death in an uncomfortably high proportion of the cases. This is due to a combination of three factors—the thin wall, the poor blood supply, and the high bacterial content of the colon, particularly in those very cases that demand surgical intervention. Although there is as yet no agreement as to which of these three difficulties is the most important, the last has certainly exercised a considerable influence in limiting the enterprise of the surgeon, for the fear of contaminating the operative field is ever present in his mind. It is natural, therefore, that the development of a technique in which this possibility is reduced to a minimum should have claimed the close attention of all engaged in abdominal surgery, and several most ingenious methods of effecting axial union of the colon have been evolved in which the mucous lining of the bowel is never exposed throughout the operation, with the result that extravasation of bowel contents cannot occur. Some of these procedures are already of historical interest only. Others are still in the experimental stage. A few have established themselves as of practical use; and the Sub-section of Proctology of the Royal Society of Medicine chose wisely when the value of closed methods in resection of the colon was selected for discussion at its annual meeting held on June 8th, and invited Professor Fraser of Edinburgh and Mr. Pringle of Dublin to give an account of their work in this direction. Professor Fraser commenced by describing the guillotine method that he had applied in a series of experiments on dogs, with uniformly successful results, and showed a number of interesting photographs illustrating the firm, smooth union that had resulted. He had only put the method into practice in the human subject on fourteen occasions, and he felt that this number was too small to permit of any generalization; but he was convinced that the method did simplify the operation of end-to-end anastomosis, and did enable it to be performed quickly and easily, even in those difficult cases where the bowel is fixed or unduly short. Time would show whether any material reduction in the incidence of infection might be expected. Mr. Pringle followed with a description of his clamp and forceps method, and claimed

for it, not only the merits of quickness and simplicity, but a high degree of security against escape of bowel contents and consequent infection. He felt that his experience had been such as to justify a claim that his own or some similar method of closed operation should definitely take the place of the ordinary open method. The two opening papers evoked an interesting and stimulating discussion, and many criticisms were brought forward, chiefly, however, on theoretical grounds, for it did not appear that the other members of the subsection had yet put the method of closed resection to any extensive trial. Mr. Lockhart-Mummery gave utterance to a pretty general misgiving when he pointed out that an essential part of the technique of both methods was reliance upon the use of a crushing clamp for haemostatic purposes, and expressed the fear that the danger of haemorrhage from the divided bowel had not been sufficiently safeguarded. The President (Mr. Grey-Turner) also reminded the meeting that there had been many deaths from haemorrhage when crushing alone, without the additional security of a ligature, had been relied upon for dealing with the stump of the appendix. Other speakers referred to the danger of diaphragm or shelf formation at the site of the anastomosis—a danger which would appear more likely with the guillotine method of Fraser than with the rather more simple technique of Pringle. Professor Fraser answered the criticisms by referring to the experiments on dogs, and explaining that in fifty operations there had been no case of haemorrhage and none of shelf formation of sufficient degree to give rise to symptoms. He had had one example in the human subject and had been obliged to operate again, but in this instance the difficulty was known to have been due to the employment of a third layer of sutures, whereas in all the other cases only two had been used. The discussion amply justified itself, for it proved the existence of a very general desire to improve the results of large bowel anastomosis, and it clearly showed that at least two methods had emerged from the experimental stage to take their place in ordinary everyday surgery.

THE LISTER INSTITUTE OF PREVENTIVE MEDICINE.

The annual general meeting of the Lister Institute of Preventive Medicine was held last week at the institute. The report of the governing body stated that the total expenditure for 1925 was over £36,500, a decrease of nearly £1,000 on that for 1924. The sale of vaccines, serums, etc., reckoning the value of the stock in hand, had yielded over £31,000. The total income of the institute was nearly £51,000, and the balance, being excess over expenditure, was over £14,000. The main part of the report is concerned with the research work done in the various departments of the institute. Professor Ledingham, F.R.S., the head of the department of bacteriology, has continued his researches in variola, vaccinia, and avian molluscum during the year. Certain anomalous reactions to small-pox virus have been observed in rabbits, and it is believed that their further investigation may throw valuable light on the irregularities met with in converting small-pox to the vaccinal form—a transformation which involves increased virulence of the original virus for the rabbit and a diminished virulence for man. Dr. Arkwright has continued his observations on the variation of bacteria *in vitro*, with regard especially to *B. paratyphosus* A. He has obtained a number of variants, and his observations, when complete, may prove to have an important bearing on pathogenesis in acute infections in animals and man, and also in chronic disease and the carrier state. Dr. Schütz has been investigating the relative potency of three recognized types of plague vaccine: (1) Haffkine's prophylactic, (2) an agar-grown heat-killed vaccine, and (3) the serum-agar prepared at the Lister Institute. It was found that of guinea-pigs immunized with the first two, 14 and 22 per cent.

respectively were protected against a lethal dose of *B. pestis* subsequently administered, whereas 44 per cent. of those immunized with the Lister Institute vaccine were protected. In rats, however, all the vaccines afforded protection to some 90 per cent. The experiments conducted by Dr. R. G. Whitto to obtain fresh evidence as to the effect of pasteurization of milk on tubercle bacilli showed that naturally infected milk from cows with tuberculous udders or milk to which cultural tubercle bacilli or emulsions of tuberculous glands were added was rendered incapable of producing tuberculous infection in guinea-pigs after it had been exposed to a temperature of 62.5° C. for thirty minutes. Among the investigations pursued in the department of biochemistry were those of Professor Harden, director of the department, in association with other workers in it, on vitamins. One of the subjects that are being investigated by Professor Harden is the nature of the substance contained in yeast and many vegetable extracts, which has a powerful stimulating effect on growth, and is considered by many to belong to the class of vitamins. Using lemon juice as the source of this material it was found possible to concentrate it very considerably and to separate it from the antiscorbutic vitamin. Fat-soluble vitamins have been studied in the department of experimental pathology. The provision of a steady supply of young rats with a constant endowment of vitamin reserves is an essential preliminary to satisfactory work, but has proved difficult to attain. Miss Henderson Smith, who supervises the breeding of rats for nutritional work, found that although the diet was maintained constant throughout the year great variation in the animals' subsequent resistance to deficiency diets occurred. The disturbing factor has been traced to the seasonal variations in the vitamin content of the fresh milk, which was an important constituent of the diet of the breeding stock. Constancy has now been obtained by employing the same preparation of dried milk throughout the year; it is now included in the diet of mothers during the last stage of pregnancy, and in that of mother and young from the time of birth until needed for experiment. A great deal of other work on vitamins is being carried on in the institute, especially on the fat-soluble vitamins, by various workers, including Miss Harriette Chick, Miss Roscoe, and Miss Ethel M. Luce. In the department for the study and preparation of antitoxins the preparation of scarlet fever antitoxin has been continued, although it appears that the type of scarlet fever in England at the present is so mild that it is difficult to be certain of the effect of the antitoxin upon the course of the disease. It is thought, however, that its administration may eventually prove to be the best method of treatment. The National Collection of Type Cultures has been maintained and extended, and over 4,000 cultures were distributed during the year.

MUNICIPAL CONSULTING OBSTETRICIANS.

The public health authority of the borough of Hampstead is introducing an experiment in maternity and child welfare treatment which seems to be free from the objections that can be raised to the schemes for an improved maternity service put forward by Professor Munro Kerr and Professor Louiso Mellroy (see *BRITISH MEDICAL JOURNAL*, June 12th, p. 999, where references are given). It appears that a special medical subcommittee of the Hampstead Borough Council, appointed on the advice of Dr. F. E. Searse, the medical officer of health, was impressed by the number of stillbirths and early infant deaths in the borough which were attributed to difficulties of labour, principally malpresentation and undue prolongation. The subcommittee consisted of three medical councillors, Drs. Boyd, George, and MacFadden, with the chairman of the Maternity and Child Welfare Committee,

Councillor Mrs. Fisher. The case of every infant dying under 2 years of age, and also of every stillbirth notified during the year 1924, was investigated by the subcommittee. Information on infant deaths was obtained partly by the attendance of health visitors at the meetings of the subcommittee, partly by a special inquiry form for ascertaining the particulars of each case. In order to discover the causes of stillbirth a circular letter was addressed to all doctors and midwives from whom notifications were received during the year. In every case a friendly answer was received, and in the course of the answers two or three useful suggestions were made. Thus one practitioner stated that "the commonest cause of stillbirth was difficult labour, including malpresentation, which should be preventable by ante-natal measurements, though contraction was extraordinarily difficult to detect." Another suggested that "it should be a condition of the employment of midwives that, in all cases attended by them alone, the mother should be seen by a medical practitioner, or the medical officer of an institution, at least once, not less than a month prior to the term." The subcommittee came to the conclusion that some of the stillbirths and early deaths might have been avoided if specialist help had been available to the general practitioner, and made a recommendation to this effect. The borough council has appointed five obstetricians of recognized consulting status, whose services will be at the disposal of the general practitioners of Hampstead in cases of difficulty or abnormality. The terms and conditions of this service are: (1) that the patient must be a Hampstead citizen; (2) that the medical practitioner must immediately inform the medical officer of health that he has called in the services of one of the obstetricians, giving the name and address of the patient, the date of call, the reason, and the result; (3) that the borough council will be responsible to the consulting obstetrician for a fee of 5 guineas for each case. This is a fixed fee to cover the whole of the consulting obstetrician's attendance on the case. The council reserves the right to recover a portion or the whole of the fee from the patient should it deem it equitable to do so, as the object is to render skilled assistance available to the practitioner only when the patient cannot afford a consultant's fee. The medical officer of health has sent a circular letter to all Hampstead practitioners drawing their attention to the scheme, and expressing the hope that they will avail themselves of it when necessary, as its continuance will depend on the use it proves to be to the general practitioner. The scheme seems well worth a trial, as it will at least help to show how far mortality connected with childbirth can be reduced by specially qualified assistance. The question whether a consultant is necessary in a particular case is left, as it should be, to the general practitioner. Difficulties, of course, may arise in carrying out the scheme. For example, if the practitioner and the consultant should happen to differ in opinion, the position of the consultant who is receiving his fee from the borough council may be one of some difficulty. Again, the timid practitioner may perhaps be inclined to avail himself too readily of the facilities offered, to the detriment not only of his own sense of responsibility but also of the public purse. But these are minor difficulties which can be avoided with tact and self-restraint. There can be little doubt that there are many cases in which the possibility of obtaining skilled assistance without financial worry will be of great value both to the practitioner and to the patient.

MEDICAL AUSTRALASIANS IN LONDON.

The Australian and New Zealand Medical Association in England exists to assist medical visitors from the Commonwealth and from the dominions with information as to the way they may best utilize the time they can give to post-graduate work in Great Britain. The two honorary

secretaries, Mr. E. T. C. Milligan, F.R.C.S., who has, we believe, the honour of being the founder of the association (1922), and Mr. Bedford Russell, F.R.C.S., have gathered much information which cannot fail to be most useful to members or intending members of the profession newly arrived from overseas. The association is open to all medical graduates or undergraduates born in Australia or New Zealand who are resident in or visiting England. The fee is one payment of 5s., and the address of the honorary secretaries is 86, Harley Street, W.1. Two general meetings, each preceded by a dinner, are held in the year; the summer dinner took place on June 11th in London under the chairmanship of Mr. Joseph Cuning, M.B.Melb. and F.R.C.S.Eng., who is a permanent resident in England, for he is senior surgeon to the Royal Free Hospital. After dinner a few short speeches were made; the first was by Dr. Arthur E. Mills, professor of medicine in the University of Sydney, one of the guests of the evening. He congratulated the association on the work it was doing, but expressed the hope that it would not rest satisfied with its present achievements, remarkable as they were. Facilities for post-graduate study in London were, he thought, inadequate, and the position in this respect was not one of which the British people should be proud. An association of 300 members, however, could impress its desires upon the authorities. He understood that there had been a movement for the establishment of a post-graduate medical school, and this, he thought, would be a great step in the right direction; he did not recommend young men from the dominions to go in for examinations to obtain higher diplomas. He concluded by proposing a toast to the association. The chairman, in acknowledging it, agreed that facilities for post-graduate study in London were inadequate, but did not wholly sympathize with Professor Mills's objection to seeking to obtain the Fellowship of the College of Surgeons. The toast of "The Guests" was proposed by Dr. L. E. Barnett, C.M.G., Emeritus Professor of Surgery in the University of Otago, who said that his claim to speak was conferred by the fact that he had been chosen to be President of the Australasian Medical Congress of the British Medical Association to be held in Dunedin, New Zealand, next February. It was the task of everyone to keep up the dignity and high status of the medical profession and to maintain the idea of community of service and research for the benefit of humanity. The help obtained from the medical journals was incalculable, and he therefore had pleasure in coupling with the toast the names of the Editors of the *British Medical Journal* and the *Lancet*. Sir Dawson Williams, in reply, concurred in the opinion which had been expressed, that the organization for post-graduate work in London was unsatisfactory. Mr. Milligan and his co-secretary could do much to help those who applied to them, and those who came with suitable introductions could no doubt get what they wanted; but there were others not so fortunate. He suggested that the association whose guests they were might approach the departmental committee now sitting under the chairmanship of the Minister of Health and place their needs before it. Sir Squire Sprigge said that there were few serious problems in the world to-day that had not a medical aspect. It was the medical men themselves who were responsible for the high standard of the medical journals, for he found that every member of the profession was always ready to respond to an inquiry, and express for the guidance of the editor his opinion in respect to any subject with which he was specially acquainted. Mr. F. F. Muecke (M.B. Adelaide and F.R.C.S.Eng.) said that he and his colleagues at the London Hospital were always ready to give all the assistance in their power to Australians and New Zealanders visiting London for post-graduate work. They could hold clinical assistantships, and he had never been without one, two, or three Australians.

ROYAL SOCIETY CONVERSAZIONE.

THE conversazione of the Royal Society, which had been postponed owing to the general strike, took place on the evening of June 16th, with the President, Sir Ernest Rutherford, O.M., as host. The library and three other rooms were devoted, as usual, to exhibits, the greater number of them illustrating phenomena in physics. An apparatus for the investigation of very soft x rays was shown by Professor O. W. Richardson, F.R.S. The x-ray tube was of transparent silica and extremely highly exhausted, and the emission of the very soft radiation—far softer than anything used in medicine—was demonstrated by the photo-electric effect it was found to produce from an enclosed copper plate. Among several exhibits of interest to naturalists was one by Dr. Heslop Harrison and Dr. F. C. Garrett illustrating the induction and subsequent inheritance of melanism in moths. It has recently been found that in manufacturing districts many lepidoptera have become melanic, and it has been suspected that the relation between industrialization and melanism must be one of cause and effect. In the experiments of these investigators larvae have been reared from typical moths from non-melanic areas, and have been fed with food collected in a melanic district, or with food artificially impregnated with salts like manganese sulphate, known to be present on foliage in manufacturing areas. After several generations melanic moths have appeared, and the dark pigmentation thus induced has been found to be inherited as a Mendelian recessive. The investigators hold the result to be of importance as proving that the germ plasma can be affected by environmental influences. Following on the work which was described recently in these columns (May 22nd, p. 876) on the cultivation *in vitro* of the undifferentiated limb-buds of fowl embryos, Dr. T. S. P. Strangeways and Dr. H. B. Fell of Cambridge exhibited a series of microscope specimens illustrating the development *in vitro* of the isolated eye of the embryonic fowl. Embryos of something under three days' incubation were used. One eye was dissected out and planted into a medium composed of fowl plasma and embryonic tissue extract, while the other was fixed as a control. It was found that the eye under cultivation grew and differentiated in a surprisingly normal way. The specimens exhibited showed the growth of the lens, the formation of pigment, the differentiation of the iris, and the development of the reticular ganglion cells, and the rods and cones layer of the retina. These were all very wonderful results, and bore out the remark in our article on the subject that further research would doubtless be stimulated by these highly successful experiments in tissue culture. The Natural History Museum sent examples of the first species of submarine insect—a two-winged fly from Samoa—which spends its whole life in the sea. All the other sea-breeding insects known have air-breathing adults. Dr. G. H. Rodman had a large exhibit of photomicrographs—the work of years—illustrating the various forms of hairs occurring on the leaves of plants. Among the plants were several, such as *Primula obconica*, known to be capable of producing lesions in some persons. The mechanism of the armoury of insectivorous plants has been studied by Dr. Rodman in the same way. On the physiological side Mr. A. C. Downing showed a number of thermopiles for measuring the heat produced by muscle and nerve on stimulation. Many exhibits were concerned with meteorology and with radiotelegraphy. Of the historical exhibits the most interesting was an early model of the microscope of the Leeuwenhoek type, shown by Mr. George H. Gabb. It was constructed by Butterfield of Paris, and dated from about 1680. It was made of silver, the three lenses being mounted in silver cells and held in position by friction in a collar at the back of the plate. It is extraordinary, in

view of the primitive character of this instrument compared with the modern microscope, that with its aid Anton van Leeuwenhoek should have been able to carry out his classical work, and to have shown himself in some respects a pioneer in microbiology. Another exhibit, going much further back into antiquity, was a reconstruction, on the basis of recently discovered manuscripts, of the actual pattern of the stomachion or lozenge of Archimedes, the pastime of the Greeks and Romans twenty centuries ago.

THE SOCIETY OF APOTHECARIES.

At the dinner of the Society of Apothecaries to the Lord Mayor and the Sheriffs of London, in the Hall of the Society on June 15th, a large number of guests were present, including His Excellency the Italian Ambassador, the Marchese della Torretta; Sir John Rose Bradford, President of the Royal College of Physicians of London; Sir Frank Dicksee, President of the Royal Academy; the Director-General of the Medical Department of the Navy, Surgeon Rear-Admiral Sir Joseph Chambers; and Sir StClair Thomson, President of the Royal Society of Medicine. The Master of the Society, Dr. Vincent Dickinson, proposed the health of the Italian Ambassador and of the Lord Mayor; Colonel Sir William Pryke, the Lord Mayor, replied. The Senior Warden, Dr. Alfred Hepburn, proposed the toast of "The Guests," and gave an interesting account of the historic connexions of the site of the Society's hall and its neighbourhood. Sir Frank Dicksee, in reply, contrasted the peaceful traditions of City dinners with the turmoil, overthrow of authority, and unrest in the outer world. Dr. Gordon Brown, Senior Past Master, proposed the health of the present Master, to which Dr. Vincent Dickinson replied.

MEDICAL RESEARCH IN MALAYA.

In the annual report for 1924, by Dr. A. T. Stanton, on the work of the Institute for Medical Research of the Federated Malay States, with which is combined the reports of the Malaria Bureau and the Chemical Laboratory, a preliminary note is given of investigations undertaken with a view to testing MacGregor's hypothesis that the degree of alkalinity or acidity in mosquito breeding waters is a main factor in determining the species of larvae found in them. It appears likely that, though the larvae of Malayan anophelines are unaffected by small variations of acidity and alkalinity in the water of stagnant pools, yet there is some evidence that definite limits of such variations exist which certain species do not usually pass in nature. The emphasis laid previously by Sir Malcolm Watson and others upon the importance of subtle chemical differences in breeding waters appears, therefore, to be justified. It is believed that this observation will be of assistance in future malarial surveys. Correlation of the various lines of research in the prevention and treatment of malaria was carried on actively during the year in spite of a depleted staff. The larvicidal powers of fishes and aquatic insects were studied, and an attempt made to determine whether the nature of the plant life in pools affords indications of the presence of particular species of larvae. A new department of the institute was opened in August, 1924, for the prophylactic treatment of rabies, and arrangements made to issue the vaccine to Government hospitals if an epidemic should occur. A special study was made also of cases of fever of obscure origin, including a form of typhus distinguishable by its low infectivity and the absence of evidence that it is carried by lice. The chemical laboratory dealt with over 7,000 samples during the year, various public water supplies were visited, and thirty toxicological analyses performed.

BICENTENARY CELEBRATIONS AT EDINBURGH UNIVERSITY.

BANQUET IN THE UNIVERSITY LIBRARY.

THE celebrations to commemorate the two hundredth anniversary of the founding of a Faculty of Medicine in the Town's College at Edinburgh in 1726 were held on June 10th and 11th. The central ceremony was the opening of the reconstituted surgical department.

The proceedings began with a dinner in the hall of the library of the University; and among the 180 persons present were 39 representatives from other universities and medical schools in Britain, on the Continent, and on the far side of the Atlantic, as well as most of the teachers in the Medical Faculty of Edinburgh University. The toast of "The Guests" was proposed by the chairman, Sir Alfred Ewing, Principal of the University. Although the University was, he said, technically the host of the evening, there were associated with it two great historic bodies—the Royal College of Physicians of Edinburgh and the Royal College of Surgeons of Edinburgh. Both were more venerable than the Faculty of Medicine. The surgeons and barbers

dated from 1505, and the Royal College of Physicians won its charter after some opposition in 1681. From these two bodies the first professors had come to form, just two hundred years ago, the Faculty of Medicine of the University of Edinburgh. The Corporation of Edinburgh also should be mentioned, for the University had begun its existence as the Town's College under the patronage of the corporation, and it had remained the Town's College for nearly three hundred years. With regard to the ten distinguished men upon whom the University was to confer its honorary degree next day, the Principal tendered to the foreign visitors some apology, for on the present occasion it had been decided to give honorary degrees only to the sons of Edinburgh. Referring to the foreign guests, he said that the stream of medical culture had come from Leyden to Edinburgh. Next to Leyden, however, Edinburgh owed a debt to Paris, which had been a centre of light for all the world. His own studies had run entirely in physics in its application to engineering, and while great blessings had been conferred on mankind by engineering it had at same time made the world more restless, less contented, and the individuals perhaps less masters of their inner selves; in the case of medicine, however, there had been no corresponding disadvantage. Professor van der Hoeve, dean of the Faculty of Medicine at the University of Leyden, in responding, brought the congratulations of his university, and expressed the hope that Edinburgh would flourish and prosper in the years to come. He referred particularly to the intimate relations which had existed in the past between

Scotland and Holland, where no fewer than 1,400 Scotsmen had studied under the celebrated Boerhaave at Leyden University. Dr. D. R. Vaudesal conveyed the good wishes of the Faculty of Medicine in the University of Paris to the Faculty at Edinburgh. Replies were also made by Professor Sir H. D. Rolleston, K.C.B., of the University of Cambridge, and by Dr. Andrew Balfour, C.B., C.M.G., director of the London School of Hygiene and Tropical Medicine. Professor Sir Archibald E. Garrod, K.C.M.G., submitted the toast of "The Edinburgh School of Medicine."

It had, he said, been the first really organized medical school in this island, and his own medical school of Oxford University had been, at its commencement, largely composed of men borrowed, taken, or acquired from Edinburgh. The students of to-day, as compared with those before the war, had a different outlook; they were brought up in association with much wider sympathies, with an interest in outside things such as politics and economics, and with a greater interest in their fellow men. Replies to this toast were made by Pro-

fessor Lorrain Smith, dean of the Faculty of Medicine, who said that there was great national need for a reform in the medical service; by Professor Robertson, President of the Royal College of Physicians of Edinburgh, who said that although the Edinburgh medical school was divided into two bodies, the University and the extramural school, the heart of the whole medical school, from which both sides drew their life blood and their inspiration, was the Royal Infirmary; for its foundation the then President of the Royal College of Physicians had started to collect money

exactly two hundred years ago, and it had been built twelve years later. Dr. Logan Turner, President of the Royal College of Surgeons of Edinburgh, who also responded, referred to some of the important steps taken by Fellows of this College in the development of the Edinburgh medical school. The toast of "The Chairman" was proposed by Sir John Roso Bradford, President of the Royal College of Physicians of London, and duly acknowledged.

HONORARY GRADUATION
CEREMONY.

The graduation ceremony was held on Friday, June 11th, at 10.30 a.m.,

in the M'Ewan Hall, and was attended by the delegates representing universities and medical schools and by a large number of the public. The University conferred the honorary degree of Doctor of Laws on ten eminent medical graduates of this school. Vice-Chancellor and Principal Sir Alfred Ewing presided, and was supported by Lord Provost Sir William Sleight and the Sheriff of the Lothians. Sir Alfred Ewing said that the University welcomed the delegates, who had come from many famous

Research Department: Research Workers' Room.

Research Department: X-Ray Room and Theatre A beyond.

schools of medicine not only in Britain but on the continent of Europe, in America, and in the dominions beyond the seas, with messages of goodwill. They were doubly proud of the fact that not a few of these were sons of Edinburgh. He felt that the great company of distinguished guests had come to do honour to the spirits of the past whose presence they seemed to feel among them, and he would like to assume that they had also come under the impulse of a living interest in order to give their encouragement to the great task of maintaining a tradition for the future. Of any institution it must be true that to review a glorious past was to apply to the present a heart-searching test. From such a gathering as the present there was bound to spring fresh hope, stronger courage, and confirmed resolution.

Congratulatory addresses were presented by delegates from the Universities of Leyden, Copenhagen, Oslo, Paris, Montreal, Toronto, Pennsylvania, Oxford, Cambridge, Ireland (National), Wales, St. Andrews, Aberdeen, London, Birmingham, Bristol, and Leeds; from the Royal College of Surgeons, London, Charing Cross Hospital and St. Bartholomew's Hospital Medical Schools, and the Carolino Medico-Chirurgical Institute, Stockholm. The Dean of the Faculty of Law, Professor James Mackintosh, K.C., LL.D.,

then introduced individually ten distinguished graduates in medicine of the University, whom he proposed for the honorary degree of Doctor of Laws. He said that the University offered them collective and most cordial welcome. They had all been reared in the Edinburgh Faculty of Medicine, choice fruits of that goodly tree whose planting two hundred years ago was commemorated that day. In their several spheres of activity they had nobly sustained the credit of their old school, and their Alma Mater on this happy anniversary was proud of the tale of their achievements. The ten honorary graduates, of each of whom the Dean gave a short biographical sketch, were: Andrew Balfour, C.B., C.M.G., M.D., Director of the London School of Hygiene and Tropical Medicine; Robert Howden, M.A., M.B., C.M., D.Sc., Professor of Anatomy, University of Durham; William Tasker Adam Jolly, M.B., Ch.B., D.Sc., Professor of Physiology and Dean of the Faculty of Medicine, University of Capetown (in absentia); Sir George Newman, K.C.B., M.D., F.R.C.P., Ministry of Health; Alexander Primrose, C.B., M.B., C.M., Professor of Clinical Medicine, and Dean of the Faculty of Medicine, University of Toronto; Sir John Robertson, C.M.G., O.B.E., M.D., Professor of Public Health, University of Birmingham; Ralph Stockman, M.D., Professor of Materia Medica and Therapeutics, University of Glasgow; Arthur Logan Turner, M.D., President of the Royal College of Surgeons of Edinburgh; Sir Norman Walker, M.D., F.R.C.P.Ed., Treasurer of the Royal College of Physicians of Edinburgh; and James Thomas Wilson, M.B., C.M., F.R.S., Professor of Anatomy, University of Cambridge.

ADDRESS BY SIR GEORGE NEWMAN.

Immediately after the graduation ceremony an address was delivered by Sir George Newman, Chief Medical Officer, Ministry of Health, who spoke of some of the facts connected with the early foundation of the Medical Faculty at Edinburgh. At the outset he described the early school of medicine in Salerno, which had been for two hundred years the centre of Greek inspiration to Europe. From this primitive medical school the medical spirit of the Italian universities had been derived. By the thirteenth century Bologna and Padua, though established for the study of law, possessed medical faculties, and these two medical schools had been the famous prototypes of Leyden and of Edinburgh. The revival of the

Hippocratic tradition had come to Western Europe in the seventeenth century by the life and labour of three men—Harvey, Sydenham, and Boerhaave. In a single generation the reputation of Leyden as a medical school had spread throughout Europe and wholly supplanted that of Padua. Boerhaave's classroom had been crowded with men from all nations, of whom 20 or 30 per cent. came from Great Britain. His clinic had been the great battleground in Europe between book learning and practical training, and from the small hospital in Leyden

had gone forth a new method of medical education. In the autumn of 1718 there had sat in Boerhaave's classroom eight or ten young men from Edinburgh. Among them was Alexander Monro, a medical student of 21, who was destined to carry the traditions of Leyden to Edinburgh; and by his side sat John Rutherford, of the same age, afterwards the grandfather of Sir Walter Scott. In 1718 Leyden was a place of splendid vision, a hive of industry, a centre of life and growth, and the University of Edinburgh was not. The whole atmosphere of Leyden was

vital, the spirit adventurous. At Leyden in that day there was a living prophet, and it was men and not methods that made a great university. Leyden had also bestowed upon the young men from Edinburgh an apprehension of the science of medicine, and they had also brought from Leyden a method of clinical education. One institution at Leyden was quite new to these Edinburgh men—the old convent infirmary which Burton called the University Hospital. There twice a week a bedside clinic was held, and it was interesting to find from Rutherford's manuscript notes that when he introduced clinical teaching at Edinburgh he followed the

exact model which he had learned at Leyden from Boerhaave in 1718-19. This had become one of the characteristic features of the Edinburgh medical school and had been copied all over the world. The early days of the medical history of Edinburgh had been fully recorded by the distinguished President of the Royal College of Surgeons. Lord Cockburn had said that "Great causes create great men, but great men elevate great causes." This interaction had done much for Edinburgh in

Teaching Department: Surgical Museum.

the eighteenth and nineteenth centuries. From all over Great Britain, and from remote parts of the earth, men had come to be nurtured in this cosmopolitan centre and had attained to a sense of citizenship in the world. Some of the remarkable discoveries of the eighteenth and nineteenth centuries had been made within the walls of this medical school—Goodsir's cell theory, Gregory on morphine, Hughes Bennett on leuco-cythaemia, Laycock on hysteria, Sir J. Y. Simpson on anaesthetics, and Lister on antiseptic surgery. These discoveries did not begin, nor were they completed, in Edinburgh, but all of them were there substantially advanced, and of all of them it might be said that they entered into the history of mankind. The design of their forefathers had been that the future of medical education as interpreted in Edinburgh would depend upon (1) integration of the several sciences which were structural in medicine, particularly in biology; (2) the application of the experimental method to all inductive study; (3) a clear recognition of the prerogative part which medicine might play in social evolution; and (4) sound clinical study. The present generation had been witnesses of a golden age of medical sciences, yet it was the medical art which endured. The effective practice of this art depended, and would always depend, upon the clinical skill, wisdom, and experience of the individual practitioner.

SERVICE AT ST. GILES'S CATHEDRAL.

A commemoration service was held at noon on June 11th in St. Giles's Cathedral, to which the Medical Faculty and Senatus of the University proceeded immediately after the graduation ceremony. The Very Rev. Professor W. P. Paterson, D.D., dean of the Faculty of Divinity, preached the sermon, taking as his text the words, "Their line is gone out through all the earth, and their words to the end of the world." Touching on the outstanding features in the history of the Medical Faculty, which furnished matter for gratitude, he said that the first and most obvious fact was that the medical school of Edinburgh had made a notable contribution to the advancement of Britain and of other lands. During the past two centuries the Medical Faculty had equipped and sent forth 16,000 graduates, of whom half had been drawn from Scotland and the other half from other nationalities. If Scotland had the distinction of having made a considerable contribution to the enlightenment and well-being of humanity, it was chiefly because it had realized, almost more than any other nation, how much it had to learn from the races of mankind. A fact brought into relief by these celebrations was the importance of the organic connexion of the medical school with a great seat of learning in other departments. A third outstanding feature of the history of the University medical school had been its permeation by the spirit of Scottish religion. The preacher thought that a collapse of faith could only be an exceptional and transitory phenomenon among those whose subject of study was the marvels of creation and the wonders of man's estate, and whose work was cast in the mould of self-sacrificing and beneficent labour for the good of man.

OPENING OF NEW SURGERY DEPARTMENT.

In the M'Ewan Hall on the afternoon of June 11th, at 3.30, Sir John Gilmour, Secretary for Scotland, formally opened the new surgery department of the University. The buildings were fully described in the *BRITISH MEDICAL JOURNAL* for June 5th, 1926 (p. 959). The large party which assembled in the M'Ewan Hall had an opportunity of inspecting the buildings either before or after the ceremony. Principal Sir Alfred Ewing, who presided, said that on the occurrence of a recent vacancy in the professorship of surgery they had been able, thanks largely to the Rockefeller Foundation of New York, to make the appointment on altered conditions, which secured a much larger proportion of the professor's time for carrying out the work of teaching and research. Professor D. P. D. Wilkie had been appointed to the chair, and his qualifications had included zeal, skill, and knowledge, with also an enthusiasm which at once inspired him to demand from the University an expenditure in aid of surgery which had not been con-

templated at the time of his appointment. He had persuaded the University to fit up what was virtually a new department of surgery, with a laboratory on a scale and with a character and quality of equipment which he believed was not rivalled in the world, and certainly not in Great Britain.

The Secretary for Scotland said that this happy event in the history of the development of a great school such as that of Edinburgh coincided with the celebration of a long period of useful service to the community. The great names which came readily to their minds at the present time were names which carried with them a tradition of which the profession must be proud. In more recent years many of them had come into personal contact with Professor John Chiene and Professor Alexis Thomson. He himself would ever remember the personality of Professor Alexis Thomson, who seemed to radiate even from his very minor actions a feeling of strength and confidence and of power. The future was in the hands of the students of to-day, and the responsibility lay with them to apply the knowledge which was given to them and to take the opportunity of using to the fullest the new buildings and their equipment. It was said that the profession of medicine knew no boundaries, and it was certain that many difficult and perplexing problems which faced governments and politicians could be solved or mitigated by it. Hand in hand with teachers of religion in eastern parts of the world the power of medicine and surgery had been a pioneer. It had often been the means of gaining the confidence of the people with whom they were dealing, and he would say to young men and young women of to-day who had the British desire to go into the outer world, and the spice of adventure in their natures, that he could conceive no profession which carried with it greater opportunities of service to humanity as a whole. America, through the Rockefeller Institute, had, in the present instance, lent aid in that direction. When they recollected that two hundred years ago the United States did not exist, and that in the interval there had been great changes in the historical development of the two peoples, it was a helpful and inspiring thought to realize that there yet remained, on the great main issues of life, a feeling that they ought to and could work hand in hand.

Professor Wilkie, in moving a vote of thanks to Sir John Gilmour, said that after the arduous and anxious and strenuous time through which the Government had lately passed, it was perhaps a pleasant change to the Secretary for Scotland to open a department in which the workers had no fixed hours, had most unceasing emoluments, and to whom the advancement of science formed a sufficient stimulus for hard work and renewed endeavour. He found that the difficulty in this department was not to exact so many hours a day from the research workers, but rather to provide keys of the department so that the workers might gain access to continue their researches during the watches of the night. The past two centuries of medicine in Edinburgh had seen remarkable changes and advances, but perhaps the most remarkable of all had taken place in surgery, and these for the most part in the past fifty years. At present many patients entered the surgical wards, desiring and often demanding operative treatment—sometimes, he regretted to say, without having consulted their own medical man. If they contrasted this with the dread, almost amounting to horror, with which the word "operation" was whispered not more than sixty years ago, the great change that had taken place in the attitude of the public towards the art of surgery would be realized. The cause of this was to be found chiefly in the application by Lister of the knowledge gained in the experimental laboratory by Pasteur. In the department which Sir John Gilmour had just opened it was hoped to combine members both of the university staff and of the extramural staff without distinction. The laboratory was to be a laboratory of the Edinburgh School of Surgery and Medicine, for medical research knew no walls but one, and that was the wall of ignorance. If they were to make any breach in that wall it could only be by combined and co-operative effort.

EVENING ENTERTAINMENTS.

In the evening of Friday, June 11th, a commemorative dinner was held in the Hall of the Royal College of Physicians. Professor G. M. Robertson, President of the College, presided. The toast of "The Town" was proposed by the President, and acknowledged by the Right Hon. the Lord Provost. "The Faculty of Medicine" was proposed by Professor Tait McKenzie of Pennsylvania University, and replied to by the Dean of the Faculty of Medicine; and the "President of the College" was proposed by the Principal of the University and suitably acknowledged. Later in the evening a civic reception was held by the Lord Provost, magistrates, and town council at Inverleith House, Royal Botanic Garden. Representatives of public bodies, as well as of the University Faculties and of the medical profession, were present, and the company included over a thousand ladies and gentlemen. The guests were favoured with a pleasant summer evening, and enjoyed the magnificent vista of the city and the rich foliage of the gardens, which at this time of the year show their best appearance.

England and Wales.

THE COMING-OF-AGE OF THE UNIVERSITY OF SHEFFIELD.

We have already announced that the coming-of-age of the University of Sheffield will be celebrated on Thursday and Friday, July 1st and 2nd. We may now give some further particulars. On Thursday morning, at 10.30, the Chancellor, the Marquess of Crewe, K.G., will receive delegates from other universities, from public bodies, and learned and scientific societies, and will receive congratulatory addresses from the delegates. Afterwards he will unveil the university war memorial and lay the foundation stone of the gymnasium. A luncheon to Princess Mary, Viscountess Lascelles, and honorary graduands and delegates will be given in the Cutlers' Hall (by permission of the Master Cutler, Mr. T. R. Ellin). Afterwards a congregation will be held in the Victoria Hall, where an address will be presented to Princess Mary, and the following honorary degrees will be conferred:

Doctor of Laws.

Princess Mary, Viscountess Lascelles.
The Earl of Derby.
Lord Hewart of Burry (Lord Chief Justice of England).
Sir Joseph Austen Chamberlain, K.G. (Secretary of State for Foreign Affairs).
The Right Hon. Sir Samuel Roberts, Bt.
Sir Percy Richard Jackson.
Mr. Harry Parker Marsh.
Miss Emily Penrose.

Doctor of Letters.

The Bishop of Sheffield.
The Right Hon. Sir Charles Eliot, G.C.M.G., at one time Vice-Chancellor of the University of Sheffield.
The Very Rev. Sir George Adam Smith.
Sir Hugh Percy Allen.
Professor A. W. Pollard, C.B.

Doctor of Science.

Professor Percy Faraday Frankland, F.R.S.

Doctor of Engineering.

Engineer Vice-Admiral Sir R. B. Dixon, K.C.B.

Later in the afternoon a reception will be given by the Lord Mayor and Lady Mayoress of Sheffield, and the University dinner will take place in the Cutlers' Hall in the evening. On Friday morning the new engineering and metallurgical research laboratories of the University will be opened and the laboratories and workshops of the applied science department of the University inspected. The afternoon will be spent at the university playing fields, Norton, where the foundation stone will be laid of the pavilion, the cost of which is to be defrayed from a bequest of Sir Albert Hobson (late Pro-Chancellor of the University) as a memorial to him and his two sons, both killed in the great war. There will be a cricket match (Liverpool University v. Sheffield University) and a tennis tournament. In the afternoon the Chancellor will give a reception at the University Buildings, Western Bank.

ROYAL DEVON AND EXETER HOSPITAL.

During the year 1925 a new radiological department was opened at the Royal Devon and Exeter Hospital. The old

department, instituted very early in the history of electrical treatment, under the supervision of the late Dr. J. Delpratt Harris, had become insufficient for the work. The completion of the new "Victory" wing of the hospital allowed a complete double ward, with convenient annexes for deep treatment and other work requiring a dark room, to be allotted to the new department, on which the hospital has spent nearly £3,000, while the Devon and Exeter Cancer Fund has materially assisted in the acquisition of further up-to-date plant. This fund was due to a letter from Mr. Russell Coombe, F.R.C.S., to the local press. A meeting was called conjointly by Lord Fortescue (Lord Lieutenant of Devon) and the Mayor of Exeter (Mr. P. F. Rowsell), and under the chairmanship of the latter £11,000 was raised in about eighteen months. Of this sum, £5,000 was voted to the Royal Devon and Exeter Hospital for immediate needs, and among the equipment purchased with this contribution were a Gaiffe constant current apparatus for deep treatment, a spare (coil) apparatus for deep treatment, and 140 mg. of radium element. A further amount of radium has been promised in the near future. The constant current apparatus for deep treatment is the first of its kind erected in this country. It has this advantage in that there is no risk in the matter of dosage should the control be delegated to a partially skilled operator. Some three years ago an experimental outfit was obtained for the more modern treatment by the ultra-violet rays. The use of this method soon became so frequent that a powerful mercurial ultra-violet lamp was purchased, which is now in almost constant use during the day, especially for the treatment of surgical tuberculosis of children. Dr. Miller Muir, the radiologist to the hospital, was largely responsible for the design of the new department. In 1925 the new massage department was completed. The total number of in-patients and out-patients dealt with in the hospital during the year was 10,168, an increase of 395 on the previous year, and a record for the hospital. The average cost of each occupied bed decreased from £109 2s. 1d. to £105 18s. 5d. Further improvements contemplated include the establishment of a surgical maternity ward, the construction of a new dispensary department, and the provision of separation wards in the basement. The ordinary income of the hospital during the year under review was £23,798, an increase of £852 over the previous year. Payments by patients now form a considerable part of the revenue, and increased substantially during 1925. There is still, however, a long waiting list, and the present income does not permit the maintenance of more than 200 beds.

THE EARLY TREATMENT OF CONGENITAL SYPHILIS.

Mr. E. B. Turner, F.R.C.S., who presided over a conference of the British Social Hygiene Council in connexion with the Nation's Health Exhibition at Leicester, on "What further steps can be taken to prevent congenital syphilis," urged that the Wassermann test should be applied to expectant mothers as a matter of routine, and suggested that treatment might be given at ordinary maternity homes and not necessarily at V.D. clinics. Dr. Norman Cruickshank emphasized the importance of the subject in connexion with infant mortality. Some 10 per cent. of the hospital class of patient showed evidence of having been infected with syphilis, and though there was less venereal disease now than a few years ago it was too early to say whether this improvement would be permanent. The most effective method of prevention was early diagnosis, and to make an early blood test should be a routine in all institutions engaged in obstetrical work; such a test might be made compulsory in connexion with the National Insurance Act, and special benefit given to those expectant mothers who accepted ante-natal supervision. Mr. John Adams said that a negative test did not necessarily mean that a patient was cured, and thought it should be negative for at least a year before marriage. When syphilis was untreated 50 per cent. of children were born dead, 75 per cent. of the remainder died within a week of birth, and most of the rest died within the first year. Every woman who had had syphilis should be specially treated for each successive pregnancy. A child born syphilitic should receive treatment at the earliest

possible moment, say within half an hour after birth. Syphilis was much less prevalent than it was four years ago and was steadily getting less and less, but he urged that the towns should establish special clinics for the treatment of ante-natal and post-natal syphilis. Dr. David Lees believed that the country had it in its power absolutely to eradicate congenital syphilis, and raised the issue as to why gross lesions were still met with. There was a need to educate the profession in the policy of preventive medicine, and every children's and maternity hospital should have on its staff someone specially skilled in the diagnosis and treatment of the disease. He thought it better for cases to be treated in such institutions than in V.D. clinics. In Edinburgh it had been found perfectly possible to give treatment in the general hospitals. There should be no stigma attaching to the disease and there was no difficulty in getting patients to accept the blood tests, if they were not regarded as outsiders.

CONFERENCE OF THE BRITISH HOSPITALS ASSOCIATION.

The sixteenth annual meeting and conference of the British Hospitals Association will be held at Portsmouth, on June 24th and 25th, under the presidency of Sir Arthur Stanley. On the first morning, after the delegates have been welcomed by the Mayor of Portsmouth, a discussion on pension schemes for officers and nurses will be opened by Dr. H. L. Eason, C.B., C.M.G. In the afternoon Sir John Paget, Bt., K.C., will read a paper on street accidents and compensation cases, and a discussion will follow. On the second day, after a business meeting in the morning, a paper will be read by Dr. S. C. Dyke on the pathological service of the general hospital, and in the afternoon arrangements have been made for visits to Portsmouth Hospital, the Royal Naval Hospital, Haslar, the dockyard, and other centres of interest. The objects of the British Hospitals Association are to facilitate the consideration of details of hospital management, to afford opportunities for discussion of points of special interest or difficulty, and generally to facilitate the acquiring of knowledge of hospital administration. The association now includes in its membership most of the chief hospitals in the country, and is recognized by Government departments as representative of the voluntary hospitals. Trustees of hospitals, members of committees, or executive and professional chief officers are eligible as members of the association. Members pay an annual subscription of one guinea.

WELSH WAR MEMORIAL HOSPITAL.

Prince Henry, accompanied by Lord Kenyon (Lord Lieutenant of Denbighshire), opened the new War Memorial Hospital at Wrexham on Wednesday, June 9th. Members of the honorary and resident staffs were presented to the Prince, including Mr. J. Oswell Bury, president of the hospital; Mr. R. W. Egerton, chairman of the board; Mr. Richard Williams, senior consulting surgeon; Miss M. A. Turner, matron; and Mr. Leslie Spencer, secretary of the new hospital. The Bishop of Bangor presided at the opening ceremony, supported by the Archbishop of Wales. The building, which will serve a population of more than 100,000, has cost rather more than £100,000. The hospital has been opened free from debt, in consequence partly of a donation of £35,000 by the William and John Jones trustees, and partly of contributions, amounting to £26,000, from the employees and miners of East Denbighshire.

Scotland.

THE LORD HIGH COMMISSIONER'S VISITS TO HOSPITALS.

The Lord High Commissioner to the Church of Scotland General Assembly, accompanied by Lady Elgin, paid the usual round of visits to hospitals and similar institutions in Edinburgh during the past week. On June 2nd a visit was paid to the Royal Infirmary of Edinburgh, where they were received by the Lord Provost and other managers. They visited in particular Wards 9 and 32, and spent some time talking to the patients, inquiring

sympathetically into their condition and admiring the appearance of the wards. They subsequently distributed the prizes gained by the nurses in the examinations. On June 3rd a visit was paid to the Royal Hospital for Sick Children, to the Children's Shelter, and to the training home of the Queen Victoria's Jubilee Institute for Nurses (Scottish Branch). Here it was stated that at the present time there were 700 Queen's Nurses in Scotland, and that during 1925 these nurses had paid over one and a half million visits to some 96,000 cases. On June 5th a party of about 150 disabled soldiers from the Ministry of Pensions Hospital at Craigleith were the guests of the Lord High Commissioner and Lady Elgin at a garden-party, held within the grounds of Holyrood Palace, and after tea the party were shown over the historic rooms in the palace. On the same day a visit was paid to Chalmers Hospital and to Newington House, the Scottish National Institution for Blinded Soldiers and Sailors. Here the workshop was specially inspected, where a number of men were engaged in mat-making, boot-making, and similar work. On June 8th the Lord High Commissioner and Lady Elgin visited the Deaconess Hospital. Lord Sands, chairman of the board of management, summarized the functions which the hospital discharged, which, he said, provided a useful supplement to the beds available in larger institutions for the sick in a densely populated industrial district of Edinburgh. In the course of the past year over 700 patients had been accommodated, and more than 5,000 persons had received treatment at the out-patient department. A distinguishing feature of the hospital was that it afforded a school of training to women who proposed to devote themselves to the service of the Church in nursing the sick poor both in Scotland and in foreign lands. Lord Elgin inspected the apparatus which had been installed since the previous year for the application of ultra-violet rays, especially in dealing with rickets and similar ailments in children. Lady Elgin afterwards distributed prizes to the nurses who had won them in examinations. On the same day Lady Elgin paid a visit to the Elsie Inglis Memorial Maternity Hospital, which is not yet completed, but has opened 45 beds for patients. A fine view of the neighbouring hills in the King's Park from the verandah, on to which the wards open, and which is utilized in the treatment of patients, was greatly admired, as well as the rows of babies receiving a sunbath in the open-air shelter provided for this purpose. On June 9th Lady Elgin visited the Edinburgh Royal Maternity and Simpson Memorial Hospital. In particular the ante-natal department, which was described in the BRITISH MEDICAL JOURNAL of March 20th, and was opened last April as a memorial to the late Dr. J. W. Ballantyne, occupied attention. It was pointed out by Dr. Nasmyth, chairman of directors, that this hospital has the distinction of being the first hospital in the world to have an ante-natal department, which is now recognized as one of the most important features of maternity welfare work.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

The syllabus of the Post-Graduate Medical Association in Glasgow for the summer session from June till October, 1926, has just been issued. The teaching facilities are in three forms—a general medical and surgical course, a certain number of special clinical courses, and clinical assistantships. The general medical and surgical course will run during the last two weeks of August and the first two weeks of September, and is a whole-time course, for which an inclusive fee will be charged. It is specially designed to include subjects of interest to the general practitioner. The forenoons will be occupied with general medicine, surgical diagnosis, and minor surgery in the Victoria and Western Infirmarys. In the afternoon special subjects will be dealt with in some of the special hospitals of the city or in the special departments of these two general hospitals. Two special subjects, such as gynaecology, radiology, skin diseases, venereal diseases, etc., will be treated each afternoon. On the Saturday afternoons, tuberculosis and infectious fevers are to be demonstrated at Ruehill Fever Hospital. Special classes in diseases of the eye, clinical obstetrics, clinical gynaecology, and

diseases of the ear, nose, and throat have been arranged to suit the requirements of general practitioners who wish to devote special attention to particular branches of hospital work. Clinical assistantships are available in various general and special departments; they are limited in number and have been designed to make provision for graduates who desire opportunities for the detailed study of some specialty. The graduates work under the direct supervision of the physician or surgeon in charge of the department and carry out various detailed investigations. Graduates desiring to act in this way must enrol for a period of three months, and in general the whole forenoon is occupied by the work required. In most cases a fee of five guineas is charged. Graduates intending to join the general medical and surgical course should apply to the secretary, Glasgow Post-Graduate Medical Association, the University, Glasgow, from whom further information and a copy of the syllabus may be obtained.

VENEREAL DISEASE.

The annual meeting of the Scottish Committee of the British Social Hygiene Council (formerly the National Council for Combating Venereal Diseases) was held on June 2nd in the City Chambers, Edinburgh. Councillor S. G. Fraser (Dundee) who presided, said that the Scottish Committee had been able to focus the attention of public health authorities and social organizations on the need for extending propaganda work. Within the last few years no fewer than 128 exhibitions of films depicting the dangers of venereal disease had been given at different places to audiences totalling about 92,000 people. In future the Council's activities would be directed also to the need for providing additional recreational facilities in populous centres. Such facilities were in many places inadequate, and their existence did much to counteract the chances of evil. Recognizing also how much evil arose from bad housing, the Council was giving attention to the great need for speeding up housing reform. Mrs. C. Neville Rolfe, O.B.E., general secretary of the Council, gave an account of the progress that had been made in the last six years. Since the Government scheme for treatment had started, over 670,000 persons had visited the treatment centres. During the last five years there had been a steady fall in the number of new cases, which was encouraging. There was reason to think that the position was satisfactory so far as men were concerned, but it was believed that women who needed treatment were not receiving it; the Council desired to give particular attention to the prevention of congenital disease in children.

DOCTOR AS HEADMASTER.

The governors of Loretto School, near Edinburgh, have appointed Dr. James R. C. Greenlees to be headmaster in succession to the late Mr. A. R. Smith. Dr. Greenlees is an old pupil of Loretto who subsequently graduated at Cambridge, taking the degrees of M.B., B.Ch. in 1906. After graduation he practised medicine in Glasgow, where he was attached for seven years to the Western Infirmary, and was on the staff of the Royal Hospital for Sick Children from 1908 to 1922. He joined the R.A.M.C. in August, 1914, served in France till the close of the war, and was awarded the D.S.O. and the Cross of the Legion of Honour. Since 1912 he has been a governor of Loretto School.

Ireland.

DR. TAYLOR OF TANDRAGEE, COUNTY ARMAH.

It was with much sympathy that the profession in the North of Ireland noticed that Dr. James Taylor had found it necessary, on grounds of health, to retire from the posts of medical officer of the Tandragee Dispensary District and of medical officer of health for the urban and rural districts. Dr. Taylor, who is the son and grandson of medical men, qualified in 1874, and shortly afterwards settled in Tandragee. His energy and perseverance in dealing with the numerous health problems of the district were soon

felt. Sanitary matters had been neglected; the water supply was bad; outbreaks of typhoid fever and of other zymotics were too frequent. Many and serious were the wars that Dr. Taylor had to wage in his endeavours to improve matters, often unaided, and with insufficient backing from the authorities of the time. He has now the satisfaction of leaving things incomparably better than he found them. As an example: in his first year in the district sixteen deaths were registered from puerperal fever, but during the last twenty years only one; and all zymotic affections, except influenza and pneumonia, have likewise much diminished. Dr. Taylor has for many years drawn attention to the large number of cases of goitre in the district. The profession will join his many friends in county Armagh in wishing Dr. Taylor many years in which to enjoy his well earned rest after fifty years of hard work.

COOMBE LYING-IN HOSPITAL.

The annual report of the Coombe Lying-in Hospital of Dublin for 1925 gives full details of the 934 cases attended during the year. The maternal deaths numbered 8 (0.85 per cent.). The morbidity rate was 4.5 per cent. (42 cases). This was a large reduction on the morbidity returns of the previous year. In 24 of these patients no vaginal examinations were made, there was no laceration of the perineum, and no operative intervention necessary. The question is raised whether the cause of puerperal sepsis is to be sought in the lowered bactericidal properties of the patients' serum before the onset of labour. A bacteriological examination before labour in 25 cases showed the presence of Döderlein's bacilli, streptococci, *B. coli*, and vaginal bacilli. Yet in none of these patients was there any rise of temperature during the puerperium. As examination of the vaginal organisms before parturition throws very little light on puerperal sepsis, investigation of the blood before labour is now being undertaken. Among the 934 patients the large number of 16 cases of placenta praevia occurred, 3 being in primiparae; in 1 there was the unusual complication of twins. The treatment adopted was usually Braxton Hicks's method of version, Caesarean section being limited to patients with a child alive at or near full term, and with a central placenta, the mother being an elderly primipara, uninfected and anxious for a living child. In 27 cases of external accidental haemorrhage all the patients had albuminuria in catheter specimens. Two cases of severe post-partum haemorrhage were attended; both patients recovered. In the one case of concealed accidental haemorrhage the patient died. It has been found in the Coombe Hospital that the administration of pituitrin in these cases is better than Caesarean section. Doses of 1/2 c.cm. of pituitrin are given every half-hour until 3 c.cm. have been injected. Eclampsia occurred in 11 women, of whom 4 were multiparae. The treatment was stomach and bowel lavage, the administration of 4 oz. of magnesium sulphate through the stomach tube, the withdrawal of 12 oz. of blood from the median basilic vein without regard to blood pressure or the condition of the pulse, and the injection of 1/2 grain of morphine, repeated if the fits continued. Threatened eclampsia was treated by absolute rest, starvation for one to three days, free purgation, and the administration of large quantities of water. For the induction of labour the method usually adopted was the administration of castor oil, 10-grain doses of quinine, and 1/2 c.cm. doses of pituitrin every half-hour, up to 3 c.cm. Similar treatment was tried in the 4 cases of uterine inertia, but without much effect. Among the 934 patients forceps were applied in 57 cases. Forty-nine abortions were treated; only 5 occurred in first pregnancies. One woman "had the large number of twenty-five pregnancies to her credit." The report expresses dissatisfaction with the ordinary textbook classification of the cause of abortion. It is considered probable that many abortions are caused by bad hygienic conditions; in some cases in the later months a breakdown in maternal metabolism is suggested. In the experience of the Coombe Hospital staff, syphilis does not account for more than 2 per cent. of these cases. The report concludes with a summary of the gynaecological work done in the hospital during the year, and with extracts from a paper on blood pressure in pregnancy by Dr. D. L. Hemmingway.

Correspondence.

THE SPAHLINGER TREATMENT.

SIR,—Though Dr. C. E. Jenkins denies that he has impugned the good faith of the Science Committee he does not withdraw his assertion that the report issued by the committee, professedly in support of the proposed trial of the Spahlinger treatment, is "drawn up with the object of discrediting the whole matter." Indeed, he emphasizes this accusation when he writes (*BRITISH MEDICAL JOURNAL*, June 12th, p. 1012) that the committee is "hostile," evidently meaning by this term that at heart the committee is opposed to the proposal which it pretends to support. He quotes no sentence or phrase to justify this conclusion but relies upon what he calls the "tone" of the report and "the attitude of mind displayed by the committee." It is upon these vague and intangible existences that he rests his charge that the real object of the committee is subtly to discredit what it professes openly to favour. And yet he protests, "I have not impugned the good faith of the Science Committee." I must, of course, allow him the virtue of sincerity. But when I have done so, how can I escape the alternative conclusion that in a debate between "good faith" and "bad faith" his capacity for judgement is sadly to seek?

Dr. Jenkins provides yet another illustration of the practice of assertion without proof. "Nobody," he writes, "could read that article [the committee's report] without forming the opinion that the committee is hostile." He will be surprised, therefore, to hear, other evidences apart, that one of the most ardent advocates of the Spahlinger treatment has already expressed a cordial and unqualified appreciation of the report and of the attitude adopted by the committee. Dr. Jenkins ought to know that a universal negative is a perilous proposition to attempt, and perhaps some day he may learn that to accuse a committee of feigning to advocate a cause which in reality it desires to discredit, is, at least among plain folk, a charge of insincerity and of bad faith.—I am, etc.,

London, W.1, June 12th.

C. O. HAWTHORNE.

COLOUR-BLINDNESS.

SIR,—In a review of Dr. Julia Bell's book on colour-blindness, in the *BRITISH MEDICAL JOURNAL* of May 29th (p. 910), it is stated that "Perhaps the most forcible argument against the Edridge-Green theory is afforded by cases of unilateral colour-blindness, since in them the affected eye can be tested against the normal one." This refers to my recent statements that red and violet are the two colours seen by the dichromic. Now one of the greatest pitfalls of those who disagree with authority in any subject is that they cannot help being influenced by the statements of previous writers. In the first edition of my book on colour-blindness, based on the examination of 116 cases, I stated that yellow and blue were the colours seen by the dichromic, and in the second edition I repeated this statement; but when my cases amounted to several thousands I found that this was not the case, and stated in my *Hunterian Lectures* on colour-blindness and in the *Physiology of Vision* that the two colours seen by the dichromic were red and violet. Even if the two colours seen by the dichromic were proved to be yellow and blue in some cases, this would not be an argument against my theory because my first book was written on this assumption. Space will not permit a more detailed explanation.

The subjects of vision and colour vision are permeated with misstatements, and as there is no appeal board for science there is no opportunity of establishing the simplest fact. Future generations will probably comment on the circumstance that it took me twenty-five years to establish that the wool test is defective, though even in the most favourable conditions and with five test colours 50 per cent. of the dangerously colour-blind escape detection by it, and of those rejected over 50 per cent. are found to be practically normal-sighted. Now let any theorist explain this on any of the older theories; it cannot be explained by the reduction of one constituent in a tri-

chromatic theory, because unequals being taken from equals the remainder is unequal. Yellow appears to be a sensation which is developed at a later date than red, green, and violet, hence the trichromic form of colour-blindness. Cases of this type see three definite colours in the spectrum—red, green, and violet, seeing yellow as red-green. A man who can see yellow (a tetrachromic) is not dangerous unless he have some accompanying defect of light perception. These cases have been classed as partially red-blind or partially green-blind on the assumption that they do not agree with the normal white equation; but 90 per cent. of the colour-blind agree with the normal, either at the normal point or when the comparison white light is increased or diminished in luminosity. The white equation is the amount of red, green, and violet light which, when mixed together, will match a given white light.

The subjects of vision and colour vision, on account of the numerous misstatements, need complete revision. It would be a great help if those societies under whose province they come had a series of discussions and demonstrations.—I am, etc.,

London, N.W.2, June 2nd.

F. W. EDRIDGE-GREEN.

SIR,—In comment on the notice (May 29th, p. 910) of the essay on colour-blindness by Dr. Julia Bell, I should like to say that my experience with regard to dichromics coincides with that of Dr. Edridge-Green in that the two ends of the spectrum are best seen as 'colours'—that is to say, that some grade of red and some sort of purple give colour sensation when the colours intermediate in the spectrum are judged mainly by their relative luminosity.

It is quite true that a yellow, especially a pale yellow, is usually spotted as such by a dichromic; but this, I think, is largely on account of its luminosity, by which I mean that it is what we call a "light" colour—that is, one which reflects a large proportion of the total light which it receives. That this is the case can be tested by slightly obscuring a yellow light by dimming its illumination or interposing a neutral tinted screen, when it is likely to be called indifferently red and green on successive exposures, while its essential yellowness is quite obvious to the normal eye. Blue also, even when containing some amount of red rays, as the blue glass in Dr. Edridge-Green's lantern purposely does, is by them always confused with green.—I am, etc.,

London, W.1, June 7th.

WM. SALISBURY SHARPE.

FUNCTIONAL ALBUMINURIA IN ATHLETES.

SIR,—The albuminuria of exercise is of interest in respect of its cause and of its possible relation to disease. Although described as "functional," it is by no means certain that it always disappears, leaving the kidney normal. Its occurrence would not be known were it not looked for; and it may more often than we think precede, introduce, or occasion such a state as chronic parenchymatous nephritis—a disease remarkable for its insidious onset, and which, uncommon as it is, yet shows a predilection for young men.

My interest in the albuminuria of exercise arose from the knowledge that albuminuria is common in pregnant women—occurring especially in the well built and strong. Imputed by some as being but the reflection of the incidence of albuminuria in the populace, the especial influence of the pregnant state in respect of it is shown by its relation with the pre-eclamptic toxæmia, which also selects the best type of pregnant woman—the young and the strong. That activity is concerned with its rise is shown by the effect of rest; and, contrariwise, by the effect of labour, during which albuminuria is especially common, occurring even in women whose urine up to term had been albumin-free.

Collier's work shows that the albuminuria of athletes is not due to a toxæmia—the rise of waste (fatigue) products in the blood. Thus, in racing rowing men it is universal; but in men engaged in walking contests, even of prolonged periods (twenty-two hours) during which more than a hundred miles were covered, albuminuria is absent (Collier).¹ Collier attributes the albuminuria of racing rowing men to acute passive congestion of the kidneys,

¹ *BRITISH MEDICAL JOURNAL*, June 5th, 1925, p. 956.

the result of temporary overdistension of the right side of the heart. But is it not likely that the heart would be dilated at the end of a twenty-two hours' walk? Many years ago I saw on the *post-mortem* table a considerably enlarged heart in which valvular disease was absent; renal disease, if present, was secondary to the cardiac condition. The state of the heart was attributed to the forced marches during the Boer war.

In the albuminuria of athletes, I submit, the state of the heart must be discounted. I agree with Dr. Abrahams "that the albuminuria . . . occurring in oarsmen is not due to the exercise *qua* exercise, but depends upon mechanical factors which are easily invoked in the case of rowing and obviously absent in running."² The two forms of movement must affect the kidney differently. In the one the abdominal muscles are rhythmically much more contracted than in the other; thus, in the one the kidneys are more compressed than in the other. Of the forty men, forming Collier's five crews, all had albumin, many had casts, and one besides had spermatozoa (Collier). The presence of the last suggests that a considerable compression of the vesiculae seminales, and thus of the kidney, was in operation. This idea is supported by the common occurrence of albuminuria during labour, when the abdominal walls and thoracic diaphragm greatly contract, and obviously compress, not only the uterus, but the other abdominal viscera.

That the functional activity of the kidney is impaired by great compressions of the abdominal visceral mass is indicated by other issues. Thus, in a strongly muscular man, with phlegmonous appendicitis, much albumin in the urine was found. After operation the albuminuria rapidly disappeared. Similarly, in a case of perforated gastric ulcer, the urine, the day after operation, not only contained albumin, but casts were numerous; it rapidly became normal with the recovery of the patient—that is, with cessation of the abdominal rigidity and of the vomiting. Similarly, in acute intestinal obstruction, the kidney functionally is impaired. This is imputed to toxæmia, but the toxæmic state varies with the vomiting, its persistence, and its violence; when it ceases normality is rapidly regained. So also in pregnancy: persistent vomiting occasions renal (as also hepatic) changes; by stopping the vomiting we cure the patient.

In my submission there is no essential difference between the effect on the kidney of great compression produced by rowing (but it must be a racing rowing—Collier) and that incidental to violent and persistent vomiting. The kidney in both is rhythmically greatly compressed, and in both it tends to become damaged. Whether the kidney is active or not is of importance. If a diuresis is present and great muscular movement, in which the abdomen is greatly compressed, occurs, as either by rowing with all one's strength, or by straining with all one's might to extrude a babe, a functional derangement is more easily produced. Indeed, it seems that chronic parenchymatous nephritis may possibly have its rise explained in this way. —I am, etc.,

Rugby, June 8th.

R. H. PARAMORE, F.R.C.S. Eng.

SIR,—I am very gratified that my letter on the subject of albuminuria after exercise should have elicited some observations from such authorities as Dr. Collier and Dr. Lempriere. But the variations of their experiences from my own are in no way surprising when the circumstances of our investigations are contrasted. My subjects were all seasoned athletes of Amateur Championship and Olympic class, whose ages ranged for the most part between 23 and 27, with a small number in the thirties, and three individuals in the early forties—men in whom one would expect the vasomotor system to have become stabilized. On the other hand, the majority of Dr. Collier's and Dr. Lempriere's subjects must have been under 21. Dr. Lempriere's were, in fact, all schoolboys. Most of Dr. Collier's, both as regards track athletes and oarsmen, were, I presume, very little older. Dr. Collier supplies in his letter (of May 27th) an interesting confirmation of my own experience. He examined the urines of a large number of men after completing twenty-two

hours of track walking—one of the most exacting athletic feats that can be undertaken. Yet in not a single specimen did he find albumin. The men engaged in this race were several years older and more experienced than the Varsity athletes, oarsmen or runners. It is clear, of course, from Dr. Collier's and Dr. Lempriere's authoritative pronouncements that any form of exercise may induce transient albuminuria in adolescents, whether on account of passive congestion or some other vascular occurrence in a comparatively labile system. The frequency of the phenomenon in young subjects—practically invariable, one gathers, in the case of schoolboys, and with a very high incidence in the case of young men—and the infrequency among older subjects supports the suggestion in Dr. Wilson's letter which provoked this correspondence, that the albuminuria of exercise is akin to physiological or adolescent albuminuria. It is not difficult to find men of mature years still active competitors on the track to co-operate in physiological investigations; it is not so easy to find veteran oarsmen. Dr. Collier will, I am sure, recall the famous Leander Olympic eight of 1908, and it is possible that among his investigations some of the older members of that crew were included.—I am, etc.,

London, W., June 7th.

ADOLPHE ABRAHAMIS.

METHOD OF TREATING ASTHMA BY RADIATION.

SIR,—Dr. S. Gilbert Scott's paper on the x-ray treatment of asthma (June 5th, p. 939) appeals to me greatly, as, though I am more interested in surgery than medicine, I believe that asthma is one of the conditions that should respond to radiation. In fact, I have used the gamma rays of radium in a tentative way for a case of asthma. Dr. Scott, though he does not say so in so many words, has, by his own showing at the least, temporarily cured a number of patients of asthma, some of them for two and a half years. This is surely a very gratifying advance in the treatment of this condition.

I should like to think that my advocacy of this form of treatment is based on clinical observations rather than theoretical grounds. From my experience with radium in the treatment of malignant and non-malignant conditions I am convinced, to put it briefly, that radiation has a marked influence in (1) relieving spasm and irritative conditions of nerve endings; (2) increasing the local resistance to bacterial infection; (3) promoting the absorption of pathological fibrous tissue, often the result of infection; (4) improving the nutrition, blood supply, and vascular tone in diseased areas; and (5) that it has a general salutary effect on tissues that, for one reason or another, are not behaving normally. I am also convinced that the usefulness of this powerful physical agent, which is capable of reaching and effecting every cell in the body, is not sufficiently recognized in the treatment of non-malignant conditions.

Dr. Scott's dosage appeals to me, for my limited experience in the radium treatment of pulmonary tuberculosis with comparatively small doses of gamma rays has also demonstrated the relief of distressing breathing, the temporary increased expectoration followed by the local improvement. I am afraid of bronchitis when I have intensely radiated a cancer of the oesophagus by a radium tube in the gullet and a cross-fire of radium in the front and back of the chest, and have personal knowledge of a case of bronchitis which proved fatal soon after a dose of high-voltage x rays for cancer of the oesophagus.

Whether radiating the chest and splenic area instead of the whole trunk would produce as good results I am not in a position to say, but it is evident that, where others have failed, Dr. Scott has worked on the right lines in the x-ray treatment of asthma.—I am, etc.,

Dublin, June 8th.

WALTER C. STEVENSON.

GANGRENE OF THE NEWBORN.

SIR,—I am prompted by the recent note of Dr. W. R. Grove (April 24th, p. 738), and by the letter of Dr. J. Inglis Cameron (May 29th, p. 921), to record a case that has just occurred.

At the request of the attending midwife I visited a female child aged 7 days. Just below the right breast a red indurated area about a handbreadth in extent was observed. It was not a

² BRITISH MEDICAL JOURNAL, May 8th and 15th, 1926, p. 846.

breast abscess, nor was there any occlusion of ducts with retention of milk. Expectant treatment was the only possible line to adopt. Next day the induration and redness had increased and there were a few patches of purple discoloration. By the following day (tenth day of child's life) there was evidence of crepitation in the inflammatory area. Later that day a portion about two inches in diameter sloughed away and a frothy appearance was observed around the margins of the sloughing chest wall. The intercostal muscles and ribs were exposed. There was some haemorrhage but practically no pus. The sloughing continued until the lower part of the chest wall towards the sternum was involved. The child died on the twelfth day, five days after the onset.

The case was obviously one of gas gangrene, but its origin is obscure. There were no abrasions observable, the cord had healed cleanly, and the mother had a perfectly easy labour. The ordinary breast abscess of infants can be ruled out. I was attending several other cases in this nurse's practice at the time, but none showed any similar signs.—I am, etc.,

H. R. FREDERICK, M.B., Ch.B. Edin.

Aberavon, Port Talbot, Glam., May 30th.

Sir,—The following case occurred about eighteen months ago.

I was called to see a female infant aged 5 days because its legs had "gone black." I found definite gangrene of both legs, with a line of demarcation on the right just below the knee-joint, and on the left side just above the ankle. The infant was premature (about seven and a half months), but beyond this I was unable to find any lesion. There was no evidence of any umbilical sepsis, but the infant was very feeble. The parents stated that the child was all right when born, that only two days later did they notice anything the matter with its legs. The child died twenty-four hours after I had seen her. The parents refused to give consent for a *post-mortem* examination.—I am, etc.,

Newport, Mon, May 30th.

F. W. ROBERTSON.

DYSENTERY IN MESOPOTAMIA.

Sir,—Professor Ledingham, in his letter (*BRITISH MEDICAL JOURNAL*, June 5th, p. 967), makes a strong point when he says, "*Epidemic dysentery* in Iraq, as elsewhere, was bacillary." He draws attention to the fact that the section of the Army Report in question deals with at least one epidemic of dysentery, for the admission rate for this disease in a particular column of troops rose tenfold. Here, then, is very strong presumptive evidence on epidemiological grounds that the bacillary agent was still playing the prominent part that one would expect.

The figures given for Egypt, where 35 out of 64 cases, or roughly 55 per cent., are stated to have been amoebic, are hardly more convincing than those for Iraq. Here the fact that the complete total of 64 cases is accounted for in one or other group would indicate that the diagnosis was not a laboratory one in every case.

The importance of the matter needs no stressing, for the *Report of the Health of the Army for the Year 1923* stands as an official record bearing the stamp of authority and carrying weight that does not attach to the publications of private individuals. It is to be hoped that an explanation will be forthcoming of figures that are so completely at variance with the known facts concerning the epidemiology and bacteriology of dysenteric disease.—I am, etc.,

Llandudno, June 10th.

KNOWLES BONE.

PREVENTIVE MEDICINE AS APPLIED TO OBSTETRICS.

Sir,—Every reader will be interested in the conception of the proper functions of the general practitioner given by the professor of midwifery at Glasgow in your issue of June 12th (p. 977). He is to confine himself exclusively to the study and practice of pure medicine. Gynaecologists, and other specialists, will relieve him of the rest of his work. Who is to decide where pure medicine ends and any kind of specialism begins, or conversely, we are not told. The logical conclusion is the replacement of existing general practitioners by men who know nothing of medicine or surgery outside their own speciality.

These attempts to divide medicine, surgery, and mid-

wifery into watertight compartments are unworkable. They do no good to the community, and they retard the real progress of medical knowledge. The system is, of course, attractive. It is so much easier to learn all that is worth knowing about one limited subject than it is to acquire a sound working knowledge of a good many; but who can doubt which system develops the best judgment or the broadest view? Surely, it is absurd to say that any man who has acquired any kind of knowledge and experience is not to make use of it when opportunity offers.

What seems to be needed in medicine is, not more concentration, but more diffusion of knowledge. The future of the profession probably lies, as Sir James Mackenzie always maintained, with the general practitioner.—I am, etc.,

London, E.12, June 13th.

A. CAMPBELL STARK.

SEPTIC SORE THROAT COMPLICATED BY ERYTHEMA NODOSUM.

Sir,—Under the above heading (*BRITISH MEDICAL JOURNAL*, May 29th, p. 902) Dr. Eleanor Shephard reports a series of thirteen cases of tonsillitis in five of which an eruption of erythema nodosum appeared, and asks if any light can be thrown on the diagnosis.

I have been interested lately in a series of cases of meningococcus septicaemia in which erythema nodosum was a striking clinical feature. So impressed have I been by my own experience and by that of other observers that a case of obscure pyrexia with erythema nodosum would at once suggest the possibility of meningococcal infection.

A report on my cases is about to appear in the *Journal of the Royal Army Medical Corps*.—I am, etc.,

J. C. KENNEDY,

London, S.W.1, June 6th.

Colonel, R.A.M.C.

The Services.

NAVAL VOLUNTEER DECORATION.

THE Royal Naval Volunteer Reserve Officers' Decoration has been awarded to Surgeon Commander F. J. S. Heaney, M.D., F.R.C.S.

DEATHS IN THE SERVICES.

Major-General Richard Henry Stewart Sawyer, C.B., C.M.G., Army Medical Service (ret.), died in Dublin on April 23rd, aged 68. He was born in that city on October 9th, 1857, and educated at Trinity College, Dublin, where he graduated as M.B. and Ch.B. in 1879, and also took the University diploma in State medicine in 1882, as well as the L.R.C.S.I. in 1880 and the F.R.C.S.I. in 1887. Entering the army as surgeon on February 5th, 1881, he attained the rank of colonel on August 3rd, 1910, and was promoted to Surgeon-General in the long promotion list of March 1st, 1915, after the first winter of the war. He retired on December 26th, 1917. He served in the Nile campaign of 1895, when he was present at the battle of Khartoum, receiving the medal and the Egyptian medal with a clasp; in South Africa from 1899 to 1902, taking part in operations in the Orange Free State, including the actions at Paardeberg, Poplar Grove, and Driefontein, and in the Transvaal, including the action at Eland's River, was mentioned in dispatches in the *London Gazette* of February 8th, 1901, receiving the Queen's medal with four clasps and the King's medal with two clasps; and in the recent great war of 1914-18, when he was five times mentioned in dispatches, in the *London Gazette* of October 19th, 1914, February 17th, 1915, June 15th, 1916, May 29th, 1917, and December 24th, 1917, and received the C.M.G. in 1915, and the C.B. in 1918, also Grand Officer of the Military Order of Avis, Portugal, in 1919. He married Flora Murray, youngest daughter of the late Malcolm MacGregor, S.S.C., of Edinburgh.

Lieut.-Colonel Lewis Allen Irving, O.B.E., R.A.M.C. (ret.), died in London on May 16th, aged 76. He was born on January 28th, 1850, the youngest son of the late Major-General Alexander Irving, R.A., and was educated at the school of the Irish College of Surgeons in Dublin, taking the L.R.C.S.I. and L.K.Q.C.P. in 1870, and also later the M.R.C.P.I. and the D.P.H. of Victoria University in 1892. Entering the army as assistant surgeon on April 1st, 1871, he attained the rank of brigade surgeon Lieutenant-colonel on December 16th, 1894, and retired on April 6th, 1898. After his retirement he was employed for some years on recruiting duty in London. He served for considerable periods in India and South Africa, but apparently had not the good fortune to see any active service. He was personal surgeon to Lord Reay when Governor of Bombay, and afterwards was in command of the Military Lunatic Asylum at Netley. During the recent war he worked on the relief of Belgian refugees, for which he received the O.B.E. in June, 1918, and also the Belgian Order of Leopold. He was twice married, and leaves three daughters. His second wife, Ethel Southey, a grand-niece of the Poet Laureate, died in 1910.

Obituary.

SIR FREDERICK MOTT, K.B.E., M.D., F.R.C.P.,
F.R.S., LL.D.,

Director of Medical Studies, Maudsley Hospital, London.

THE deeply regretted death of Sir Frederick Mott, which was briefly reported in the last issue of the JOURNAL, has removed one of the most illustrious members of the profession. The value and importance of his contributions to psychiatry can scarcely be overestimated, and he has very definitely made additions to our knowledge of one of the most obscure and difficult branches of medicine.

Frederick Walker Mott was the son of Henry Mott, and was born at Brighton on October 23rd, 1853. Before entering as a medical student at University College Hospital he was for a time a pupil at the Royal Sussex County Hospital, Brighton, along with several young men who afterwards attained distinction in various departments of medicine. His career as a student was not remarkable for prize getting, his mind, perhaps, not being of the type which took in facts easily to turn them out at competitive examinations. He, however, passed all his examinations punctually, and took the degree of M.B. in the University of London with first-class honours, winning the University scholarship and the gold medal in forensic medicine; this was in 1881, and at the same time he took the B.S. degree. Before this he had been ophthalmic assistant at University College Hospital. He took the M.D. in 1886, and in the same year became a Member of the Royal College of Physicians. He was elected to the Fellowship in 1892. He became F.R.S. in 1896.

After graduating Mott worked for a couple of years in Professor Schafer's laboratory at University College, his attention being specially directed to the effect of various sections of cord and the connexions of the cells of Clarke's column. In 1883 he was appointed assistant professor of physiology at Liverpool, but in the following year became lecturer in that subject at Charing Cross Hospital Medical School; in 1888 he was appointed medical registrar to Charing Cross Hospital, and in 1891 was elected assistant physician; in 1900 he exchanged the lectureship in physiology for that in pathology. Seven years later he became lecturer in medicine. When his long connexion with the active staff terminated he was appointed consulting physician.

In 1895 Mott was appointed pathologist to the London County Council Asylum and director of the Pathological Laboratory which had been established at Claybury Asylum for the purpose of research in mental diseases. On his appointment he insisted on retaining his position as physician to Charing Cross Hospital. He was alive to the intimate relation that exists between psychiatry and general medicine, and realized that by keeping in touch with a large general hospital his field of investigation would be much wider than by confining it to the clinical material of a mental hospital. How great his interests in medicine were is shown from the fact that he was examiner, not only in mental diseases to the Conjoint Board and London University, but in physiology, pathology, and general medicine to various universities and the Royal Colleges. Mott soon began to exert a great influence upon British psychiatry. He was an indefatigable worker, and his contributions to medical literature would fill many volumes. Many of his papers are to be found in the *Archives of Neurology and Psychiatry*, which he edited. His work was many-sided, and the various directions in which he furthered the progress of psychiatry may be conveniently summarized under three headings—research, early treatment, psychiatric education.

Research.

In his early days Mott was profoundly influenced by the teachings of the late Dr. Henry Maudsley. He always regarded him as a great pioneer in the study of mental diseases, and was never tired of quoting from Maudsley's Goulstonian Lecture on "Body and mind," delivered over fifty years ago, the passage in which he said: "The time has come when the immediate business which lies before every one who would advance our knowledge of mind.

unquestionably is a searching scrutiny of the bodily conditions of its manifestations in health or disease." How fruitful this doctrine has been is evidenced by the work of Mott, who spent the greater part of his life in putting it into practice.

Mott soon gained an international reputation. His name will, for example, always be associated with his classical researches into the relation between syphilis and general paralysis. At the time when many investigators were opposed to the view that general paralysis was a syphilitic affection Mott was firmly convinced of the invariability of the association. One of the strongest arguments he brought forward in favour of his view was based upon his important researches in regard to the juvenile form of general paralysis. In all his cases he found evidence of congenital lues and its physical signs in nearly every patient, and he was unable to exclude syphilis in any instance. The introduction of the Wassermann reaction, and the discovery by Noguchi and Moore of the *Spirochaeta pallida* in the brain, furnished later the evidence which had hitherto been lacking, and, as Bolton, one of his former pupils, pointed out in his work on *The Brain in Health and Disease*, Mott went still further, and found living spirochaetes in film preparations of the second frontal convolution four days after death. It is interesting to note that when he was first appointed pathologist to the London County Asylum syphilis as a cause of general paralysis was not mentioned in the asylum reports. His unrivalled experience of the disastrous effects of syphilis in the community led him to take an active and influential part in the campaign directed towards its prevention. He often urged the view that prevention and early treatment of syphilis would not only effect a rapid decline of general paralysis, but that the number of cases of organic brain disease, dementia, and mental deficiency would likewise diminish.

Mott made a number of important investigations into the problem of heredity and mental disorder. They were based upon exhaustive inquiries into the family history of psychotic patients. He made these investigations the subject of his Huxley Lecture, and also of his address at the opening of the Phipps Institute. His combined experience of hospital and asylum cases enabled him also to make additions to our knowledge of the relationship of alcohol and insanity. His contributions to neurology were numerous and varied. His Croonian Lectures were devoted to the neurone doctrine; his Oliver-Sharpey Lectures to the cerebro-spinal fluid; his Lettsomian Lectures to the effects of high explosives on the nervous system; his Bowman Lecture to the visual cortex; and he wrote a number of articles on neurological subjects for many standard works on medicine. He was the author of one volume of the reports of the Commission on Sleeping Sickness.

His work on the pathology of dementia praecox is perhaps his most important contribution to psychiatry. His researches on this obscure disorder led him to the view that it was the expression of a failure of vital energy of the cells of the whole body, manifested especially in the closely interrelated systems—the sexual and the cerebral—affecting particularly that part of the brain which constitutes the highest psycho-physiological level, the last to come phylogenetically and ontogenetically and the first to go. The correlation between the morphological, micro-chemical, and chemical changes which Mott discovered in cases of dementia praecox and the clinical manifestations of this disorder is very remarkable, the physical regressive changes in the sexual glands being such as might be anticipated in view of the regressive mental phenomena which characterize the disease.

The laborious researches upon which his conclusions were based were reported by him in a long and fully illustrated paper published in our columns in November and December, 1919. As we pointed out in a leading article at the time, this paper covered much ground, including as it did observations on general paralysis and other forms of mental disorder. But attention was directed particularly to the distinctive findings in respect to dementia praecox. Our article concluded with the observation that it was only when the psycho-physical organization is looked at as a whole, as Mott in his paper had looked at it, that the biological significance and purpose of psychoses becomes clear. As

the result of Mott's pathological research, we said, much light had been shed on the mental reactions included under the term "dementia praecox." Mott made the same researches and the conclusions to which they led him the subject both of his Morrison Lectures in Edinburgh and his Maudsley Lecture to the Medico-Psychological Association. In 1910 he gave the Huxley Lecture at Charing Cross Hospital Medical School, choosing for his subject the hereditary aspects of nervous and mental diseases. It was copiously illustrated by interesting pedigrees worked out in diagram form, and was published in our columns on October 8th, 1910 (p. 1013). Later on, in his Harveian Oration last year,¹ he correlated his researches on dementia praecox with his views on heredity in relation to mental disease. Finally, we publish this week a report of a Chadwick Lecture he delivered to the University of Liverpool early this year on heredity in relation to mental disease and mental deficiency.

Though Mott devoted his life to pathological research he was an extremely practical man, and his researches always had a practical aim. He remained throughout his career a true physician, the aim of his work being to cure, relieve, or prevent disease. His outlook was essentially hopeful, and he eagerly investigated any avenue which suggested therapeutic possibilities. This aspect of his character is exemplified by his fondness for quoting in his papers the following extract from the writings of Francis Bacon:

"A work therefore is wanting upon the cures of reputed incurable diseases, that physicians of eminence and resolution may be encouraged and excited to pursue this matter, so far as the nature of things will permit, since to pronounce disease incurable is to establish negligence and carelessness as it were, by a law, and screen ignorance from reproach."

Mott's practical interest in the welfare of asylum patients was strikingly manifested by his beneficial work in relation to "asylum" dysentery. This disorder was prevalent in most asylums and was responsible for a number of deaths. It had been thought by some that dysentery in the insane was essentially a trophic lesion of the intestine, that the ulceration of the mucous membrane of the colon was due primarily to death of the tissue consequent upon a degeneration of the nerve supply to the part, with a secondary infection by pyogenic microbes. Mott and Durham presented a report to the London County Council on "colitis" in 1900, in which it was stated that there did not appear to be any proofs of such an etiology, and in an article published three years later Mott observed that probably nothing did so much to retard the prevention of the disease as the theory that it was due to a hypothetical nerve lesion, and therefore not preventable. He, on the contrary, took the view that asylum dysentery was an infectious disease which could be prevented if suitable precautions were taken, such as isolation and close attention to disinfection. The striking reduction in both the incidence and mortality of the disease since his recommendations have been acted upon in asylums is a great tribute to the value of his work. Although it may be regarded as a side issue, the whole story is a good illustration of the shrewdness and practical ability which formed, as it were, the background of his highly skilled and specialized work in psychiatry. The Stewart Prize of the British Medical Association, founded to afford an opportunity of recognizing work regarding the origin, spread, and prevention of epidemic disease, was awarded to Mott by the British Medical Association in 1903 for what he had accomplished in connexion with the prevention of asylum dysentery.

Mott received many other honours for his scientific achievements, and was appointed to various lectureships in addition to those already mentioned. He was elected a F.R.S.; was awarded the Fothergill gold medal of the Medical Society of London and the Moxon gold medal of the Royal College of Physicians; he was Fullerian Professor at the Royal Institute; and corresponding member of many foreign learned societies. Many of his most important articles were published in the *BRITISH MEDICAL JOURNAL*, and when some book struck him as being of special consequence he would offer to write a review. In his quiet way he was a good friend of the Association.

He was secretary of the Section of Pathology and Bacteriology in 1893 (Aberdeen); vice-president of the Section of Pathology, 1898 (Edinburgh); president of the same Section, 1905 (Leicester); and president of the Section of Neurology and Psychiatry, 1914 (Aberdeen). He received the honorary degree of LL.D. at Edinburgh, and was made K.B.E. in 1919.

Early Treatment: Education in Psychiatry.

These two aspects of Mott's work, in which he exercised a paramount influence and did so much to further the progress of psychiatry, are so closely interrelated that they may be conveniently considered together. With Mott as director, the Claybury Laboratory soon began to attract a number of enthusiastic workers from this country and abroad. Many well-known psychiatrists and neuropathologists began their careers under his guidance, and he stimulated research in mental disorders in a way that had hitherto been impossible. Many of the medical officers became interested in clinical psychiatry as a result of his visits to the various asylums; no systematic instruction had hitherto been given, and the medical staff of these institutions had to gain a knowledge of psychiatry as best they could and without much encouragement to do so. In the preface to the third volume of the *Archives of Neurology* (1907) Mott made a strong plea for the development of a psychiatric institution on lines similar to that at Munich. His ideal was a fully equipped and well organized psychiatric clinic, under the control of a university, in which early and curable cases could be treated without certification. He suggested also that if suitable post-graduate training in psychiatry were established the universities and licensing bodies might be induced to establish a diploma in psychological medicine. As far as London is concerned, his wishes have been realized, and that this is so is largely due to his incessant efforts since this article was published. Psychiatry owes him an immense debt of gratitude for throwing all his weight and influence into the furtherance of these projects. Shortly after this article was published Maudsley offered £30,000 to the London County Council if it would build a hospital in London for the study and treatment of mental disorders in their early and curable stages. It was not until 1912, however, that the present site of the Maudsley Hospital was purchased and the plans were drawn. The hospital was only partially completed when the war broke out. King's College Hospital, which is on an adjoining site, formed the 4th London General Territorial Hospital, upon the staff of which Mott served in the rank first of major, afterwards as brevet lieutenant-colonel, as neurological specialist. The Maudsley Hospital was opened for neurological cases early in 1916 as a part of the 4th London General Hospital. The laboratory at Claybury was dismantled and the equipment transferred to the more convenient laboratory at the Maudsley.

The Maudsley Hospital soon became widely known, and successive groups of American officers were sent there for training in the treatment of the war neuroses. Many of these have spoken with gratitude of Mott's training, and also of his personal kindness, for he was extremely hospitable, welcomed them to this country, and entertained them in his house in London. Several distinguished foreigners who were driven from their country were also enabled by grants from the Medical Research Council to work in the laboratory. In 1919 the hospital was transferred to the Ministry of Pensions, and Mott, under the auspices of the London County Council, started a course of instruction for graduates, especially for asylum medical officers, to enable them to pass the D.P.M. of the University of Cambridge, which had been established just before the war. Mott was shortly afterwards gratified by seeing his wishes fulfilled by the establishment of a D.P.M. by several other universities and by the Royal Colleges—an innovation for which he was himself largely responsible. Thus were started courses of lectures at the Maudsley which opened up a new vista for the medical officers in mental hospitals. The value of these lectures has been very great. Both in London and the provinces there are now a large number of keen and well equipped medical officers who are in a position to take quite a different attitude towards their

¹ *BRITISH MEDICAL JOURNAL*, 1925, ii, p. 727.

work than was possible in former days, and who are psychiatrists in the full sense of the term.

It might be supposed that when Mott resigned his position in the service of the London County Council in 1923 he would have relaxed his energies. This was not the case, however, and he threw himself unsparingly and with undiminished zeal into other activities. He continued to lecture at the Maudsley Hospital, and was director of medical studies there at the time of his death. He undertook a great task at Birmingham, where his services were eagerly welcomed both by the university and the city council. It speaks volumes for his driving power and influence that he was able to accomplish so much in so brief a time. He accepted the position of lecturer on

morbid psychology at the university, and, with his advice, a joint board of research of the university and corporation of the city of Birmingham was established with a well equipped central laboratory. At the time of his death he was actively directing important researches at the Holmwood Mental Hospital laboratory. Recently he had been engaged in studying by histological methods the effect of veronal and its congeners on the central nervous system, and had, we understand, already obtained some important positive results. It was evident from some remarks he made at the annual meeting of the Royal Medico-Psychological Association, of which he was the president this year, that he visualized in Birmingham a clinic for early mental cases on lines similar to those followed at the Maudsley Hospital.

Mott's interests were numerous and varied. He was especially attracted to music, and was associated with societies interested in its cultivation. He was the author of an excellent little book, *Brain and Voice in Speech and Song*. He was kind, hospitable, and very human. He

was in no sense remote from real life; he was a part of the busy world around him, and entered with equal zest into his researches, his recreations, and his social life. He had the simplicity and lack of affectation of the really great man, and no one could have been more friendly or accessible to the younger members of the asylum medical service than he was. Those who served under him regarded him with great affection, and the expressions of regret and tributes of admiration which he received upon his retirement from those who were, and had been, associated with him during his long service with the London County Council abundantly demonstrated the esteem and affection in which he was held. Sir Frederick is survived by Lady Mott and four daughters. To all of these our sincere sympathy is extended.

The cremation took place at Perry Barr Crematorium, Birmingham, on June 11th. In the course of a short address the Bishop of Birmingham said that Sir Frederick Mott was one of the great men of science who gave distinction to our era. He had devoted his life to the

investigation of the causes of certain types of mental disease the existence of which imposed a heavy burden on the community and caused widespread social and family distress. To his investigations Sir Frederick Mott had brought patient care and the indefinable quality of genius. He had succeeded where others had failed in elucidating the physical basis of such maladies as general paralysis of the insane and dementia praecox. He established the connexion between moral imbecility and organic disease of the brain, and had done highly important work on the micro-organisms which produced sleeping sickness. For his work in connexion with general paralysis of the insane Sir Frederick Mott deserved to rank among the great benefactors of humanity. Birmingham owed him special

thanks in that he was honorary director of the Research Board on Mental Diseases established by the joint action of the city and the university. His kindness of heart won him the friendship of all sorts and conditions of men and women.

MEMORIAL SERVICE. *Address by Professor Starling.*

A memorial service for Sir Frederick Mott was held at the church of St. Martin-in-the-Fields, Charing Cross, at noon on Wednesday, when Professor E. H. Starling delivered an address.

Professor Starling said that they mourned a great leader, but at the same time rejoiced in the work he had accomplished for science and for mankind. His achievements had not only placed him in the foremost ranks of neurologists, but had made all humanity his debtor. Mott was one of the select few who received early their call to service in the temple of science, and he responded to the call in an eager and self-sacrificing spirit. He took up research as the serious business of his life as soon as he had completed his medical studies in 1881, and he became associated

at once with a small band of workers who were actively engaged in elucidating by the experimental method the functions of the brain. His interest in the localization of cerebral functions continued throughout his life, and he was particularly interested in vision. He was one of the first to appreciate the great part played in the evolution of the human brain and the intellectual powers of man by the development of vision with two eyes and the correlation between vision and the movement of the hands. When the London County Council established at Claybury the laboratory for its mental hospitals, Mott was the one man in England fitted by training, temperament, and past achievement for the post of pathological director, and he entered joyfully upon its duties. It enabled him to devote his whole time to an investigation of the causes of insanity. The bulk of the work he did, together with that of the young men working under his inspiration, was recorded in the eight volumes of the *Archives of Neurology*, which appeared under his editorship. His research at Claybury, and later at the Maudsley Hospital, laid foundations on which other workers might build. Perhaps his most notable

J. Russell and Sons, London.

SIR FREDERICK MOTT, K.B.E.

achievement was the definite discovery that general paralysis of the insane was due to infection, part of a general disease, and therefore preventable, and possibly, on further investigation, curable. Another discovery of his was that asylum dysentery was not a necessary condition of asylum life, but was due to the absence of precaution against infection. The outbreak of war brought to Mott the further problem of shell shock, on which he did some masterly work. Since the war his attention had been occupied largely with dementia praecox. Among his other activities mention might be made of his analysis of the part played by alcohol in the causation of insanity, his examination of the influence of the internal secretions on the development of mental functions, his advocacy of mental hospitals for the treatment of early cases of disordered mind, his interest in eugenics, and his notable contributions to the physiology of speech and song. "I have said nothing," Professor Starling concluded, "of the man himself. His personality is too fresh in our minds to need me to recall him to you. But his scientific achievements would have been impossible had it not been for certain inherent qualities. Single-hearted in his search after knowledge and his devotion to science, he was free from prejudice and from that type of vanity which makes a man adhere to a view simply because he has been previously associated with it. There was no man freer from envy, or fuller of generous admiration for the work of others. Though we regret his loss, we must not sorrow overmuch that he should have laid down his task while still in the plenitude of his powers and with his mental vision undimmed, and when the main objects which he set himself to carry out were in full course of accomplishment."

Among those present in the very large congregation, in addition to Lady Mott and her daughters, were Sir John Rose Bradford, President, and Dr. Sidney Phillips, Treasurer, of the Royal College of Physicians; Dr. H. H. Dale, representing the Royal Society; Professor W. E. Dixon, F.R.S., representing the British Medical Association; Sir Dawson Williams, representing the *BRITISH MEDICAL JOURNAL*; Sir Herbert Waterhouse, Charing Cross Hospital; Dr. J. H. Sequeira, representing the Society for the Prevention of Venereal Disease; Dr. R. Worth, general secretary, Medico-Psychological Association; Sir Frederick Willis, chairman of the Board of Control; Dr. C. Hubert Bond, Sir Maurice Craig, Sir W. Arbuthnot Lane, Sir Bryan Donkin, Sir James Crichton-Browne, Sir W. Hale-White, Sir D'Arcy Power; Dr. Herbert Spencer, University College Hospital; Dr. F. N. Kay Menzies, chief medical officer, London County Council; and many other representatives of medical societies and public bodies with which Sir Frederick Mott was associated. Members, present and past, of the London County Council—the past members including the Right Hon. John Burns—and officers of the mental hospitals and public health departments of the Council also attended.

SIR HENRY MORRIS, Bt., F.R.C.S.,

Consulting Surgeon, Middlesex Hospital; ex-President, Royal College of Surgeons of England.

We regret to announce the death of Sir Henry Morris, Bt., which occurred on June 14th at his home in London, in the 83rd year of his age, after an illness of three weeks' duration.

Sir Henry Morris was the son of Mr. William Morris, surgeon, of Petworth. He was educated at Epsom College, being one of the first boys admitted to that institution, and subsequently at University College and Guy's Hospital. He graduated B.A. of the University of London in 1863, M.B. in 1867, and M.A. in 1870. In 1866 he was admitted

M.R.C.S., and became a Fellow of the Royal College of Surgeons in 1873. He served as assistant medical officer and house-surgeon at Guy's Hospital, and afterwards for a short time as resident medical officer of the dispensary in Stanhope Street, Strand. He commenced his association with Middlesex Hospital in January, 1870, when he was appointed surgical registrar. He was appointed assistant surgeon in August, 1871, and surgeon to the cancer out-patient department. He was appointed surgeon in 1879, and he remained in charge of the cancer out-patient department until 1889. He resigned from the surgical staff at the end of 1905, and was appointed consulting surgeon to the hospital. In the medical school he held the appointments of lecturer in practical surgery from 1871 to 1882, lecturer in anatomy from 1872 to 1881, and lecturer in surgery from 1881 to 1896. When he resigned from the active staff he was appointed emeritus lecturer in surgery in the medical school. Sir Henry Morris had a great belief in the maintenance of a "complete" medical school, and used his in-

(J. Russell and Sons, London.

SIR HENRY MORRIS, Bt., F.R.C.S.

fluence and eloquence to avert the closing of the preliminary and intermediate departments of the medical school. By a gift of £1,000 he started an endowment fund, in the hope that the school finances would be put on such a footing that, should any concentration scheme be carried through in the future, Middlesex might not be compelled to join through necessity, though the school might possibly elect to go in, because of the advantages offered. In his speech at a farewell dinner, given to him by his old pupils on February 20th, 1906, Sir Henry Morris, referring to the Endowment Fund, said:

"It is only by means of such a fund that the Middlesex Hospital Medical School—which, be it remembered, has as many students as some of the richly endowed provincial Universities such, for instance, as Birmingham—can be maintained. And I would add that it is only by such a Fund that the Medical School can be delivered from the net of the Medical Schools Amalgamation Scheme of the University of London."

For many years no substantial advance was made in the endowment fund which Sir Henry Morris so generously inaugurated, but since the war great efforts have been made to secure substantial endowment for the school, and

the funds invested for medical education and research at the Middlesex Hospital Medical School now amount to about £130,000.

Sir Henry Morris was the editor of a well known *System of Anatomy* and the author of a book on the *Anatomy of the Joints of Man*, and of an article on injuries to the lower extremities in Holmes's *Surgery*. He had always given special attention to the surgical diseases of the urinary organs, and was the author of a book on *Surgical Diseases of Kidneys and Ureter*, which reached its second edition in 1901. Another book from his pen was on the injuries and diseases of the genital and urinary organs. His Hunterian Lectures before the Royal College of Surgeons, which were devoted to the surgery of the kidney, were published in the first volume of the *BRITISH MEDICAL JOURNAL* for 1898. The operation for nephro-lithotomy, or the removal of a calculus from an undilated kidney, was performed for the first time by Sir Henry Morris at the Middlesex Hospital. The diagnosis was made by Dr. Sidney Coupland; the case was reported to the Clinical Society on October 22nd, 1880, and is recorded in the society's *Transactions*, vol. 14. The stone is preserved in the museum of the Middlesex Hospital, as well as a very large collection of urinary calculi which had been removed by Sir Henry Morris by operation.

Sir Henry Morris was a member of the council of the Royal College of Surgeons of England from 1893 to 1914, and represented the College on the General Medical Council from 1904 to 1917. From 1907 to 1917 he was treasurer of the General Medical Council. Sir Henry was President of the Royal College of Surgeons from 1906 to 1908. He gave the Bradshaw Lecture in 1903, choosing cancer and its origin as his subject. He gave also the Hunterian Oration, on John Hunter as a philosopher, in 1909. For six years he was chairman of the Court of Examiners of the Royal College of Surgeons. He was also examiner in surgery at the University of London, and in anatomy at Durham University. He was president of the Royal Society of Medicine from 1910 to 1912.

Apart from his surgical achievements, Sir Henry will be most remembered for his work in connexion with Epsom College, in which he took a lifelong interest. For many years he was treasurer to that institution, and guided its finances in a most capable manner. The present position of the school is largely due to the energy, the sustained interest, and the business capacity of Sir Henry Morris, and those who sat with him on the council know the enormous amount of time he spent in the interests of the school. In his later years Sir Henry, as was natural in one who had long been surgeon to the cancer wards of the Middlesex Hospital, took a great interest in the activities of bodies formed to direct public attention to cancer. He was treasurer and vice-president of the Imperial Cancer Research Fund, which was started in his house.

Sir Henry Morris's connexion with the British Medical Association was chiefly before the reorganization. In 1877 he was secretary of the Section of Surgery when the Association held its annual meeting in Manchester; in 1889 he was vice-president of the Section of Surgery when the meeting took place at Leeds; in 1895 he was president of the Section of Anatomy and Histology at the annual meeting in London. He was a member of the council of the Metropolitan Counties Branch in 1888. The honour of a baronetcy was conferred upon him in 1909; he leaves no heir.

Sir Henry was a man of imposing presence, with very firm convictions and considerable ability in inducing others to accept them. As a speaker he was fluent, and often impressive.

Dr. JOHN HEDLEY CROCKER, who died suddenly in Brighton on May 17th, at the age of 67, received his medical education at Charing Cross Hospital and Owen's College, Manchester; he obtained the diplomas L.S.A. in 1883, and M.R.C.S., L.R.C.P. in 1884. After holding the posts of assistant demonstrator in anatomy, house-surgeon, and house-physician at Charing Cross Hospital, he graduated M.B., Ch.B. Vict. in 1892, proceeding M.D. in 1894, in which year he obtained the D.P.H. and started practice at Eccles, Lancashire. Soon afterwards he was

appointed medical officer of health for the borough of Eccles and the port of Manchester. In 1900 he was appointed medical officer of health for Richmond, Surrey, and held the post until 1919, when he retired to live in Brighton. He held the rank of captain in the Sanitary Service, R.A.M.C.(T.F.), and published several articles on public health. He was a member of the British Medical Association. A colleague writes: Dr. Crocker's retirement simply meant for him change of occupation, not cessation. He was soon elected chairman of the Patcham Parish Council, and similar honours came to him unsought. He was a most popular man; his kind heart and his smile, which always gave confidence, made him friends wherever he went.

Dr. R. G. BELL of Sunderland, who died on June 4th in his 66th year, was educated at Glasgow University, where he won the Lorimer Scholarship in anatomy, botany, and chemistry. He graduated M.B., C.M. in 1890, and M.D. with commendation in 1898. In 1904 he took the diploma of F.R.C.S.Ed. At one time he took a prominent part in societies connected with the university, and was chairman of the Joint Committee of Conservative and Liberal Unionists, which supported the election of Mr. (now Lord) Balfour for the Rectorship in 1889. For a time he held the appointments of demonstrator and assistant lecturer at the university; but in 1891 he entered private practice in Sunderland, subsequently becoming assistant surgeon to the Throat, Ear, and Nose Hospital, Rye Hill, Newcastle, surgeon to the Sunderland Northside Hospital, to the Monkwearmouth and Soutwick Hospital, and to the Sunderland Maternity Home, and Admiralty surgeon and agent for Sunderland. For a long period Dr. Bell was a member of the Sunderland Town Council, and in 1917 became an alderman of the borough. He took a great interest in educational and health matters, especially in technical education. He was a member of a committee which persuaded the council to use the "whisky money," awarded to local authorities under the Local Taxation and Customs Exemption Act of 1890, for technical education purposes. This led to the establishment of a technical college in Sunderland. At the time of his death he was chairman of the Higher Education Subcommittee and the representative of the authority on the council of the Durham Colleges in the University of Durham. He had been a borough magistrate since 1901. He was an active member of the Sunderland Division of the British Medical Association, and its chairman in 1920. He had been a member of the council of the North of England Branch, and was vice-president of the Section of Oto-rhino-laryngology at the Newcastle meeting of the Association in 1921. Dr. Bell leaves a widow, but no family.

Universities and Colleges.

UNIVERSITY OF LONDON.

ESSAYS for the Paul Reithinger Prize, awarded for the best essay embodying the result of some research work on a medical subject carried out by the candidate, must reach the University by October 1st. Regulations for the award of the prize can be obtained on application to the Academic Registrar.

UNIVERSITY OF BIRMINGHAM.

THE following appointments are announced: *Lecturer in Diseases of the Ear, Nose, and Throat*, E. Musgrave Woodman, M.S., F.R.C.S.; *Lecturer in Orthopaedic Surgery*, Noughton Dunn, M.A., M.B., Ch.B.; *Honorary Assistant Curator (Surgery Section)*, W. Stirk Adams, M.B., Ch.B., F.R.C.S.

UNIVERSITY OF BRISTOL.

THE following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B., PART I (including Forensic Medicine and Toxicology).—E. C. Bernard, J. M. Camps-Campins, A. J. McD. Grimston, T. M. White. PART I (only).—D. E. C. Andrew, H. E. C. Bentley. PART II. S. P. Taylor (with distinction in Pathology), R. E. East (with distinction in Pathology), Muriel E. Dr. Vincent. Group I (C).—Harvey, A. A. B. Hayhurst. Group I (only).—Cecily France.

UNIVERSITY OF GLASGOW.

THE University Court has appointed Dr. David Shannon to the Royal Samaritan Lectureship in Gynaecology, which has been founded through a gift of £5,000 from an anonymous donor.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary Council meeting was held on June 10th, when the President, Sir John Bland-Sutton, was in the chair.

Diplomas of Fellowship were granted to the following twenty-nine candidates:

C. H. Thomas (Manch. an (Camb. an Guy's), *C (St. Mary's), F. W. M. Pratt (St. George's), D. A. Davies (St. Thomas's), F. Louis (Univ. Coll.), C. A. Lupton (Camb. and St. Thomas's), R. Brooke (Guy's), H. C. Edwards (King's College), G. G. Penman (G. and St. Thomas's), D. H. Brown (G. and St. George's), F. I. (Guy's), H. P. S. D. P. Marks (Cam), K. H. Hadley (G. and Guy's), A. L. McGregor (Edinburgh), J. D. McLaggan (Aberdeen and St. Bart's), D. S. Middleton (Edinburgh), D. W. G. Murray (Toronto and Lond.), H. J. Taggart (Belfast and Lond.).

* Under the Medical Act, 1876.

Diplomas of Membership were granted to two candidates who have now complied with the regulations.

Mr. L. B. Rawling was reappointed a member of the Court of Examiners. Mr. Fagge, Mr. Rawling, Mr. Clogg, and Mr. Legg were re-elected members of the Board of Examiners in dental surgery for the year ending June 30th, 1927.

Sir Guthbert Wallace and Professor Bulloch were elected to conduct the examination in pathology which candidates for the diplomas of M.R.C.S. and L.R.C.P. will be required to pass under the new regulations. A physician and pathologist will also be appointed by the Royal College of Physicians.

The following were elected examiners for the Fellowship for the ensuing year:—*Anatomy*: William Wright, Frederick Gymer Parsons, Wilfrid Edward Le Gros Clark, Cecil Pembrey Grey Wakeley. *Physiology*: David Henriques de Souza, Ffrangcon Roberts, John Beresford Leathes, Herbert Eldon Roaf.

house, Clifford White. *Diploma in Public Health*: Part I, Richard Tauner Hewlett; Part II, Francis Joseph Stevens. *Diploma in Tropical Medicine and Hygiene*: Pathology and Tropical Hygiene, William Porter MacArthur; Tropical Medicine and Surgery, Philip Henry Manson-Bahr. *Diploma in Ophthalmic Medicine and Surgery*: Part I, Charles Bernard Goulden, Herbert Willoughby Lylo; Part II, Malcolm Langton Hepburn. *Diploma in Psychological Medicine*: Frederick Lucien Golla. *Diploma in Laryngology and Otolaryngology*: Part I, Herbert Tilley, Arthur Henry Cheatle; Part II, Sydney Richard Scott.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

An extraordinary meeting of the College was held on June 8th, when the President, Dr. G. M. Robertson, was in the chair.

The case of William Lloyd, a licentiate of the College, registered as of 53, Brook Street, Grosvenor Square, London, W.1, came up for determination. It was resolved that he be censured for having acted in an unbecoming and unprofessional manner.

Final arrangements were made for holding a dinner to celebrate the bicentenary of the Faculty of Medicine of Edinburgh University.

The College voted a donation of 100 guineas to the Scottish National Memorial to Queen Alexandra, and a sum of 100 guineas to the extension fund of the Incorporated Edinburgh Dental Hospital and School.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on June 7th, Sir Hector Clare Cameron, C.B.E., M.D., LL.D., and Dr. George Stevenson Middleton, LL.D., were admitted as honorary Fellows of the Faculty.

The following were admitted after examination as Fellows of the Faculty: J. M. Damany, G. B. Fleming, M.B.E., T. Jackson, R. A. Lennie, J. K. Rennie, C. Rudd, W. S. Syme, jun., J. N. Tenuent.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

THE following have been admitted to the Membership of the College: G. Bewley, R. W. Nesbitt, F. J. O'Meara, K. R. Patil, H. M. Trilokekar.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

THE following officers have been elected for the ensuing year: President, Andrew Fullerton, F.R.C.S.I.; Vice-President, Thomas E. Gordon, F.R.C.S.I.; Secretary, Sir F. Conway Dwyer, F.R.C.S.I.

The newly elected President has served for many years as an examiner in surgery, as a member of Council, and for the past two years as Vice-President. Mr. Fullerton is surgeon to the Royal Victoria Hospital, Belfast, and to the Belfast Hospital for Sick Children, and is Professor of Surgery, Queen's University, Belfast. He served during the war for over three and a half years as consulting surgeon to the British Expeditionary Force in France, with the rank of colonel. He was thrice mentioned in dispatches, and was awarded the C.B. and the C.M.G. He is an honorary Fellow of the American College of Surgeons.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week considered the Finance Bill, the Estimate for the Mines Department, and the Scottish Estimates. It approved the clauses in the Finance Bill which abolish the system of assessing profits under Schedule D on the income on an average of three years, and substitute, with certain reservations, assessment on the full amount of the income of the year preceding the year of assessment. During the discussion on the Mines Department Estimates the Prime Minister announced that the Government proposed to introduce a bill authorizing an optional return to the eight hours' working day in coal-mines, and another bill increasing the provision for the miners' welfare fund, and taking other steps towards the reorganization of the mining industry.

The Parliamentary Medical Committee, at its meeting on June 9th, passed a resolution welcoming the appointment of a layman as a member of the General Medical Council. It also resolved, on the motion of Dr. Drummond Shiels, that revision of the definition in the Mental Deficiency Act was urgently needed, and should be obtained as early as possible. Dr. Tredgold, chairman of the Medical Committee, Central Association for Mental Welfare, addressed the Committee on the need for redefining mental deficiency and on the distinctions between different types of deficiency.

The Parliamentary Medical Committee agreed that the Society of Members of the Royal College of Surgeons had made out a prima-facie case for representation on the Council of the College, and that this matter should be considered with the application of the Council for a supplemental charter. Subsequently Dr. Fremantle informed the Earl of Balfour, Lord President of the Council, that this was the view of the Parliamentary Medical Committee.

Medical Branches of the Fighting Services.

On June 15th Dr. Fremantle asked the Prime Minister if the Government had arrived at any decision as to the recruiting of medical officers for the Navy, Army, and Air Force. Mr. Baldwin replied as follows: Yes, sir. The Government has considered the report of the committee appointed last autumn to consider questions relating to pay and other matters affecting recruitment of officers and nurses to the medical branches of the fighting services, and has decided to give effect to its recommendations as from July 1st next. Lieut.-Commander Kenworthy: Is the Government contemplating amalgamation of the three medical services? Mr. Baldwin: No, not that I am aware of. Dr. Fremantle: When shall we get details of this decision? Mr. Baldwin: The necessary orders, I understand, are to be published forthwith.

Midwives and Maternity Homes.

The Midwives and Maternity Homes Bill was considered on the report stage in the House of Lords on June 15th.

Part 1 of the bill amends the Midwives Acts, 1902 and 1918. Clause 1 provides that if any person, being either a male person or a woman not certified under the bill, attends a woman in childbirth otherwise than under the direction and personal supervision of a duly qualified medical practitioner, that person shall, unless he or she satisfies the court that the attention was given in sudden or urgent necessity, be liable on summary conviction to a fine not exceeding £10. During the committee stage of the bill, last week, the clause was amended by the addition of the following proviso: "Provided that the provisions of this subsection shall not apply in the case of a person who, while undergoing training with a view to becoming a duly qualified medical practitioner or a certified midwife, attends a woman in childbirth as part of a course in practical instruction in midwifery."

The Marquess of Salisbury (Lord Privy Seal) now moved to amend this proviso, so as to make it read, "a course in practical instruction in midwifery recognized by the General Medical Council or by the Central Midwives Board." In this, he said, the Government accepted a suggestion of Viscount Knutsford made during the discussion in committee. The amendment was agreed to.

Clause 11 of Part 3, which is the interpretation clause, enacts that a local supervising authority may grant exemption from the operation of Part 2 of the Act, which provides for the registration of maternity homes, of any hospital or other premises for the conduct of which a duly qualified medical practitioner resident therein is responsible, or any hospital or institution not carried on for profit and not mainly used as a maternity home. It also provides that any person aggrieved by the refusal of a local supervising authority to grant exemption under Part 2 in respect of any hospital, premises, or institution, or by the withdrawal of any such exemption previously granted by the authority, may appeal to the Minister of Health, who shall give such directions as he thinks proper, and that the authority shall comply with any directions so given.

On the motion of Lord Muir Mackenzie it was decided to transfer the provisions from Part 3 to Part 2 of the bill.

This concluded the report stage of the bill.

Registration of Nursing Homes.

On June 8th further evidence was given before the Select Committee of the House of Commons on the registration of nursing homes. Miss Ethel Phillips said that she was a fully qualified nurse, and had been proprietress of a nursing home in Doncaster for fifteen years. She was in favour of registration in order to ensure that trained persons were in charge. She thought that in many homes it was necessary to employ assistant nurses who had been trained in cottage hospitals. To staff a home entirely with fully trained nurses would mean an increase of at least a guinea a week in the fees paid by the patient. Miss Phillips was of opinion that inspection of homes should be done by male doctors, who, she considered, could be relied on to see if anything was wrong, even in the kitchen, and would say exactly what they thought. She believed that doctors, if they had any complaints, would make them; and that patients would know at once if the nursing was bad. In reply to questions, Miss Phillips reiterated her conviction that no one but a trained nurse should be allowed to establish a nursing home; she would not agree that an unqualified proprietress might take charge of the business side, with a trained sister in charge of the nursing.

Dr. Marguerite A. G. Douglas-Drummond (assistant medical officer of health, Manchester) was of opinion that all nursing homes and maternity homes should be registered. In Manchester maternity homes run by doctors were exempt from inspection, and she thought the same rule should apply to nursing homes run by doctors, provided the doctor notified the authority of the names and qualifications of his nursing staff. She instanced cases in which registration as maternity homes had been refused, or the proprietresses prosecuted, and yet the women continued to take medical and surgical cases. She considered that women inspectors were better than men; they were more expert in noticing dirt. Before registration was granted to a maternity home the witness went with the sanitary inspector and decided whether the premises and the woman were suitable. Cross-examined by Dr. Davies, the witness did not agree that it was necessary, though it might be desirable, that homes for chronic or border-line cases run by a doctor should be inspected. The chief abuses in nursing homes in Manchester were dirty houses, inefficient staffs, lack of money for repairs, bad or scanty food, linen, and bedding, and the fact that the husband of the proprietress sometimes assisted in the work of the home.

A further sitting of the Select Committee took place on June 10th, when Sir William Hart, town clerk of Sheffield, gave evidence on behalf of the Law Committee of the Association of Municipal Corporations. That association, he said, had no objection to registration of nursing homes, but had not asked for it. The authority should be the local authority and not the county council. The Municipal Corporations Association did not approve of co-opting outsiders on to committees for registration. Nor did it think that nursing homes run by medical men should be exempt from inspection; but would not object to an appeal to the Ministry of Health by a duly qualified practitioner responsible for the management of the home. In reply to Sir Joseph Nall, the witness said that one or two of the nursing homes in Sheffield were practically annexes of doctors' surgeries. There was no inspection of maternity homes in Sheffield. In reply to Dr. Davies, Sir William thought there was little risk of details about patients being canvassed if inspection were carried out by officials of the smaller boroughs. Medical officers of health were a very competent body of men, and he thought that in most cases the inspector would not need a woman to help him. Personally, Sir William saw no objection to universal inspection if the evidence heard by the Committee showed it to be desirable.

Dr. R. A. Lyster (medical officer of health for Hampshire) represented the County Councils Association. He thought that the buildings of, and the amount of nursing in, some nursing homes were thoroughly unsatisfactory. When medical practitioners took two or three patients into their own homes they should be exempt from registration and inspection, as such homes were, in his experience, very well run. He thought the medical officer of health should be the inspector, and that power of entry and inspection should be confined to qualified medical men; but a medical inspector might have a trained nurse with him if he desired. The witness was inclined to exempt from inspection all homes with a resident medical man, until Dr. Davies mentioned that there had been evidence of gross abuses in such cases. Dr. Lyster then withdrew the suggestion, as he did not think that the best medical men would object to inspection. He would keep inspection to the county and county borough medical officer of health, as local jealousies were strong in smaller authorities. A date should be fixed after which all new nurses in homes should be qualified, present employees and proprietresses being allowed to continue in their positions. In his district, Dr. Lyster said, there was at present a serious deficiency of homes with moderate prices. Sir Joseph Nall asked why the witness's association had never reported to the Ministry of Health the defects of nursing homes. The reply was that it was no part of the statutory duty of members of the association. While saying nothing in favour of the continuance of the small nursing home with practically no qualified staff, Dr. Lyster thought it would be a calamity if the present number of nursing homes were reduced. The Chairman asked if it would not be more economical to extend the accommodation in voluntary hospitals to meet the deficiency. Dr. Lyster replied that he had made use of voluntary hospitals in Hampshire in maternity and venereal disease schemes; but the economy had not been noteworthy.

Miss Barber (registrar of the College of Nursing) said that from particulars she had obtained from 135 nursing homes she found that 105 of these took maternity as well as medical and surgical cases. She thought that registration of maternity homes should be extended to cover all nursing homes; and that maternity cases

should not be excluded from surgical or general homes. She did not think medical men were fit persons to inspect nursing homes. She had no use for local authorities as inspecting bodies. Inspection should be done by the Ministry of Health through a body of nurses under a chief nurse. The witness quoted several abuses in nursing homes to show that medical men had no knowledge of what went on and were not competent to inspect.

Foot-and-Mouth Disease.

To prevent the introduction of foot-and-mouth disease the Minister of Agriculture has arranged for the issue of licences to individual importers of bristles from the Continent, subject to certain conditions. He does not propose to prohibit the landing of brushes.

On June 14th Mr. Guinness (Minister of Agriculture) informed Sir A. Hunter-Weston that the Superintendent Veterinary Inspector of the Ministry had visited the Carlisle bacon factory, where, in the examination of pig carcasses newly arrived from Rotterdam, he discovered definite lesions of foot-and-mouth disease in some of the carcasses. Subsequent examination of other portions of the cargo, which had been distributed to other bacon factories, revealed further infected carcasses.

Smoke Abatement Bill.—In the House of Commons, on June 9th, the Smoke Abatement Bill was read a second time without debate. It has already passed through the Lords.

Puerperal Septicæmia.—Answering Mr. Pethick Lawrence, on June 9th, Sir Kingsley Wood said the attention of the Minister of Health had been called to the death from septicæmia following childbirth upon which the Kingston coroner made comments; an inquiry was being made by one of the medical officers of the department. Mr. Pethick Lawrence asked whether the inquiry would survey the whole means of prevention of this disease; and other members recalled that five similar deaths had occurred at Kingston, but Sir Kingsley Wood said the Ministry of Health was confining itself, for the moment at any rate, to inquiry into this particular case.

Pensions Medical Officers.—Replying to Mr. Robert Young, Major Tryon (Minister of Pensions) said that on June 10th there were 338 medical officers in the regular employment of the Ministry, of whom 252 were employed in a full-time and 86 in a part-time capacity. Of the full-time officers 50 were permanent civil servants, and the remainder were serving under contracts of temporary service varying from one month to three years. The total cost of these officers for the financial year ended March 31st, 1926, was £261,185, and the estimated cost for the current financial year was £222,240. In addition to the medical staff in regular employment, it was still necessary to have frequent recourse to the assistance of private medical practitioners who acted as examining medical officers (formerly described as medical referees), members of medical boards, supervisors of clinics, visiting surgeons, anaesthetists, etc., and were paid fees varying from £5 5s. to 5s. according to the nature of the services rendered. The total number now employed was 1,752, and the fees paid during the financial year ended March 31st amounted to £230,446.

Relief under the Maternity and Child Welfare Scheme.—Mr. Barker, on June 10th, asked Mr. Chamberlain whether the Welsh Board of Health was advising that no relief under the maternity and child welfare scheme be given to relieve distress arising out of the dispute in the mining industry. The Minister replied that it was no part of the maternity and child welfare scheme to relieve distress. Milk could only be supplied under that scheme to mothers and young children who were certified to need it on medical grounds. The policy of the Welsh Board of Health in this matter was adopted on his instructions. If a maternity and child welfare authority spent more money on milk because of the mining dispute the additional expenditure must be found out of the rates.

Appointment of a Medical Officer of Health.—Mr. Chamberlain told Mr. Robert Young that he was in communication with the Golborne District Council, Lancashire, regarding its appointment of a medical officer of health. The choice of the Council had been submitted for his approval. Mr. Young alleged that although the Council advertised for a medical officer of health possessing the D.P.H., the person appointed did not possess it, and that candidates having it were passed over.

Certifying Factory Surgeons.—On June 14th the Home Secretary told Mr. Hore-Belisha that the appointments of certifying factory surgeons were made by the Chief Inspector of Factories, under Section 122 of the Factory and Workshop Act, 1901. Vacancies as they occurred were advertised in the London Gazette and communicated to the medical press, and applicants were required to give particulars of their experience and of any other appointments they might hold. The applications were carefully scrutinized, and, in the case of important districts, arrangements were made for the candidates to be interviewed by one of the medical inspectors. Where there was more than one candidate the advice of the senior medical inspector was taken. The chief inspector was satisfied that under this procedure the best men available were secured, and he had received no complaints.

Treatment of Flour with Chemicals.—On June 14th Sir K. Wood told Mr. Harland that the departmental committee which had been investigating the question of the treatment of flour with chemical substances had not yet reported, and until the report was received it was not desirable to introduce legislation on the subject. The Minister of Health had no knowledge of grain being treated with chlorine gas or other chemicals either before or after importation.

Poison Gas.—Sir L. Worthington-Evans informed Captain W. W. Benn, on June 14th, that experiments with animals were essential in order to obtain the necessary data for ensuring adequate defence against poison gas and for evolving efficient methods of treating gas casualties. The Government did not feel that the Washington Conference, Treaty, 1922, and the Geneva Protocol, 1925, against the use of poison gas in warfare justified it omitting to take all possible precautionary measures to protect the Forces of the Crown and the inhabitants of the country against gas attacks in war. For this reason the experiments must continue.

Notes in Brief.

On June 9th, in committee on the Finance Bill, Mr. Hannon moved that vehicles belonging to charitable societies or institutions, when used solely for the purposes of those bodies, should be exempted from the motor taxes. Colonel Ashley (Minister of Transport) said a concession had been given by the Finance Act, 1920, in the case of ambulances. The amendment was rejected.

On June 14th Earl Winterton informed Sir R. Luce that the Secretary of State for India hoped very shortly to receive the Government of India's final proposals with regard to the future of the Indian Medical Service.

The Government of India has directed the attention of the provincial governments to the recommendation of the International Labour Conference of October, 1923, favouring the appointment of women for certain classes of factory inspection work.

On March 31st, 1925, the latest date for which complete returns are available, there were 148 spare places in day schools for the deaf and 251 in residential schools in England and Wales.

The Reading University Bill was read a second time in the House of Commons on June 14th.

On June 15th Mr. Groves presented a bill to amend the law relating to compulsory vaccination, and Mr. Mackinder a bill to amend the Rag Flock Act, 1911. Both were read a first time.

THE TESTING OF THERAPEUTIC SUBSTANCES.

THE laboratories established by the Pharmaceutical Society to fulfil the conditions regarding the control of therapeutic substances the purity or potency of which cannot be adequately tested by chemical means, as laid down in the Therapeutic Substances Act, 1925, were opened by the Minister of Health on June 16th.

Mr. P. F. ROWSELL, who has recently vacated the chair of the society, said that work of this kind had only become necessary during the last twenty-five years, but the field seemed to be rapidly widening. Dr. J. H. BURN, formerly a member of the staff of the Department of Biochemistry and Pharmacology of the Medical Research Council's Institute at Hampstead, who has been appointed director, said that the success that had attended the use of thyroid extract, pituitary extract, and insulin, were examples of what might be expected to happen. Already pharmaceutical chemists and pharmacologists had an extensive field to investigate in co-operation.

Mr. CHAMBERLAIN, in declaring the laboratories open, said that as knowledge increased new weapons for the unceasing warfare against disease were being forged and an army of investigators—doctors, pharmacists, chemists, engineers, and architects, as well as nurses—was working together in the interests of health. To the Pharmaceutical Society, which might be regarded as a training college, it was a source of pride that throughout its career it was constantly raising its standard. It was now entering on a new branch of activity, which promised to be of great value both to the medical profession who prescribed, and the manufacturers who produced, these new remedies. By post-graduate courses it was enabling members of the pharmaceutical profession to lift themselves above ordinary commercial considerations.

Afterwards the large company inspected the laboratories under the guidance of Dr. Burn. It will be remembered that under the Act a general committee was set up consisting of the Minister of Health, the Secretary for Scotland, and the Minister for Home Affairs for Northern Ireland. This committee has the assistance of an advisory committee consisting of eight members—one each being appointed by the Minister of Health, the Scottish Board of Health, the Home Minister for Northern Ireland, the Medical Research Council, the General Medical Council, the British Medical Association, the Council of the Pharmaceutical Society of Great Britain, and the Council of the Institute of Chemistry. On this committee the British Medical Association is represented by Dr. C. O. Hawthorne. The committee will make regulations as to the standard of strength, quality, and purity of the therapeutic substances

to which the Act applies; as to the tests for determining the standard; and as to fixing units of standardization; it will also have authority to add to the schedule therapeutic substances the purity or potency of which cannot be adequately tested by chemical means.

The laboratories have been set up in the premises of the Pharmaceutical Society at Bloomsbury Square.

Medical News.

PROFESSOR HUGH CABOT (professor of surgery in the University of Michigan) has recently for a fortnight taken charge of the teaching of surgery in Sir Holburt Waring's clinic at St. Bartholomew's Hospital and Medical College. On June 9th Professor Cabot was admitted at a meeting of the council an honorary perpetual student of St. Bartholomew's Medical College—an honour conferred only once before, when Professor Harvey Cushing had charge of the teaching of surgery in Professor Gask's clinic at St. Bartholomew's in 1922.

As announced in our advertisement columns, the Association of Surgeons of Great Britain and Ireland invites applications for a surgical scholarship of £350 a year. The scholarship, which is tenable in the first instance for one year, is to enable the holder to pursue a definite line of research or to study surgery in specified clinics at home or abroad. Full details can be obtained on application to Mr. C. H. S. Frankau, Honorary Secretary, 51, Wimpole Street, London, W.1.

THE Fellowship of Medicine and Post-Graduate Medical Association announces that on June 24th, at 2.30 p.m., Mr. H. Tyrrell Gray will give a special clinical demonstration in surgery at the Hospital for Sick Children, Great Ormond Street, and on June 25th, at 12.45 p.m., Mr. Goulden will give a clinical demonstration in ophthalmology at the Royal London Ophthalmic Hospital. Both are open to the medical profession without fee. At the North-East London Post-Graduate College (Prince of Wales's General Hospital), Tottenham, there will be a course in medicine, surgery, and the specialties, lasting from July 19th to 31st, and occupying all day. From July 5th to 17th the National Hospital for Diseases of the Heart will give an all-day course in cardiology, and between the same dates there will be a course in dermatology at the Hospital for Diseases of the Skin, Blackfriars. On July 19th, at 5 p.m., a course consisting of lectures and clinical demonstrations upon selected cases will begin at the West End Hospital for Diseases of the Skin, and terminate on August 14th. A series of demonstrations on the treatment of diseases of the eye will take place at the Royal Eye Hospital from July 12th to 24th, at 3 p.m. Copies of all syllabuses and of the general course programme may be had on application to the Secretary of the Fellowship of Medicine, who will also supply copies of the *Post-Graduate Medical Journal*.

THE Tuberculosis Society will meet on Saturday, June 26th, at 3.30 p.m., at the Queen's Hospital, Sidcup. A visit to the ultra-violet ray department of the hospital will be followed by a lantern demonstration of radiograms. The commandant has kindly invited members to tea at the close of the meeting. If members intending to be present will notify the secretary, Dr. F. J. C. Blackmore, as early as possible, Colonel Colvin will endeavour to arrange transport for them from the station to the hospital.

THE chairman of the General Board of the National Physical Laboratory (the president of the Royal Society) will hold a reception within the grounds of the Laboratory on Tuesday, June 22nd, at 3 p.m.

THE annual meeting of the Research Defence Society, founded by Mr. Stephen Paget, whose death we have recently had to lament, will take place at the house of the Medical Society of London (11, Chandos Street, Cavendish Square, W.) on Friday next. Lord Lamington will take the chair at 3 p.m., and an address will be given by Dr. J. A. Murray, F.R.S., Director of the Imperial Cancer Research Fund, on the experimental attack on cancer.

At the annual meeting of the Brussels Medical Graduates' Association, held on June 9th, it was unanimously decided to change its name to the Brussels University Medical Graduates' Association. Dr. Fielden Briggs was elected president and Drs. Arthur Haydon and A. D. Woolf honorary secretaries. The annual dinner will take place in October.

THE KING has directed Dr. Joseph Anthony Ferriere to be appointed a nominated member of the Council of Government of the Colony of Mauritius.

WE are asked by the Honorary Secretary of the British Spa Federation to state that the coal shortage has not so far interfered with the service given by British spas.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 4361 Central).

QUERIES AND ANSWERS.

PHENOLAIN IN OPHTHALMOLOGY.

IN consequence of the memorandum published under this heading in the **BRITISH MEDICAL JOURNAL** of May 22nd (p. 865), Mr. ARNOLD FERGUSON has received a number of inquiries, and he asks us to publish the following information, which may be of use to those who have not read Nesfield's *Ophthalmic Surgery*:

Any wholesale druggist should be able to procure the drug. The composition is supplied with it. I feel sure that the quantity injected per eye is 30 to 40 minims of 2 per cent. cocaine in the solution subconjunctival. I have used it for months on the same subject. The solution keeps well.

INCOME TAX.

"D. J. G. J.," having succeeded to a practice, has applied under Rule 11 (Cases 1 and 11, Schedule D) to have his assessment reduced to the profits of the actual year; in making the reduction the local inspector of taxes has refused a claim to include the cost of replacing a car on the ground that such an expense should be regarded as capital outlay in a commencing business.

Rule 11 does not specify the basis on which the revised assessment is to be computed, but it was held in *Inland Revenue v. Fairie*, 1878, Sc. L.R., 189, that the effect of the rule is to introduce the provisions of the common law, leaving the assessment to be made upon the actual profits of the year. We know of no legal ground on which it can be claimed that expenses should be regarded differently according to whether they are incurred early or late after the acquisition of a practice. If the expense would be allowable in the third or sixth year (and apparently that is admitted by the inspector), we consider that it cannot be refused for the first year. Further, Rule 11 applies not only to the year when succession to a practice takes place, but also to each year for which the predecessor's profits enter into the average—for example, if the change took place at January 1st, 1925, Rule 11 can be invoked up to 1927-28 inclusive, since the 1924 profits enter into the three years' average for that year. Would the inspector be prepared to maintain his claim to exclude such expenses in computing the 1927 profits?

LETTERS, NOTES, ETC.

THE SMOKE EVIL.

DR. A. VERNON DAVIES, M.P., writes: There is a slight error in your "Medical Notes in Parliament" (June 12th, p. 1018). What I said was (1) that I had been in communication with the health authorities at Chicago, who had given me every information about the numerous methods in use there for dealing with the smoke evil; (2) that an apparatus designed by an eminent English engineer had been tested by me at a cotton mill in Lancashire; the apparatus practically eliminated the "black

smoke," but as the fuel consumption was increased by about 13 per cent. it was not an economic proposition, and the apparatus was removed.

MENTAL IRRITABILITY AND BREAKDOWN IN THE TROPICS.

DR. FRANK BRYAN (Ipswich) writes as to the cause of mental breakdown of Europeans in the tropics: May I suggest that it is largely because the white man tries to insist on natives adopting the same "time sense" as the Westerner. The diagnosis and end-result of this is shown by Kipling most aptly and most truly in his lines:

Now it is not good for the Christian's health to hustle the Aryan brown.
For the Christian riles, and the Aryan smiles and he weareth the Christian down;
And the end of the fight is a tombstone white with the name of the late deceased,
And the epitaph decries: "A Fool lies here who tried to hustle the East."

DR. L. J. GREEN (South Tottenham) writes: In your interesting leader upon mental irritability and breakdown in the tropics (**JOURNAL**, May 29th, p. 909) stress is laid upon the avoidance of overeating as a prophylactic measure. May I point out the importance of an equally careful avoidance of the reverse—namely, under-eating—in hot weather? There is a strong tendency among many people, especially those who accept their ideas from physical culturists and vegetarians, to keep a special watch upon their diets in summer, so as to reduce materially the quantity consumed in general, and the proteins in particular, while at the same time they swallow, considering it wisdom, undue quantities of fruit and salads. This restriction of diet below the normal requirements, when maintained for some weeks, leads to lassitude and weakness, not to mention digestive disturbances.

POSTURE IN HEALTH AND DISEASE.

DR. H. V. CANTOR (Jersey, Channel Islands) writes: I cannot agree with Mr. Alexander's criticism (May 29th, p. 928) of your article of April 17th (p. 690). I have prescribed the exercises to two patients recently recovered from serious iliacses, and one other, and in addition have carried them out regularly myself. In every case the exercises have not only given a feeling of well-being for the time immediately following, but have rapidly improved both the posture and the general health. This seems to be an instance where practical experience is of more value than condemnatory criticism based on mere theory.

SEPTIC SORE THROAT COMPLICATED BY ERYTHEMA NODOSUM.

DR. FRANK BODMAN (Bristol) writes: I read with interest Dr. Eleanor Shephard's memorandum in the issue of May 29th (p. 902) reporting a series of cases of ulcerative tonsillitis. I have under my care at present an epileptic, whom I am treating with luminal. The patient is suffering from enlarged tonsils, and from time to time develops acute tonsillitis. (Operation has been refused by the parents.) I notice that during each of these attacks the patient develops a papular rash, which I have ascribed to the luminal. I do not know whether luminal is employed at Liagfield Colony, but it has occurred to me that, the metabolism of the patient having been disturbed by the acute infection, an attempt is made to eliminate the luminal in other directions.

TESTS FOR DRUNKENNESS.

"ANOTHER EX-NAVAL SURGEON" writes elaborating the statement made during the discussion by the Marylebone Division last February—that in the navy it was the officer of the watch who decided the question of drunkenness by applying the test whether the man was, or was not, fit for duty. *King's Regulations and Admiralty Instructions*, he thinks, lays it down that the officer is to be guided in his decision by "whether or not, in his opinion, the man is fit to be entrusted with his duty." The fact that the man has been doing his duty makes no difference to the decision, which is final if the man is regarded as unfit to be entrusted with his duty. Our correspondent wishes to see a similar system applied to motor drivers. The police surgeon should be given the responsible duty of saying whether or not a man is fit to be entrusted with a car. He should see the accused very shortly after he has been arrested, and his decision should be final.

EXCRETION OF ALCOHOL BY THE URINE.

THE publication in our issue of March 13th of the paper by Drs. Southgate and Carter on excretion of alcohol in urine as a guide to alcoholic intoxication (p. 463), and of the report of a discussion on this subject at the Medico-Legal Society (p. 482), has prompted Dr. J. BARKER SMITH to send some personal observations: I have (he writes) taken alcohol at night and found in the morning small quantities of alcohol in the urine; another time I have found none. I have examined the urine of an old man living on beer alone at the time. In his urine there was no alcohol, but there was an increase of the oxidizables acting as alcohol to my simple test. This test was given for lactic acid several years ago in the **BRITISH MEDICAL JOURNAL**, and it is a very simple and rapid (five minutes) quantitative test for alcohol—1 c.c.m. of a 1 per cent. dilution of alcohol can be estimated by it. All ordinary constituents of urine are in fair rapport with the specific gravity of the urine: so are the oxidizables examined by my test. The normal heat degrees given by urine, say specific gravity 1020, are 2°—average of 300 examinations gave a little less than 2° F. If there should be 5 per 1,000 of alcohol there would be 2° higher than normal. A chart made of observations per minute will distinguish

alcohol from sugar. My carbohydrate test was described in the *Scalpel*, 1898-1900. I will for convenience describe it again. The essentials are: 4 c.cm. of saturated solution of potassium permanganate, 1 c.cm. acid sulph. dil., a long stoppered half-ounce phial, and a short stem thermometer going easily into the phial. The temperature of the oxidizer is first taken and recorded, 1 c.cm. of urine of the same temperature is added, the phial is briskly shaken a few seconds by the rim, the thermometer introduced and left *in situ*. The maximum for alcohol is obtained about the third minute. One measured droplet of spirits (gin, whisky, brandy) can be easily estimated quantitatively.

ULTRA-VIOLET RAYS IN TUBERCULOSIS.

Dr. H. RENDELL (St. John's, Newfoundland) writes: In the report in your issue of April 3rd (p. 629) of the joint meeting of the Tuberculosis Society and the Tuberculosis Institution I was interested to note the following words by Dr. Crockett with reference to ultra-violet rays—"the rays are intensified from reflection from snow and sea." Those of us who have to work where there is much snow and ice have learned to guard against the sometimes serious effects of the glare of bright sun on ice—otherwise night blindness is very likely to result. Is it not probable this is produced by the ultra-violet rays, and does this not convey a note of warning to patients and mechanicians? For centuries the Eskimos have worn most ingenious goggles, made of wood with very narrow slits in front; these enable them to see well and yet shade the eyes from direct or reflected rays.

LETHARGIC ENCEPHALITIS: PARKINSONISM: AORTIC REGURGITATION.

Dr. L. F. BECCLE (Merthyr Tydfil) writes:—The following case might be of some interest: A youth, aged 19, seen on April 30th, gave a typical history of an attack of encephalitis lethargica some eighteen months previously. He had been healthy up to the time of this illness, and, in fact, was a very keen and promising boxer. I found that he was suffering from post-encephalitic Parkinsonism. He also had a typical aortic regurgitant murmur and enlargement of the left side of the heart. He gave no history of rheumatic fever or, in fact, of any illness with which this valvular defect could be associated. Is it possible that the encephalitic virus attacked the aortic valve, or did the latter condition arise insidiously from some unknown cause?

COMMON SENSE IN RELATION TO DOUBTFUL TUBERCULOSIS.

Dr. F. G. BUSHNELL (Plymouth) writes:—The issues raised in the *BRITISH MEDICAL JOURNAL* of May 8th and 15th (p. 846) on ending doubtful cases of tuberculosis to sanatoriums appear to be: (1) Against such a course: The risk of infection in sanatoriums in which open or potentially infective cases cohabit with non-tuberculous patients—that is, in which there is no "observation section"; and the grave social disadvantages that follow the labelling of a non-tuberculous person "tuberculous" which follow notification and treatment in a sanatorium. (2) For such a course: The assumed certainty of absolute control of infection during such intimate and prolonged sanatorium life; and the advantages of the open-air sanatorium *per se* for non-tuberculous cases, even without an "observation section." As one who has spent all his life working in the clinical, bacteriological, and administrative aspects of tuberculosis respectively, and especially as an ex-tuberculosis officer of fourteen years' experience, I share with many of my former colleagues the belief that the national public health resources should be applied to the common-sense separation—and control under medical supervision—of the active and potentially infective tuberculous population from the susceptible public, whether it be at the cradle, the home, the workshop, or the sanatorium. In brief, we rely largely on an antituberculosis ring of preventive measures. As long as we allow the seed to be sown broadcast, so long will the weeds spring up. The vast amount of research and statistics of tuberculosis officers of "contact" cases (shown so dramatically and tragically in tuberculous meningitis in infants and young children) in this country, and of Confamilial observers, especially Grancher, Léon Bernard, and Debré, establish this as a truth. In no way do they minimize the importance, however, of all measures which render the soil unsuitable, of which perhaps good housing is one of the greatest.

LATE SEQUELS OF WAR GASSING.

The medical service of the United States Veterans' Bureau is making a special study of the residual effects of war gassing by investigating the present or recent condition of over 70,000 ex-service men with hospital records of injury due to this cause. In view of the uncertainty as to the permanence of the injury so caused, the present inquiry is of considerable importance, and Dr. Crossman, medical director of the bureau, invites communications from readers of the *BRITISH MEDICAL JOURNAL*, so that the information at the disposal of the bureau may be as complete as possible. The inquiry is not concerned with the better known and more immediate effects of war gases, but information in answer to the following questions is desired: (1) Does any war gassing received in action result in disability which is relatively lasting and permanent? (2) Does it cause lasting anatomical (pathological) changes, with or without disturbance of function (symptoms and disability)? (3) What organs or systems may thus be permanently affected or disturbed? (4) What symptomatology may exist in these circumstances? (5) If war gassing does produce relatively permanent effects, may a similar condition or conditions be produced by other agencies (diseases such as influenza, tuberculosis, effort syndrome, etc.)?

Two reprints of any articles on this subject are also desired. Correspondence should be addressed to Dr. E. O. Crossman, United States Veterans' Bureau, Washington.

MEDICAL LEGISLATORS.

THE Congress of the United States is made up of 96 Senators and 435 members of the House of Representatives. The *Journal of the American Medical Association* stated some time ago that there is only one member of the medical profession in the Senate, and only five in the House of Representatives, which also contains three dentists. About two-thirds of the Congressmen are lawyers or have had legal training. The remainder are mostly business men, farmers, and publishers, with a sprinkling of educators and engineers. Our contemporary has recently published some information about the legislatures of South America. In Uruguay, which has 19 Senators and 125 Representatives, five medical men were at the last election elected to the Senate and twenty-five to the House of Representatives. In this country there are two medical members in the House of Lords and fourteen in the House of Commons.

MILTON IN THE MAKING.

For those (and there are many) fond of sauntering down literary hy-paths the book, *Some Newly Discovered Stanzas written by John Milton on Ovid's Metamorphoses*, on which Mr. . . . evidently expended much loving . . . considerable interest. This Milton-Ovid script, he says, was written circa 1623; discovered, 1921; first printed in *Notes and Queries*, 1922-23; and is now revised and reprinted in one volume, with many additional notes. In number the verses here printed are almost exactly equal to all the English verse hitherto known to exist in Milton's handwriting; they are closely related to his favourite classic, and replete with evidence which confirms and illustrates the accepted traditions of his early literary development. Mr. Candy claims that the evidence of identification "is adequate in amount and both cumulative and corroborative in character." After perusal the reader is left in agreement with these conclusions. The stanzas, in what is claimed to be Milton's handwriting (and care is taken by many comparisons to prove this), amount in all to 166, and the lines are grouped in the decasyllabic couplet used by Milton in his "Paraphrase of Psalm 114," "Vacation Exercise," "Hodson Verses," "At a Solemn Musick," and occasionally in "Comus." Eight leaves of the small octavo volume (printed at Frankfurt in 1563) on which the script is written are lost, and it is estimated that seven stanzas have thus disappeared. This volume bore the title "Johan. Posthili Germersheim Tetrasticha in Ovidii Metamor. Lib. XV quibus accesserunt Vergilii solis figurae elegantiss. & jam primum in lucem editae," and it is in description of the illustrations therein that the stanzas were written. Above each engraving is printed a quatrain in Latin, and, below, a similar quatrain in German summarizing the scene. The verse of each folio is blank and unnumbered; it was on these that the scribe had written a stanza of English verse interpreting the succeeding plate. The English verse is not a translation of either of the foreign quatrains or of Ovid's text, but the composition is original, though the subject is prescribed by the corresponding plate. If the scribe was indeed Milton, and if the stanzas were written circa 1623, it follows that the poet was then about 15 years of age, the age when he wrote the paraphrases of Psalms cxlv and cxlvi which incur the disdain of Sir A. Quiller-Couch; but after reading Chapter VI of Mr. Candy's book ("the complete text with annotations") there seems little doubt of his having a good case, and of his having made it out well. For its interest from the point of view of folk-medicine we may quote stanza III ("The Tranel of Alcmena"):

"Seven nights and dayes Alcmena sore oppress
With bearing pains, to Jove her prayers adrest

MEDICAL GOLFING SOCIETY.

THE Medical Golfing Society held its twenty-ninth annual summer meeting at Wentworth (by kind permission) on June 10th. The course was in excellent order. The results were as follows: *Lancet Challenge Cup* (scratch).—H. D. Gillies, 1 down. *The Nilson Rees Challenge Cup* (scratch in Class II).—A. H. Gosse, F. A. Juler.

Class I.—D. S. Gordon and A. Galletly tied at 1 down.
Class II.—A. Scott Gillett and F. A. Juler tied at 2 down.
Foursomes.—These were won by T. P. Kolesar and W. R. Bristow.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 50, 51, 52, 53, 56, and 57 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 54 and 55.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 227.

A Lecture

ON

ENCEPHALITIS LETHARGICA
IN ENGLAND.*

BY

ARTHUR SALUSBURY MACNALT, M.A., M.D. OXON.,
M.R.C.P.

ENCEPHALITIS LETHARGICA, or epidemic encephalitis, which may be classed under the head of general infectious diseases, is distinguished by certain manifestations originating in the central nervous system. One of the most characteristic of these manifestations is due to a lesion in or about the nuclei of the third pair of cranial nerves. The progressive lethargy and stupor which are often present caused von Economo¹ to give the descriptive term "lethargica" to the disease. The name "sleepy sickness," which, for the same reason, is sometimes popularly used, is to be deprecated, as it is apt to lead to confusion with the sleeping sickness of African countries—an entirely different malady due to a trypanosome.

HISTORY OF THE DISEASE.

1. Past Appearances of Encephalitis Lethargica.

Crookshank² has pointed out that scattered through the medical literature of the last four or five centuries are many records of cases and epidemics that may possibly correspond to the various types of encephalitis lethargica now recognized. Some of these outbreaks are ascribed to food poisoning; others are associated with catarrhal epidemics which were probably influenzal. For practical purposes the disease is a new phenomenon.

2. Appearance of Encephalitis Lethargica in England.

Encephalitis lethargica was first recognized in this country in 1918, when an outbreak simulating food poisoning occurred in the spring of that year. A notable feature of the outbreak was its wide and sparse distribution. From careful investigation instituted by the Local Government Board, with the collaboration of the Medical Research Council, the malady was recognized as a distinct clinical entity and later found to be identical with that described in the previous year by von Economo and von Wiesner in Austria. The clinical characters of the disease and the features which distinguish it from such closely allied conditions as acute poliomyelitis and polio-encephalitis are described in detail in the two official reports on the subject which have been published by the central health authority.[†]

PATHOLOGY AND ETIOLOGY.

The pathological histology of the disease consists in the main of a perivascular cellular infiltration of lymphocytes with occasional plasma cells in scattered areas of the central nervous system. For this no visible parasitic cause (for example, bacteria, protozoa) can be found. The distribution throughout the central nervous system is uneven. The sites of election are the region of the nuclei of the third nerve and the basal ganglia, but other areas may be attacked.

The cerebro-spinal fluid shows a slight increase in the total protein content and an increase in the number of cells (lymphocytes with occasional plasma cells) per cubic millimetre.

Various observers (McIntosh,³ Levaditi,⁴ Doerr,⁵ etc.), by inoculating a virus obtained from human cases, have provoked in rabbits and monkeys brain lesions indis-

tinguishable from those characteristic of encephalitis lethargica. Levaditi,⁴ Perdrau,⁶ and others find that a virus obtainable from the vesicles of herpes febrilis (not herpes zoster) used in the same way produces the same results. Much further experimental work is needed, and is being actively conducted in this country and abroad.

In the Milroy Lectures for 1925⁷ I have considered certain possible explanations, not necessarily incompatible, that may be advanced on the subject of an apparently increased, and rapidly increasing, susceptibility of the central nervous system to attacks of epidemic nervous diseases, including encephalitis lethargica.

CHIEF CLINICAL FEATURES.

The disease attacks all ages, with a preference for the early and middle periods of life, and both sexes nearly equally.

From the clinical point of view three types are distinguished: (1) general disturbance of the functions of the central nervous system but without localization; (2) various localizations in the central nervous system; (3) mild or so-called abortive cases.

After a period of incubation, the duration of which cannot at present be specified, a prodromal period ensues; this includes the first seven days, but may extend to two or three weeks, during which lethargic somnolence, headache, double vision, general lassitude, and occasionally vomiting and diarrhoea, may occur. Soreness or dryness of the throat may also be present. The acute symptoms which follow include a febrile temperature (101° to 102° F. = 38.3° to 38.8° C.), marked asthenia, stupor (alternating often with nocturnal delirium), difficulties in speech, and spasmodic twitchings of the face and limbs. Skin eruptions are occasionally noted. There is no characteristic rash; an erythema is most often seen, but the eruption may be petechial, papular, morbilliform, or scarlatiniform. The rashes when present appear early in the disease and during the pyrexial period. They are transient, fading in twenty-four hours as a rule. In the type of the disease with localizations in the central nervous system paralysis of accommodation with diplopia is very frequent and occurs early. There may be ophthalmoplegia, external or internal, with ptosis. The muscles innervated by the facial nerve may also be paralysed as well as the muscles of the tongue, pharynx, etc., rarely those of the limbs. The paralysis is progressive in character. Sensory troubles are the exception. There is often urinary or faecal incontinence and sometimes retention of urine. Death appears due to paralysis of the respiratory nervous centres. It is preceded by an increase in delirium and stupor merging into coma. It occurs most frequently before the end of the third week.

The severest cases lie in bed like a log or resemble a waxen image in the lack of expression and of mobility. The immobility may be accompanied by cataplexy. Various degrees of stupor have been noted. The condition may be one of deep coma, with open eyes, total lack of facial expression, and inability to be roused. More commonly the condition is not so grave, but the patients are in a profound sleep, from which they can be aroused to answer questions or to partake of food. When undisturbed they quickly lapse again into stupor. Certain patients resent being roused and display intense irritability or utter moaning cries when touched. The duration of the stupor is very variable. It may last for only two or three days, or more often may persist for two to five or even eight weeks. Periods of remission may occur in the course of the malady. The onset of coma, although grave, does not always imply a fatal issue. Many patients display extreme emotion and are "childish" in demeanour.

It may be mentioned that the clinical type of case seen during the present period of prevalence (1924-25) appears, on the whole, to be less severe than the above description, which is based on the study of cases seen in preceding years. In many instances the prodromal period appears to exceed the usual seven days. The onset is often ascribed to "influenza," and a fortnight or more elapses before the definite signs of encephalitis are manifest. Patients do not remain for lengthy periods in profound stupor or

* Delivered under the Chadwick Trust, at the Royal Society of Medicine on December 9th, 1925.

† (1) Report of an Inquiry into an Obscure Disease. Encephalitis Lethargica: Reports to the Local Government Board on Public Health and Medical Subjects, N.S., No. 121, London, 1918. (2) Ministry of Health Report on Encephalitis Lethargica: Reports on Public Health and Medical Subjects, No. 11, London, 1922.

coma, and some have made an unusually rapid recovery; catalepsy is rare.

While the prominent symptoms in a material proportion of cases remain those of lethargy and ocular paralyses, many are chiefly characterized by myoclonic movements and sometimes by fibrillary twitchings of the abdominal muscles. Affections of the cortex of the brain are more frequently seen than in previous outbreaks; these are characterized by epileptiform convulsions and are sometimes associated with maniacal outbursts or insomnia.

EPIDEMIOLOGY.

1. Incidence.

Encephalitis lethargica was made compulsorily notifiable in England and Wales on January 1st, 1919, and from that date fairly complete records of all recognized cases are available. The number of cases of encephalitis lethargica notified in 1924 was 5,039. This number exceeds the sum of all the notification tables for the preceding five years, as may be seen from the following table.

England and Wales: Notifications and Deaths from Encephalitis Lethargica since this Disease became Generally Notifiable.

Year.	Notified Cases.			Deaths.		
1919	541	264	...
1920	890	471	...
1921	1,470	724	...
1922	454	337	...
1923	1,025	530	...
1924	5,039	1,419	...

There was an unusual prevalence also in Scotland and Ireland in 1924.

2. Incidence in Urban and Rural Communities.

Encephalitis lethargica has been reported chiefly from urban districts. In 1924 the rural districts only contributed 12.8 per cent. of the total number of cases, while the county boroughs alone were responsible for 46.6 per cent. Large cities and industrial centres have been particularly affected, probably on account of the enhanced opportunities for the spread of personal infection, although possibly the better facilities for medical diagnosis possessed by large towns may also be a contributing factor. In 1918 I found a restricted topographical distribution of cases of encephalitis lethargica in certain districts, notably in the county borough of Stoke-on-Trent. The same tendency for examples of the disease to clump in certain areas of a town or city was noted in 1924 in Sheffield, Bristol, and elsewhere, probably associated with density of population and increased opportunities for case-to-case infection. Parsons has found in Bristol and elsewhere that this topographical grouping in towns tends to be the same in different epidemic years—a circumstance which suggests the presence of endemic foci of the disease.

3. Mortality.

In 1918, in the first outbreak in this country, out of 168 cases of the disease 37 died—a case mortality of 22 per cent. Variant case mortality rates are quoted by Parsons, ranging from 53 per cent. (McClure) to 15.7 per cent. (Bramwell). The notification figures (England and Wales) for 1919-23 gave a case mortality rate of 54 per cent. In view of the failure to notify cases of epidemic nervous disease generally, and through failure to recognize mild non-fatal types of encephalitis lethargica, these figures cannot be taken as a true estimate of the number of deaths that occur among persons attacked by encephalitis lethargica. No definite opinion can be expressed at present as to the case mortality, except that it is probably under 50 per cent.

4. Age and Sex.

All ages may be attacked, from the newborn babe to the octogenarian. A woman of 84 has died from the disease. The main incidence of the disease begins to be apparent in those approaching adult life; 25 per cent. of a series of British cases occurred in persons between the ages of 10 and 20 years. The incidence appears to be fairly evenly distributed over the years 20 to 40, but the tendency to

acquire encephalitis lethargica declines with advancing age. The records of the Ministry of Health show that the sexes are equally affected. Of 1,273 cases, 634 were males and 639 females. This proportion is evenly maintained at different age periods.

5. Seasonal Prevalence.

The first outbreak occurred during the first quarter of 1918. James early called attention to the difference between the seasonal incidence of the disease and that of poliomyelitis. Since then the increase in the number of cases in the colder months of the year has been annually noted in this country, the rest of Europe, and in North America. The increase in the incidence of encephalitis lethargica usually begins towards the end of December and continues during the first quarter of the new year. The second quarter also shows many cases, but by the end of May the epidemic has waned and many fewer cases, as a rule, are notified in the third and fourth quarters of the year.

6. Predisposing Causes.

Careful inquiries have been made by the Ministry of Health into possible predisposing causes, but little of value has resulted from the quest. The influence of pregnancy is regarded as of importance by some writers. Jorge, in reviewing a series of 18 pregnant cases, found that the mortality rate was 72 per cent. On the other hand, the Ministry's figures show that the mortality rate in respect of all the cases of encephalitis lethargica which were associated with a pregnancy, past or present, is 44 per cent.; this percentage also represents the general case mortality among all women between the ages of 20 and 40 who contracted the disease during 1919 and 1920. Social conditions appear to exert no influence upon the disease. As regards occupation, from a study of 1,070 patients, Parsons found that 734 followed indoor occupations, 133 engaged in outdoor occupations, while 203 patients belonged to an indeterminate group. He concludes that the disease chiefly attacks those who spend the greater part of the day indoors in pursuit of their avocations. Overwork is often assigned as a predisposing cause. The specific infectious diseases and diseases generally do not appear to dispose to the disease beyond the circumstance that any antecedent or associated disease may lower the patient's resisting powers to infection.

EVIDENCE FOR REGARDING ENCEPHALITIS LETHARGICA AS AN EPIDEMIC DISEASE.

The epidemiological evidence already available in regard to cerebro-spinal fever and acute poliomyelitis greatly facilitates an understanding of the behaviour of encephalitis lethargica. No evidence has been elicited that the virus of this disease is conveyed through intermediate agencies, such as water, soil, food, clothing, biting insects and flies, etc. The chief facts relating to the spread of encephalitis lethargica by personal contagion are as follows:

- (1) The restricted topographical distribution of cases to which allusion has been previously made.
- (2) The cases reported by Harris, Kononowa, Novaes and Sousa, and others, of infection *in utero* or placental transmission.
- (3) The examples of multiple cases in families and localized outbreaks in small communities.
- (4) Examples of case-to-case infection, where infection from a common source was apparently excluded.

Dr. Parsons and I have put on record in official reports several examples of multiple cases of encephalitis lethargica in families, and Netter⁹ has reported a number of similar instances in France.

An interesting example is that communicated by Van Boeckel¹⁰ at Ruddervoorde, in West Flanders, in 1919, where the disease attacked four families who were closely interrelated. Of 26 persons, 17 were attacked, and 4 of these died. Kling and Liljenquist¹¹ of Stockholm found, in February, 1921, that encephalitis lethargica was prevalent in certain villages in Lapland, the morbidity rate varying from 7.1 to 45 per cent. In some families several members contracted the disease simultaneously,

and in two houses almost all the inhabitants were affected. Side by side with the severe and typical cases were catarrhal and febrile cases, cases with slight affection of the ocular movements, and a few cases of obstinate hiccup.

In the Annual Report of the Chief Medical Officer of the Ministry of Health for 1919-20¹² I recorded an institutional outbreak of encephalitis lethargica in a home for girls at Derby: 12 persons were attacked out of 22 inmates, and there were 5 deaths. John and Stockbrand¹³ have reported a similar outbreak in an asylum at Mulheim in the summer of 1922. Here 28 cases with 13 deaths occurred in twenty days, 6 being in nurses and 2 in doctors. Dysphagia and ophthalmoplegia were frequent symptoms.

It is known that mild and ambulant cases of illness exist in association with declared cases of encephalitis lethargica; several instances of the kind were encountered in 1924 in Liverpool, Sheffield, and elsewhere; through their medium the conveyance of infection from one person to another seems to be more than probable. I would suggest that the presence of these "carriers" in encephalitis lethargica indicates that the disease is in accord with cerebro-spinal fever and poliomyelitis as one in which the pathogenic agent is more frequently present in the human organism than the clinical evidence would imply. The work of Eastwood, F. Griffith, and Scott¹⁴ has already established this conception as true for cerebro-spinal fever. Encephalitis lethargica appears to be equally infective and liable to manifestation in epidemic form.

THE QUESTION OF REINFECTION.

It is impossible at present to say whether the disease may occur more than once in the same individual. Netter,¹⁵ G. E. Price,¹⁶ and Buzzard¹⁷ have recorded cases in which patients have apparently recovered and eventually have succumbed to encephalitis lethargica. On the other hand, the frequent occurrence of sequelae, mental changes, symptomatic paralysis agitans, and the like, may be due to persistence of the virus of the disease, which, like the virus of syphilis, may be capable of lurking quiescent in the body for long periods and of returning to activity from time to time.

ROUTE OF INFECTION.

Like cerebro-spinal fever and acuto poliomyelitis, it seems a fair assumption that the virus of encephalitis lethargica first infects the upper respiratory passages, where it may either lurk and give rise to the carrier phase in the person affected or may pass on to attack the brain. There is no definite catarrhal stage associated with its early manifestations, but sore throat is a frequent concomitant. There is reason to believe, in view of the frequency of initial conjunctivitis, that the virus may enter the brain through the eyes; infection by the gastro-intestinal route is also a possibility.

EPIDEMIC HICCUP.

Sir John Robertson, medical officer of health for Birmingham, from his experience in the Birmingham epidemic of 1924 is strongly of opinion that epidemic hiccup may be a symptom of encephalitis of a mild type. The disease has been seen in definite association, for instance, in the same household with encephalitis lethargica; an attack of hiccup may precede or accompany the nervous symptoms of the major disease, and there is good reason, in view of the cumulative evidence, for regarding epidemic hiccup as a mild or frustrated form of encephalitis lethargica.

CHRONIC ENCEPHALITIS LETHARGICA OR SEQUELAE OF THE ACUTE FORM.

The sequelae are both of neurological and medico-legal importance. They may appear (1) in the course of the original acute malady and persist after partial or complete disappearance of all other symptoms, or (2) after the original acute attack has apparently terminated or possibly has passed unrecognized. Such effects are declared after a variable latent period ranging from some weeks to over two years. No definite opinion, therefore, can be expressed

until after some years as to whether an attack of acute encephalitis, however mild in appearance, may or may not result in serious sequelae. The more important of these after-effects are:

1. *Mental Symptoms.*—In all probability these are dependent upon lesions of the cortex of the brain. Irritability, maniacal outbursts, hebetude, complete change in moral character and self-control, lying and theft, may appear for the first time in the conduct of the victim of encephalitis lethargica, as well as grosser mental defects (including even homicidal attacks) which result in the patient's transference to a mental institution. These symptoms are of all grades of severity and may be associated with nervous lesions. They are usually seen in children or in the young adult.

2. *The Parkinsonian Syndrome.*—This condition closely resembles and may be identical with paralysis agitans as seen in the elderly or middle-aged adult. Fewer cases of disease are more pathetic than juvenile examples of this condition, and alike in children and adults it must be regarded as one of the gravest sequelae.

3. *Excito-motor Sequelae.*—Myoclonus: sudden, shock-like muscular spasms of limbs, sometimes also of diaphragm and larynx. Halting and slowed movements (bradykinesia).

4. *Other Sequelae.*—Of these, increased tone of muscles, paralysis, various sensory symptoms, and curious respiratory spasms (polypnoea, periods of apnoea, Chayne-Stokes respiration) may be mentioned.

It is as yet unknown whether these manifestations are true after-effects or if they are indicative of persistence of the original infection. It is impossible also, at present, to say what proportion of surviving cases of encephalitis lethargica exhibit after-effects, whether mental or physical. Investigations are now being made on this question. It appears to be probable that mental after-effects, especially in children, occur in a large proportion of the surviving cases. Of the seven survivors of the Derby outbreak, two subsequently developed mental symptoms.

PREVENTION AND TREATMENT.

As advised in the memorandum of the Ministry of Health, the medical officer of health faced with an outbreak of encephalitis lethargica in his district should pursue the following lines of action:

- (a) Full determination of the associated conditions and any facts which may throw light on the epidemiology of the disease.
- (b) Search for mild and abortive cases.
- (c) Aiding in any practicable pathological investigation and in obtaining material for the purpose.
- (d) Aiding in securing the treatment of the disease in hospital or otherwise.
- (e) Enjoining the precautions required in the case of a disease apparently capable of transmission from person to person, especially through mild and abortive cases capable of carrying infection; and
- (f) "Following up" and recording the after-history of patients; in particular, as to any mental after-effects which may be observed. In this connexion inquiry should also be made into the previous history of children who begin to exhibit changes in behaviour or unusual accentuation of undesirable qualities; these symptoms not infrequently point to an overlooked attack of epidemic encephalitis at an earlier date.

In view of the severity of the disease and the importance of good nursing, it is important to secure hospital treatment as far as possible. The isolation hospitals of local authorities should be available for this purpose; at the same time a number of cases may have to be treated in their own homes; for these public nursing facilities, possessed by or arranged with the authority, should be available. The other occupants of a house in which a case of encephalitis lethargica has occurred or is being treated may be assured that owing to variations in individual susceptibility the disease is one of low infectivity, and that slight risk, as a rule, is run by association with the patient. It is desirable that such association should be limited to the necessities of proper care and nursing, and the patient should be well isolated in a separate room. School children in the affected household may be kept from school for three weeks after the isolation of the patient as a precautionary measure. There is

no necessity to place restriction on the movements of other occupants provided they are frequently examined and remain well. Those in contact with the case may be advised to use antiseptic nasal sprays, douches, and throat gargles. Any persons in the infected household who suffer from sore throat or other symptoms suggestive of an abortive attack should be medically treated and isolated until they have recovered. The sick-room should be thoroughly cleansed and disinfected at the end of the illness.

Although there is no specific treatment, much may be done to sustain and tide the patient over the acute period of attack. Confinement to bed, the services of a trained nurse, and treatment as an infectious disorder are primary essentials. In many cases transient or permanent relief with diminution of stupor follows on the withdrawal of cerebro-spinal fluid by lumbar puncture. It is seldom advisable to administer hypnotics, morphine, or other preparation of opium; urotropine, if prescribed, should be administered in small doses with caution and with suitable tests as a guide. Hall advises belladonna in the treatment of chronic forms of the disease.

CONCLUSION.

To encephalitis lethargica we may apply the words of Harvey: "Nature is nowhere accustomed more openly to display her secret mysteries than in cases where she shows traces of her workings apart from the beaten path; nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual law of nature, by the careful investigation of cases of rarer forms of disease."

The study of encephalitis lethargica has made many problems in neurology and physiology plain; but the existence of this tragical disease in our midst is a heavy price to pay for the acquisition of new learning. Sir Thomas Brown wrote: "Some will allow no diseases to be new, others think that many old ones are ceased; and that such which are esteemed new will have but their time." But even if this last is true of encephalitis lethargica, it behoves us all to endeavour to shorten the time of visitation. You will have gathered from what has been said how serious is the disease and how deplorable and frequent are its after-manifestations.

Further study of the malady will add to our knowledge and will furnish us with fresh weapons for attack and defence. In this crusade the team work of the epidemiologist, the physician, and the pathologist is all-important.

THE ABSORPTION OF MERCURIALS FROM OINTMENTS APPLIED TO THE SKIN.

BY

R. B. WILD, M.D., F.R.C.P.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF MANCHESTER; HONORARY CONSULTING PHYSICIAN TO THE MANCHESTER AND SALFORD HOSPITAL FOR SKIN DISEASES;

AND

IVY ROBERTS, M.Sc., Ph.C.,

ASSISTANT LECTURER IN PHARMACEUTICAL CHEMISTRY IN THE UNIVERSITY OF MANCHESTER.

In two previous papers by one of us¹ an attempt was made to determine the relative values of the different substances used as bases for ointments, both as regards protection and absorption, and it was found that lard and hydrous wool-fat were absorbed more readily than the paraffin bases. We have no information as to whether the drugs combined with these bases to form ointments are absorbed *pari passu* with the base, or whether the bases readily part from the drugs so that the latter may be absorbed either more quickly or more slowly than the base; neither do we know whether a drug dissolved in the base behaves differently from one which is merely mechanically mixed with it. It seemed desirable, therefore, to attempt to determine these points by the method described in the previous papers, but work on these lines was interrupted for some years by the war, and has only recently been completed and the following results obtained with respect to certain mercurial ointments.

The mercurial ointments were selected for study for two reasons: first, because the absorption of mercury through the skin is of importance in regard to its clinical use—in some cases desirable, in others to be avoided; and secondly, because mercury and its compounds can be quantitatively estimated with great accuracy. It was found, however, that the accurate determination of mercury and its compounds when combined with fats or paraffins of various composition presented special problems in analysis and required special methods; these methods were first worked out and the results have already been published by one of us.²

The method employed was to make an accurate determination of the mercury in a sample of ointment; a carefully weighed quantity of this was then rubbed into a definite area of skin, about 20 square inches, for a definite time. The unabsorbed ointment was then scraped off the rubbing finger and the surface of the skin by a dulled Gillette safety razor blade fixed in a convenient handle, and again weighed. To avoid the necessity of wiping the instrument the scraper was weighed with the ointment both before and after rubbing. The amount of mercury in the unabsorbed ointment was then determined. The loss of weight represents the amount of ointment absorbed together with that lost by manipulation, and as the latter is fairly constant in dealing with preparations of similar consistence the results afford a relative indication of the respective amounts absorbed. From a comparison of the analysis of the ointment before rubbing with the analysis of the unabsorbed ointment it is easy to calculate the amount of mercury, or mercurial salt, absorbed as well as the amount of base.

It was found, after doing a number of preliminary experiments, that absorption was not so good when the skin was cold—as, for example, in the morning in cold weather. In order, therefore, to reduce the number of variable factors as much as possible the experiments were always carried out in the afternoon, and the skin area was well washed with hot soapy water and thoroughly dried immediately before rubbing. It was also found that the variable thickness and texture of the skin in different parts of the body and in different persons affected the amount absorbed, and the experiments from which any conclusions were drawn were all carried out on the same

person and on the flexor surface of the forearm from the wrist upwards, a surface free from hair and convenient to use. In order to verify the results obtained a number of the more important experiments were repeated independently after twelve months' interval, with substantially the same results. Over 130 experiments were done in all.

The following tables summarize the results obtained by this method, an average experiment being given in each case; for the sake of uniformity the amount of mercury or mercurial salt absorbed has been calculated as the weight in grams which would be absorbed from 100 grams of the original ointment. In the case of the mercury ointments this is estimated as metallic mercury, in the case of the oxido and oleate as mercuric oxide, in the case of calomel as HgCl_2 , in the case of ammoniated mercury HgNH_2Cl , and in the case of the salicylate as metallic mercury.

METALLIC MERCURY.

All ointments used were nominally of B.P. strength 30 per cent. The amount of mercury absorbed was found to vary with the size of the globules of mercury examined microscopically; the absorption from one sample of hand-made ointment with large globules was practically negligible, so all ointments were examined microscopically before they were used for experiment, and rejected unless the mercury was in a fine state of division and equally diffused through the fatty base.

Lard Base.—A comparison of experiments in which the duration of the rubbing was varied shows that at first the lard is absorbed more rapidly than the mercury, but on continued rubbing the mercury is absorbed more rapidly than the base. Thus the proportion of mercury in the unabsorbed ointment rises about 2 per cent. after a short rubbing, but only 0.88 per cent. after prolonged rubbing. The total absorption of the ointment with a lard base reached 22 per cent. in some cases; the average was 15.98 per cent.

Soft Paraffin Base.—The proportion of mercury in the unabsorbed ointment rose about 1.4 per cent., and then remained constant, showing that in the first instance the

† B.P.; nominal 20 per cent.

paraffin is absorbed more rapidly than the mercury, but on continued rubbing they are absorbed at the same rate. It was found that the total absorption of paraffin ointments never rose above 12 to 13 per cent., the average being about 8 per cent. As the percentage of mercury in the unabsorbed ointment does not fall on continued rubbing it appears impossible for a high absorption of mercury to be obtained by using a paraffin base.

Hydrous Wool-fat.—Here the proportion of mercury in the unabsorbed ointment rises about 5 per cent. after two minutes' rubbing, and continues rising up to 8 per cent. after ten minutes' rubbing, showing that the wool-fat is absorbed much more rapidly than the mercury; this may partly be due to the water present. The highest absorption of mercury in the case of hydrous wool-fat was 2.75 after a very large total absorption of 28 per cent. This compares with an absorption of 6 of mercury with a total absorption of 22 per cent. in the case of the lard ointment, and the highest absorption of mercury from a paraffin ointment of 2.55 after a total absorption of 13 per cent. Hydrous wool-fat, therefore, appears to have no advantage over paraffin as a base for mercurial ointment, as the wool-fat is absorbed and the mercury left behind. Lard appears to be the best base, as it is the only one in which, after the preliminary high absorption of the base, the mercury tends to pass in more rapidly than the base. As hydrous wool-fat gives a high total absorption, while lard appears to act better in carrying the mercury through the skin, experimental bases containing a mixture of the two were tried. The percentage of mercury in the unabsorbed ointment continued to rise, showing that these bases were absorbed more rapidly than the mercury, and that the larger total absorption obtained by the addition of hydrous wool-fat has no advantage over the lower total absorption of the lard alone.

MERCURIC OXIDE.

Ointments were made containing yellow mercuric oxide:

- (a) 10 per cent. in soft paraffin.
- (b) 10 per cent. in 10 per cent. soft paraffin and 80 per cent. hydrous wool-fat.
- (c) 10 per cent. in benzoated lard.
- (d) 20 per cent. in benzoated lard.
- (e) 30 per cent. in benzoated lard.
- (f) 40 per cent. in benzoated lard.

With the lard base there is, after a short rubbing, a slight rise in the percentage of mercury in the unabsorbed ointment, but not so marked as in the case of the mercurial ointment, and with longer rubbing this falls to the original percentage and remains constant, showing that the mercury and the base are absorbed at the same rate; the highest amount with the 10 per cent. ointment was 1.25 of mercury. The amount of mercury absorbed increased with the strength of the ointment; the 20 per cent. ointment gave approximately twice as much mercury absorbed as the 10 per cent., and the 30 per cent. three times as much with the same base. The 40 per cent. gave rather more than the 30 per cent., but not in proportion; this appears to be about the limit for maximum absorption.

With the paraffin base the percentage of mercury in the unabsorbed ointment remained fairly constant and almost the same as in the original ointment, so that the mercury and the base are absorbed practically at the same rate. The highest absorption from the 10 per cent. ointment with the paraffin base was 0.89.

With the hydrous wool-fat base, as in the case of mercury ointment, the percentage of mercury in the unabsorbed ointment continues to rise with prolonged rubbing, showing that the base is absorbed more quickly than the mercury, which is left on the surface of the skin. The highest absorption obtained from the 10 per cent. ointment in hydrous wool-fat was 1.18.

A comparison of the results obtained from the 30 per cent. mercuric oxide with those from mercury ointment of equal strength shows that the mercuric oxide is absorbed more rapidly than the metallic mercury in proportion to the total absorption.

MERCURIC OLEATE.

The B.P. preparation nominally contains 20 per cent. of mercuric oxide combined with oleic acid; a sample prepared according to the B.P. directions was found to contain 17.41 per cent. of mercuric oxide, and formed a sticky and adhesive product not easy to rub into the skin. The percentage of mercury in the unabsorbed oleate showed no change, so that the mercury and the base were absorbed at the same rate, probably without any decomposition of the oleate. The total absorption did not rise very high, and as the rubbing of it was not very satisfactory an ointment was prepared which contained 50 per cent. of the mercuric oleate and 50 per cent. of benzoated lard; the percentage of mercury in this was found to be 3.13. After ten minutes' rubbing the percentage of mercury in the unabsorbed ointment was reduced, showing that the oleate was absorbed more rapidly than the lard. On the whole it was found that mercury was absorbed more rapidly from the oleate than from mercuric oxide or metallic mercury ointments of equal strength.

CALOMEL.

The B.P. ointment of 20 per cent. mercurous chloride in benzoated lard was used and compared with 20 per cent. of the mercurous chloride in soft paraffin and 20 per cent. in a mixture of 20 per cent. soft paraffin and 60 per cent. of hydrous wool-fat. In the case of the lard base the proportion of calomel in the unabsorbed ointment rose about 2 per cent. and then remained constant, so that the calomel appeared to be absorbed less readily than any of the mercurials previously considered. The highest figure obtained was 1.2, which is low for a 20 per cent. ointment. With a paraffin base the highest figure obtained was 0.8, and the same figure with the paraffin and hydrous wool-fat base. In the latter case the proportion of calomel in the unabsorbed ointment rose from 20 per cent. in the original ointment to 25.8 per cent., showing the rapid absorption of the hydrous wool-fat, leaving the calomel behind. In

the case of the paraffin base the rise in the percentage of calomel in the unabsorbed ointment was much less (under 1 per cent.) and remained constant.

The results obtained were not in accord with the experiments on rabbits of Schamberg, Kolnor, and Raizios,³ who state that calomel ointments are as well absorbed through the skin in rabbits as the ordinary blue ointment, if not better.

AMMONIATED MERCURY.

The following ointments were prepared and estimated as to content of mercuric ammonium chloride:

- Ammoniated mercury 5% in benzoated lard (B.P. 1914).
- Ammoniated mercury 10% in benzoated lard.
- Ammoniated mercury 5% in soft paraffin.
- Ammoniated mercury 10% in paraffin ointment (B.P. 1893).
- Ammoniated mercury 10% in 40% hydrous wool-fat and 50% soft paraffin (U.S.P. formula).

The amount of absorption with the 10 per cent. ointments was about twice as great as with the 5 per cent. ointments. With the lard and paraffin bases the percentage of mercurial in the unabsorbed ointment showed little change; the base and the mercury were absorbed at practically the same rate—there was no initial rise as in the case of metallic mercury and calomel; ammoniated mercury, therefore, showed a rate of absorption similar to mercuric oxide. With the hydrous wool-fat base the proportion of mercury in the unabsorbed ointment was raised by 1 to 2 per cent., showing that the hydrous wool-fat had been absorbed more quickly than the mercury; this effect was also noted in the fact that the mercury was more easily extracted from the unabsorbed ointment owing to the smaller amount of hydrous wool-fat left in it. The maximum of absorption with the hydrous wool-fat base was 1.

MERCURIC SALICYLATE.

It was thought desirable to compare some organic salt of mercury with the inorganic preparations, and for this purpose the salicylate was chosen, because it is a stable compound, insoluble in water, forms a fine amorphous powder, and is official in the U.S.P.

A 20 per cent. ointment was prepared with benzoated lard, and the results were very similar to those obtained with the yellow oxide and the ammoniated mercury ointments of the same strength. There was a slight rise in the percentage of mercury in the unabsorbed ointment, and the maximum absorbed was 1.5.

MECHANISM OF ABSORPTION.

While we are ignorant as to the exact mode in which absorption through the skin occurs, whether through the epidermis, the sebaceous glands, or the sweat glands, a study of the experiments already carried out does afford some facts which have a bearing upon this problem.

It is evident that the absorption of the medicament depends upon the following factors when the same area of skin is used for the experiments: (a) nature of the base; (b) nature of the medicament; (c) strength of the medicament.

As regards absorption of the base itself the results are entirely in agreement with those previously published by one of us in the papers already referred to—namely, that hydrous wool-fat is absorbed most rapidly, provided the proper amount of water is present, which is rarely the case unless the ointment is freshly made; lard is absorbed almost as well—15 per cent. as compared with 20 per cent.—and soft paraffin considerably less, the time of rubbing being the same in each case. These differences may partly depend upon physical characters. In connexion with this factor the appearance on rubbing is important; on the skin lard becomes liquid and scrapes off still in a liquid condition; soft paraffin only becomes semi-liquid, and scrapes off stiff at about its original consistence; hydrous wool-fat is quite firm when scraped off the skin. The melting point of soft paraffin is not so much higher than that of lard as to account for this difference: possibly a difference in viscosity may be a factor. That the liquid character of the lard is not the only factor in the absorption is shown by the high absorption of the hydrous wool-fat which remains firm on the skin.

The chemical character of the base may be an important factor; lard and wool-fat are both esters and both absorb well, the absorption increasing on continued rubbing, so that probably part at least of the absorption takes place through the sebaceous glands. Possibly the difference between them in the absorption of medicament may be due to the glyceryl esters of the lard, which may assist the secretions of the glands to form oleates or other easily absorbed compounds; the oleate, as shown above, is itself easily absorbed. The cholesteryl esters of the wool-fat may not form similar compounds. It has been generally assumed that the wool-fat would be the better base for absorbent ointments because it approximates more nearly to the natural fats of the skin; though this may be an important factor in the absorption of the wool-fat itself, it evidently does not aid the absorption of the mercurial medicament.

Paraffin composed of hydrocarbons and comparatively inert chemically is not likely to form compounds with the sebaceous secretions; it has not much power of penetrating the skin, and possibly that which is absorbed may be taken up by the epidermal layers; the fact that absorption does not increase with increased rubbing seems to point to this possibility.

One factor undoubtedly influencing the amount of absorption by the skin is the temperature; it was always found that rubbings done in very cold weather gave less absorption than usual. This may be partly due to the increased vascularity of the skin at the higher temperature, and partly to the higher temperature making the ointment softer and more easily rubbed into the skin. That the latter is not the only explanation is shown by the fact that rubbings taken on an exceptionally hot day in July, 1923, gave figures slightly below the average—namely, 10 per cent. for a lard and 5.5 per cent. for a paraffin base. Possibly the moist condition of the skin from perspiration on that day had an adverse influence on absorption.

An attempt was made to compare the amount of absorption through the skin of the palm, which contains no sebaceous glands but many sweat glands, with the amount absorbed through an equal area on the arm. The rubbings were carried out on the palm and the arm on the same day, and the same mercurial ointment with a lard base was used. The total absorption through the palm was 4.3 per cent., and through the arm 7.3 per cent.; the amount of mercury absorbed in the palm was 0.8, and through the arm 1.8; the lessened absorption through the palm may be due either to the greater thickness of the epidermis or to the absence of sebaceous glands, or more probably to both of these factors.

CONCLUSIONS.

1. Under the conditions of these experiments it was found that when rubbed into the skin all mercurials were absorbed to some extent from all the bases tested.
2. That in all cases the greatest absorption took place from the lard basis, and that the amount of absorption with the lard basis increases more with a prolonged rubbing than with other bases.
3. That hydrous wool-fat was absorbed to a greater extent than lard, but that the mercurial was not absorbed with it, so that the absorption of mercury was actually less than from a lard ointment of equal strength.
4. That the absorption from a paraffin base was always less than from a lard base.
5. That the amount of mercurial absorbed was proportional to the amount of mercurial in the ointment, at any rate up to 30 per cent. of the mercurial.
6. Of the different mercurials examined the mercuric oxide was the most readily absorbed, either as an ointment or in the form of the official oleate. This, however, is not suitable for use when the general absorption of mercury is desired, as ointments containing over 10 per cent. of the oxide cause considerable irritation of the skin.
7. Ammoniated mercury and mercury salicylate were absorbed almost as well as the oxide. Calomel was absorbed to a less extent than any of the other mercurials examined.

8. Metallic mercury was absorbed rather less than the oxide, but can be used in stronger concentration without causing undue irritation of the skin. The official mercurial ointment with a lard base seems to be the best preparation for ensuring the general absorption of mercury. The union of 4 grams (about 1 drachm) for two minutes gave, on an average, an absorption into the body not exceeding 0.12 gram (about 1.84 grains) of mercury, and after ten minutes' union an absorption not exceeding 0.17 gram (about 2.61 grains).

THE TREATMENT OF POST-ENCEPHALITIC PARKINSONISM BY NICOTINE.

BY

HENRY MOLL, M.D., M.R.C.P.,

MEDICAL TUTOR AND REGISTRAR, UNIVERSITY OF LEEDS.

THE use of tobacco in various modes, internally as well as externally, for the purpose of relaxing muscular action in diverse forms of disease, was in vogue some sixty years ago.¹ In view of this and our present knowledge of the action of nicotine on the preganglionic cells and that of the sympathetic on muscular tone, I decided to try it in the treatment of a series of cases of post-encephalitic Parkinsonism. Although it did not lead to any permanent cure of the disease, it had an undoubted beneficial effect, which, although only temporary, was sufficiently encouraging to merit further consideration and trial.

Parkinsonism, a very frequent sequel of encephalitis lethargica, is recognizable by the typically expressionless face, the staring look, the monotonous voice, the stiff and shuffling gait, the short steps by which the patient moves, holding the arms motionless by his side. Other common symptoms are sialorrhoea and a rise of the pulse rate.¹ The retraction of the eyelids (which gives rise to the peculiar stare), the sialorrhoea, and the rise of the pulse rate all point to sympathetic stimulation, and it is reasonable to suppose that the increase of muscular tone may be produced in a like manner.

Hunter has remarked how the rigidity exhibited in post-encephalitic Parkinsonism conforms in all its characters with that due to an excess of plastic tone. It is diffuse, the selective incidence of the muscles is absent, and the resistance to passive movements is the same throughout all the range of movement. Moreover, there is a tendency to fixation of the limbs in any posture passively imposed on them, and poverty and slowness of voluntary movement.² In some very interesting experiments on birds he observed that the removal of the corpus striatum gave rise to diffuse muscular rigidity of the wing remarkably similar to the Parkinsonian rigidity in man. He concluded that the corpus striatum in man, with the cortex intact, might possibly control through the intermediation of subpallidal nuclei, as the substantia nigra, the sympathetic prepsinal reflex arc subserving the plastic tone.³

Many observers have described, in cases of encephalitis lethargica of the Parkinsonian type, profound degenerative changes in the cells of the substantia nigra in the mid-brain and calcareous arterial degeneration of the anterior part of the globus pallidus of the lenticular nucleus, sometimes accompanied by thrombosis of the affected vessel.³

Lesions of these higher centres may possibly interfere with the normal control of the prepsinal reflex arc, an increase of plastic tone thus resulting in the same manner as a lesion of the upper motor tracts leads to an increase of contractile tone which is subserved by the somatic reflex arc. Nicotine, inasmuch as it paralyzes the preganglionic

sympathetic cells; may block the sympathetic prespinal arc at (A) and in this way reduce the plastic tone (Fig. 1).

The theory that tonus may be divided into "plastic" and "contractile" elements has received now support from the work of Hunter and Royle. According to this theory there would be two kinds of fibres in the striated muscle

FIG. 1.—The corpus striatum and the substantia nigra, the centres chiefly involved in post-encephalitic Parkinsonism. The arrow marks the site where nicotine blocks the prespinal sympathetic reflex arc. 1, Afferent sensory nerve. 2, Preganglionic sympathetic cell. 3, Efferent sympathetic cell. 4, Sympathetic ganglion. 5, Posterior root ganglion. 6, Ponto-spinal tract. 1-6, Prespinal sympathetic reflex arc.

of vertebrates distinguished by contrasted morphological and physiological properties: large fibres innervated by medullated (or somatic) nerves, and slender fibres innervated by non-medullated (or sympathetic) nerves. The fibres receiving somatic nerve endings are responsible for the contractile tone, whilst the other set of fibres innervated by the sympathetic system exhibit plastic tone. The latter are comparable to the fixing muscles of invertebrates and take part in fixing the length of the muscles exhibiting contractile tone.⁴

The cases of post-encephalitic Parkinsonism which may be expected to benefit from treatment by nicotine are those where voluntary muscular control is intact but movement is hampered by excessive plastic tone. By depressing and subsequently paralysing the sympathetic nerves with the drug, we attempt to eliminate the plastic tone and free the limbs from spasticity.

Nicotine was administered by hypodermic injections, the pure alkaloid being used. Signs of intolerance, such as nausea and vomiting, fainting, and tachypnoea, were carefully watched for, and for this reason the patients were kept in bed throughout the whole course of treatment.

The pulse rate, respiratory rate, and the blood pressure were recorded immediately before and after the nicotine injections. The estimations were carried out at half-minute intervals for three minutes and at minute intervals for a further seven minutes. The commonest type of response was characterized by an initial fall in the pulse rate, followed by a rise, with a return to normal within seven to ten minutes (Fig. 2). This was found in 60 per cent. of cases. In 30 per cent. there was no initial slowing of the pulse. The rise of the pulse rate was in many cases well marked, with an average increase of 20 beats a minute and with a maximum of 40. The rise usually took place one and a half minutes after the injection and reached a maximum height in two to three minutes. The initial slowing of the pulse seldom lasted more than two minutes. The blood pressure in 40 per cent. of cases showed a gradual rise of both the systolic and diastolic pressures, followed by a return to normal within ten minutes, but in 25 per cent. there was no response, and in the remainder it was quite irregular. The respirations in half the cases

showed an initial quickening, followed by a slowing of the rate; in the remainder the response varied, the secondary fall being often absent.

Following nicotine injections other phenomena were noted, such as flushing of the face, profuse sweating, tremors, thirst, nausea, vomiting, and tachypnoea. In two cases a fit occurred a few minutes after the nicotine injections. In one case the fit followed an injection of 1/10 grain, and was characterized by twitchings of the mouth, tonic spasms of the arms and legs, and incontinence of faeces and urine; it lasted a few minutes. In the second case the patient tolerated three doses, each of 1/10 grain, but after the fourth suddenly had a fit, with tetanic spasms of the hands, cyanosis, and profuse sweating, and was unable to speak for two minutes. Vomiting followed the fit.

With the help of the pulse, respirations, and blood pressure charts it was possible to check the action of the nicotine and to measure the degree of tolerance of each patient to the drug. An initial dose of 1/30 grain was given thrice daily at the beginning of the treatment and continued for a few days. If at the end of this period the pulse chart did not show any appreciable change the dose was increased. Such a procedure was adopted every time the dose was increased until the full dose was reached. This varied between 1/10 and 1/5 grain thrice a day, and was always followed by a well marked rise of the pulse rate of at least 12 to 20 beats a minute. The patient was afterwards kept on the full dose for two to three weeks or until symptoms of intolerance set in. In many cases, however, it was found that nausea and vomiting promptly disappeared after the dose had been repeated a few times, and that the treatment could be continued.

A series of 13 cases of post-encephalitic Parkinsonism have been treated in this way with nicotine. Every case presented the typical signs and symptoms of Parkinsonism, which in most cases were of several months' standing.

All the cases had a history of an attack of "flu" or of a pyrexial disease with the typical accompaniments, such as diplopia, headache, and vomiting which revealed that the illness had been an attack of encephalitis lethargica. The attack either marked the beginning of their present state, into which they had gradually crept, or was definitely separated from it by a latent interval of nine to twelve months or even longer. In one case there was a definite history of head injury preceding the onset of Parkinsonism.

Of the 13 cases, 9 showed an improvement after nicotine treatment, whilst 4 were unaffected. Of the latter, one proved later on to be a case of true Parkinson's disease. The improvement in some cases was really striking. The patients volunteered the statement that they were feeling better because "their joints felt looser" or because "their limbs were freer."

A man, aged 30, a 'cello player, in February, 1921, had an attack of encephalitis with diplopia and delirium, followed by drowsiness of three months' duration. For the last four years he had been complaining of neuralgic pains in the legs, of

FIG. 2.—Charts of the pulse rate, blood pressure (systolic and diastolic), and respirations taken immediately before and after an injection of 1/5 grain of nicotine. The pulse chart shows an initial slowing followed by a rise, the rate returning to normal within ten minutes.

periods of sleeplessness, and of impairment of memory. In April, 1925, he developed a tremor and stiffness of the fingers of the left hand, which seriously interfered with his playing. He underwent a fortnight's course of nicotine treatment, the dose being gradually increased from 1/30 grain to 1/10 grain three daily. A further increase to 1/5 grain three daily was tried, but had to be stopped because it caused vomiting. The patient was discharged much improved; although the mask-like expression was still present the movements of the limbs were much freer and the gait steadier. The patient thought that he would be able to play the cello again, and, when seen a month later, stated that he had resumed his work and that he was feeling much better.

A youth, aged 17, had an acute attack of encephalitis lethargica in April, 1924, with diplopia, squint, headache, and delirium, followed by lethargy. He recovered completely and felt quite well until February, 1925, when all the movements commenced to be slow and required a great effort on the patient's part. When I saw him in May, 1925, he was an obvious case of Parkinsonism, with the typical facies, rigidity of the limbs, and marked retraction; he would commence to sway backwards, and in order not to fall would start walking backwards, and continue to do so until arrested by a wall or by falling. He underwent nicotine treatment for three weeks, with increasing doses up to 1/10 grain three daily. At the end of this course of treatment he had greatly improved; the back-stepping gait had disappeared, and he walked briskly, swinging his arms alongside of him. The expression in his face had also returned, and he could smile normally.

The tone of the muscles was repeatedly examined before and after the nicotine injections, and more especially the capacity of the limb (brought by a passive movement into a new posture), when released, to remain in that new posture. Such a property Sherrington has termed "plasticity" of the musculature, and was measured by him by means of the "shortening and lengthening reaction." Thus, if the leg be flexed at the knee, so lengthening the extensor muscles of the thigh, this position is retained ("lengthening reaction"); if the knee be now extended, so shortening the extensor muscles, the new position is again maintained ("shortening reaction").

The "shortening and lengthening reaction" was found in many cases to be definitely diminished after the nicotine injections, and in some it disappeared entirely after the course of treatment.

A man, aged 39, in January, 1924, had a dizzy attack whilst at work, followed by diplopia and drowsiness. He recovered completely from his illness, and was quite well for seven months. Six weeks before his admission to the hospital he gave up his work because of his inability to use his tools or to wheel a barrow. He presented a typical Parkinsonian syndrome, with mask-like face, marked stiffness of the muscles of the neck, and loss of lateral rotation of the head when looking sideways. "Shortening and lengthening reaction" of the upper limbs was well marked, and sialorrhoea was present. He received nicotine treatment for three weeks, the dose ranging between 1/30 and 1/10 grain three daily. At the end of the three weeks the stiffness of the neck muscles had disappeared, and likewise the "shortening and lengthening reaction" of the upper limbs. The sialorrhoea was, however, unaltered.

Nicotine had no effect on either the tremors or the sialorrhoea. The persistency of the tremors in some cases masked the improvement of the patient's stiffness, so that no real relief was obtained, and the patients would complain of not feeling better because the tremors had not improved. In one case the phenomenon known under the name of "kinesia paradoxa" was observed. A girl, aged 15, who had been undergoing treatment for a fortnight, was seen one day to run up the stairs as if her fetters had suddenly fallen off, but shortly afterwards relapsed into her Parkinsonian state. Some cases showed a marked improvement one week, only to fall back worse than ever the next. Any improvement of this kind was ascribed to the sudden variations and to the spontaneous recoveries so commonly seen in this disease, and not to any therapeutic effect of nicotine.

In observing the patient's progress allowances were made for improvements which might have been caused by suggestion; leading questions were therefore purposely avoided, and objective findings, such as a definite diminution of tone, a return of facial expression, or an improvement of the gait, were taken to be of more importance than subjective ones. All the patients were seen again six months later. The cases which had benefited by nicotine treatment had all relapsed into their previous state, and a case which had not responded to it had died. In one case the improvement lasted a month, after which the patient felt as bad as ever. In another the relapse occurred after only a week, and was ascribed to a sudden bereavement in the family.

In concluding, I may say that treatment by nicotine failed to give any permanent cures, although the immediate results were indisputable. The treatment should therefore be repeated at frequent intervals, say, of two to three months. Nicotine had an undoubted action in reducing muscular rigidity, and this was ascribed to the paralytic effect of the drug on the prespinal reflex arc subserving plastic tone, thus throwing new light on the dual nature of muscular tone and adducing fresh evidence that one element of muscular tone is under the control of the sympathetic nervous system.

AN EXPLANATION

OR

THE TWO FORMS OF BILIRUBIN DEMONSTRATED BY THE VAN DEN BERGH REACTION.

BY

G. A. COLEINSON, M.Sc., A.I.C.,

RESEARCH ASSISTANT TO SIR BERKELEY MOYNIHAN, Bt.,

AND

F. S. FOWWEATHER, M.D., M.Sc., F.I.C., D.P.H.,

LECTURER IN CHEMICAL PATHOLOGY, UNIVERSITY OF LEEDS; CHEMICAL PATHOLOGIST, LEEDS GENERAL INFIRMARY.

(From the Department of Pathology and Bacteriology, University of Leeds.)

To Ehrlich is due the discovery of the fact that bilirubin in acid-alcoholic solution couples with diazotized sulphanilic acid to form a dyestuff, azobilirubin. Van den Bergh has applied this reaction to the detection of bilirubin in blood serum, and hence to the clinical study of jaundice. He made the important observation that the bilirubin in the serum of patients suffering from obstructive jaundice reacts at once with the diazotized sulphanilic acid to give a deep red colour, while the bilirubin in serum from patients with haemolytic jaundice gives the reaction slowly or not at all in untreated serum, but gives a fairly prompt response after treatment of the serum with alcohol and removal of the protein which is thereby precipitated. The colour obtained in the latter case is purple. With some serums an intermediate type of result is obtained—namely, the prompt development of a red colour which later becomes purple.

To interpret these results van den Bergh assumed that two forms of bilirubin exist—the one reacting directly with the sulphanilic acid reagent, and present typically in cases of obstructive jaundice, and the other reacting to an appreciable extent only in the presence of alcohol and after precipitation of protein, and present typically in cases of haemolytic jaundice. Intermediate types of result he assumed to be due to the presence of both forms.

On this assumption of two forms of bilirubin largely rests the modern theory of jaundice as described, for example, by McNee.¹ The actual difference between the two forms of bilirubin which is responsible for their different behaviour has not yet been clearly demonstrated. It is considered by some that the presence of protein is responsible for the different behaviour of the two forms, the bilirubin of haemolytic jaundice being thought to be in combination with protein; while in obstructive jaundice it is in combination with an alkali. Others have attributed the different properties of the two forms to physical differences between them. It seems to us to be of considerable importance to ascertain if possible the actual mechanism underlying these different reactions, since such a knowledge must necessarily help in explaining the production of bile pigment in the body and the production of jaundice. It is with this object in view that the work about to be described has been undertaken.

It appears to us that the most important fact bearing on the problem is that bilirubin is an acid, having, according to the formula suggested by H. Fischer, two carboxyl groups. It is therefore capable of forming salts which

will differ in certain properties from the free acid. This fact is already well recognized, and it is well known that bilirubin is frequently present in gall stones, principally in the form of the calcium salt, while it is generally believed that in animal fluids the pigment is present in combination with an alkali, the particular alkali not being specified.

The view we wish to put forward, together with certain experimental evidence in support, is that while the bilirubin giving the prompt direct van den Bergh reaction is an alkali salt, which we believe is probably the ammonium salt, the form which is responsible for the indirect reaction (that is, in presence of alcohol and after precipitation of protein) is the free acid. We propose first to discuss the experimental evidence in support of this view, and then to discuss its implications.

The experimental evidence may be divided into two parts—namely: (1) Comparison of the properties of free bilirubin and its salts. (2) Experiments on body fluids (bile and blood serum) containing bile pigment.

1. Comparison of the Properties of Free Bilirubin and its Salts.

For this purpose a quantity of free bilirubin was isolated from heavily pigmented gall stones.

The first important differences between the free acid and the alkali salts are those of solubility. Free bilirubin is easily soluble in chloroform, somewhat less soluble in alcohol, and insoluble in water; while the alkali salts are insoluble in chloroform and in alcohol, and readily soluble in water. They are moderately soluble, however, in alcohol of the strength used in the indirect van den Bergh reaction in which 2 c.cm. of 95 per cent. alcohol is added to 1 c.cm. of blood serum (that is, approximately 60 per cent. alcohol). The next important differences are in behaviour towards the van den Bergh reagent. In aqueous suspension free bilirubin only shows a colour development after standing in contact with the reagent for about twenty-four hours. The colour is of the purplish hue associated with the indirect reaction. When the free bilirubin is in solution in 60 per cent. alcohol (forming a "true" solution) colour development occurs readily, the colour again being purple. On the other hand, the aqueous solutions of the alkali salts of bilirubin react very promptly with the van den Bergh reagent, giving a deep ruby colour. In the case of aqueous suspensions of free bilirubin it is reasonable to assume that, with decreasing size of particles and increasing uniformity, the very long interval required before colour development occurs will be progressively shortened, the shortest interval occurring when the bilirubin is in colloidal suspension, though this is not likely to approach the rapidity with which the reaction would occur if the bilirubin could be obtained in true solution. As will be shown below, free bilirubin is in a colloidal state when present in blood serum, this accounting for the "delayed direct" and "biphasic" results on certain serums.

From a consideration of these chemical properties it will be seen, therefore, that with free bilirubin and its alkali salts all the results of the van den Bergh reaction can be very closely imitated.

2. Experiments on Body Fluids containing Bile Pigment.

(a) The pigment of fresh bile, and of the serums of obstructive jaundice, passes readily through a parchment membrane when subjected to dialysis, whereas the pigment of the serums of haemolytic jaundice does not pass through such a membrane unless alcohol is added. These differences in diffusibility have already been noted by Hoover and Blankenhorn² with respect to collodion membranes, and confirmed by others. Brulé, Garban, and Weissman³ correlated these differences with the promptness of the diazo-reaction. These results show that the pigment of bile and obstructive serums is in true solution, and we have found the same to be true of the alkali salts of bilirubin, while the pigment of haemolytic serums is in colloidal suspension.

(b) Both bile and obstructive serums, which normally give the prompt direct reaction, can be made to give the indirect reaction only, if acidified with hydrochloric acid

(which liberates the free bilirubin from its salts) before adding the van den Bergh reagent. The addition of hydrochloric acid to bile and obstructive serums also renders the pigment, originally insoluble in chloroform, soluble and extractable in that medium, thus having the properties of the free acid, while the reverse is brought about by the addition of ammonia to haemolytic serums.

The evidence in favour of the salt being that of ammonium and not one of the metals rests upon the following facts:

1. By using a technique similar to that of Nash and Benedict⁴ for the determination of ammonia in blood, the presence of ammonia can be demonstrated in bile, and in greater quantity than is found in blood.

2. The sodium and potassium salts of bilirubin being combinations of strong bases with a weak acid are dissociated in water to a very considerable degree, and the solutions have a markedly alkaline reaction. In attempting to convert an indirect van den Bergh reaction to a direct reaction by the addition of a caustic alkali unsatisfactory results are obtained unless the alkalinity is of a degree which cannot be conceived of as ever being present in the body fluids concerned.

3. If bile or an obstructive serum is heated, it fails to give the direct reaction, the pigment having been rendered insoluble in water, and soluble in chloroform, by the heating process. The same is found to be true of solutions of the ammonium salt of bilirubin, heating evidently resulting in the decomposition of the ammonium salt by loss of ammonia and consequent production of the insoluble bilirubin. This change does not occur when the metallic salts of bilirubin are similarly treated.

It will be seen, therefore, that all the experiments attempted completely confirm the view we have put forward as to the chemical nature of the two forms of bilirubin. Further support of this view, in so far as it postulates a form of bilirubin in bile which must be in true solution, is to be found in the work of Graham on cholecystography. He showed that any dyestuff which is eliminated in the bile with any degree of rapidity must be a crystalloid. Rowntree in his work on liver function tests depending on excretion of dyes into the gall bladder reaches the same conclusion. It would appear from these findings that the liver cells are only capable of allowing to pass into the bile, with any appreciable facility, such bodies as are in true solution in the blood stream.

There remains to be considered the relation of the view put forward to the modern theory of jaundice. According to the view now very generally held bilirubin of the "haemolytic" form is produced by the cells of the reticulo-endothelial system, in the liver and elsewhere. In its passage through the liver cells to the bile capillaries it becomes converted to the "obstructive" form in which it is found in the bile. Applying our views to this theory it follows that the bilirubin produced by the cells of the reticulo-endothelial system is in the form of free bilirubin, and the site of formation of the ammonium salt is in the liver cells.

The probability of this site of formation of the ammonium salt is supported by various considerations. In the first place a condition of alkalinity is required. That such a condition may be found in the liver cells is suggested by work on other subjects; thus Wells,⁵ discussing certain aspects of sugar metabolism, says: "It might be assumed that all sugars upon entering certain phases of the cells (phases especially well represented in liver cells) meet conditions which are equivalent to those met in weakly alkaline solutions. . . . That is, especially in the liver there may be the equivalent of dilute alkali for all sugars."

Apart from these speculations, many observers are agreed that the pigment of bile, of whose origin in the liver there is no doubt, is in the form of "bilirubin-alkali."

In the second place there must be a source of ammonia. This is probably to be found as a result of the functions of deamination of amino-acids and formation of urea carried on by the liver cells. Though the actual mechanism of the production of urea from amino-acids is still a matter of speculation it is probable that ammonia is the immediate, if short-lived, precursor of urea. The presence of

bilirubin at the site of production of ammonia, though the latter may exist as such for only a very short time, is sufficient to explain the formation of the bilirubin ammonium salt. The liver cells are, in fact, the most probable site of formation of the ammonium salt.

Our views, therefore, as to the chemical nature of the two forms of bilirubin do not in any way conflict with the modern theory of jaundice, but on the other hand appear to lend it some support.

DOUBLE VAGINA AND SINGLE UTERUS.

BY

R. C. BARTLETT, M.R.C.S., L.R.C.P.,

ROMSEY, HANTS.

In the JOURNAL of March 13th (p. 476) Dr. Macgown of Kong-Kong reports a remarkable and interesting case of double uterus with double vagina, in which, occasion for Caesarean section having arisen, he was given the opportunity of verifying his previous clinical observations as to the degree of duplication of the uterus.

In the rare lapses on the part of Nature from her usual wonderful precision the departure from normal in failure to effect fusion of the Müllerian ducts increases as the failure extends from the level of the Fallopian tubes downwards. Thus uterine didelphys (or uterus septus) with double vagina, as met with by Dr. Macgown, is an exceedingly rare condition. A reversal in the order of fusion by which double vagina is associated with complete coalescence in the body of the uterus and the uterine cavity is probably the rarest of all such abnormalities. In the limited field of research at my immediate disposal I find no such case recorded, but that a few cases similar to the one I now wish to describe can be cited I do not doubt.

A woman, aged 29, married seven years, nulliparous and desirous of children, consulted me solely in respect of the infertility of her marriage. She was of good physique and health, menstruation had been regular, and she was aware of no sexual incapacity or anatomical defect.

On digital examination the ostium vaginae and the vagina itself appeared normal, and the cervix uteri was fully developed and centrally situated, but, as it seemed, a thin membrane covered the whole of the vaginal cervix, intervening between it and the examining finger. On preparing to insert a vaginal speculum I noticed (almost by chance, I think) to the left of the ostium vaginae, and tucked away against the left labium, what at first sight looked like a second meatus urinarius. The meatus urinarius proper was in its natural position anteriorly. On drawing the labium further aside there was displayed an intact left hymen having a natural opening no larger than would easily admit a No. 10 catheter. The next day, under a general anaesthetic, I broke down this left hymen and discovered a completely separate left vagina with a normal cervix and cervical canal beyond it. This was, of course, the cervix I had previously felt through the septum from the right vagina. Right up in the fornix of the right vagina was a rudimentary bud-like right vaginal cervix no larger than a hazel-nut. It had an umbilicated central depression but no patent cervical canal, and it appeared to spring from the side of the left (main) cervix at the level of the internal os. The body of the uterus, as far as I could determine its outline bimanually, was neither bicornuate nor unicornate. The vaginal septum was thick and fleshy below, thin and membranous above, and it extended the whole length of the vagina right up to the angle formed by the rudimentary right cervix. Either vagina admitted a 1½-inch Ferguson's speculum easily, the septum being deflected to the opposite side. The two blades of a bivalve speculum, being passed, one into each vagina, displayed the septum and its attachments perfectly.

Evidently the menstrual flow had always been through the left vagina, and probably the vaginal condition of the right hymen had been similar to that of the left. Had the left hymen given way instead of the right on the patient's marriage, I could see no reason to doubt that impregnation would have occurred, or to suppose that the vaginal septum would have opposed any resistance in parturition, and so have been destroyed. I think it even possible that the very existence of the right vagina might then have been unnoticed in the ordinary course of obstetric attendance. However that may have been, in deference to the patient's paramount desire to have children, and to give her the greater chance of its fulfilment, I decided to throw the two vaginae into one by division or excision of the septum. Accordingly the septum was divided by scissors from below upwards, and the cut edges of the lower thick parts were sewn over by a few loops of

continuous suture. The flaps retracted and shrivelled, and when I next saw the patient, eight months later, little more than an anterior and a posterior raphe remained. She was then already five months pregnant. Gestation was perfectly normal throughout and went to its full term, and in due course I delivered her of a well developed male child after a rather easy labour. She subsequently, as I was informed, bore another (female) child—again without difficulty.

Apart from the fact that neither before nor during pregnancy could I detect a separate right uterine body, or any vestige thereof (although therein I may have been mistaken), my reasons for believing that only the vagina was double are: (1) that there was no history of haematometra or other pelvic crisis arising from puberty, and (2) that the vaginal septum, while thick and fleshy below, thinned almost to the vanishing point at the fornix. Against such view may be urged the existence of a rudimentary right cervix. But this appeared to be integumentary rather than substantial in structure, and, that being so, would it not morphologically belong to the vagina rather than to the uterus?

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TUBERCULIN LINIMENT.

THE value of tuberculin in the treatment of tuberculosis is enhanced if one realizes the conditions under which the best results are likely to be obtained. Some two years ago, as the result of an analysis of 96 cases treated with tuberculin, I formed a working theory as to the class of case in which it was likely to prove beneficial. The details were published in the JOURNAL.¹ I have had no reason to alter the conclusions to which I then came, which were:

1. That fibrosis is an important factor in tuberculin therapy, and that, other things being equal, the less fibrosis there be the more satisfactory will be the results with tuberculin.
2. That hypersensitiveness is no contraindication to tuberculin therapy.
3. That in subsensitive cases much improvement cannot be expected except in asthma.

By far the best results, in my experience, are obtained in hypersensitive cases and in asthma. The difficulty is that if hypersensitive subjects be treated with hypodermic injections of tuberculin the general reactions may be unduly severe, and in the asthmatics an attack of asthma may be precipitated. For these reasons one is apt to be deterred from giving tuberculin in the very cases in which it is such a powerful agent for good. Fortunately, there are other ways of exhibiting tuberculin besides the hypodermic method.

Sir Robert Philip has advocated² the administration of tuberculin as an ointment. I use this method frequently with satisfactory results. It has, however, the disadvantage that the dosage cannot be accurately regulated. Dr. James Crockett³ speaks favourably of tuberculin liniment. I have given this method an extensive trial and have found it valuable. A description of the procedure adopted may therefore be of interest.

The patient is first tested as to sensitiveness to tuberculin by the von Pirquet method modified by Ellis. This consists in performing a cutaneous test with dilutions of "old tuberculin." Those cases which react to 1 in 500 dilution are classified as hypersensitive, those to 1 in 100 as sensitive, and those to 1 in 10 as subsensitive. A skiagram of the lungs is taken and the extent of fibrosis, if present, is noted. The test is essential and the x-ray report most desirable, for, as indicated above, a knowledge of the degree of sensitiveness to tuberculin and the amount of fibrosis is the keynote to successful tuberculin therapy and to prognosis.

The patients take their own temperatures four times a day and their weight is recorded weekly. They attend hospital once or twice a week for treatment, which is conducted as follows: 0.01 c.c.m. of T.A.F. ("tuberculin albumosae frei") is diluted with a suitable quantity (say 0.5 c.c.m.) of compound camphor liniment. The patient rubs into the back of his upper arm. If there be no local reaction to this the dose is doubled at the next sitting, and doubling is continued at each subsequent sitting till

¹ BRITISH MEDICAL JOURNAL, June 14th, 1924.

² *Ibid.*, March 24th, 1923.

³ *Edinburgh Medical Journal*, March, 1924.

a local reaction is obtained or till 0.1 c.cm. of tuberculin is reached. After this the dose is increased with more caution. The treatment is continued till 1 c.cm. of tuberculin is reached.

I have under consideration 36 cases treated on these lines. All were afebrile, and in no case were tubercle bacilli found in the sputum.

Result of Treatment.

| 10 were sensitives (reacted to 1 in 100) ... | All improved. |
| 4 were subsensitives (reacted to 1 in 10) ... | None much improved. |
| 16 were cases of asthma ... | All much improved. |

It is interesting to note that all the cases of asthma reacted to either 1 in 10 or 1 in 100, not one to 1 in 500 tuberculin. I have never yet found a tuberculous asthmatic who was hypersensitive to tuberculin.

I use the word "improved" advisedly. By it I mean the symptoms cleared up and there was a gain in weight. The more I see of tuberculosis the less I like to use optimistic expressions, such as "cured" or "disease arrested."

I do not consider that this form of treatment will displace other methods of tuberculin therapy. Some cases seem to do better on injections, but the absence of general reactions and the simplicity of the technique are much in its favour.

F. E. GUNTER, D.S.O., M.D.,
Lieut.-Colonel, R.A.M.C. (ret.).

London, E.C.2.

ANAPHYLAXIS FOLLOWING ADMINISTRATION OF SERUM.

I was much interested by the note in the *Epitome* of the *JOURNAL* of June 5th (para. 559) of a paper by C. A. Stewart in the *Journal of the American Medical Association* on anaphylaxis following serum injection in children who had previously received diphtheria toxin-antitoxin. I have recently had such a case myself, and although, as I believe, they are practically never really dangerous, these reactions are sufficiently alarming to make it desirable, in general practice at any rate, to take every precaution against their occurrence.

A boy, aged 8, was inoculated in December, 1925, with combined scarlet fever and diphtheria prophylactic, and at that time had not any reaction of exceptional degree. At the beginning of May last he had fairly severe tonsillitis, accompanied by carditis, as evidenced by dilatation and a definitely harsh mitral systolic murmur. An almost pure culture of haemolytic streptococci was grown from a throat swab, and early tonsilectomy was decided on. With the idea of diminishing the toxæmia, 10 c.cm. of scarlatinal antitoxin was given by intramuscular injection. In about an hour a pretty severe "immediate reaction" had begun—generalized urticaria with intense itching, oedema of the lips and tongue, rising pulse rate and temperature, and slight dyspnoea. The symptoms gradually subsided in about thirty-six hours, and all seemed well. On the fourth day, however, they recurred, and were if anything more severe than before. Adrenaline and pituitrin were given by intramuscular injection and apparently hastened the subsidence of the symptoms. On the eighth day there was a third and final attack similar to the other two. The subsequent progress was good, and the boy has apparently made a complete recovery.

Two interesting points seem to me to arise. First, was the attack one of acute rheumatism, and, if so, had the antistreptococcal treatment, prophylactic and therapeutic, anything to do with the rapid recovery? Or, secondly, was it, as it were, an abortive scarlet fever, in which, owing to prophylactic injection of scarlatinal toxin, there was sufficient antitoxin in the blood to prevent the appearance of the toxic erythematous rash? These, however, are speculative considerations; the practical points are those made by Stewart—namely, that serum reactions are at least not unlikely to occur in children who have had toxin-antitoxin inoculation, and that it is most desirable that some non-serum or even non-protein (if possible) method of antidiphtherial inoculation, such as Larson's, should be made available.

The sister of my patient, aged 5—also previously inoculated—who was, I am afraid, imperfectly isolated, subsequently developed a similar tonsillitis. Serum was not employed in her case.

Abdeen.

Reports of Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF LARYNGOLOGY.

The summer meeting of this Section was held on June 3rd and 4th, with the President, Dr. W. H. Kelson, in the chair.

Nasal Sinusitis as a Cause of Toxæmia.

Sir WILLIAM WILCOX opened a discussion on nasal sinusitis as a cause of toxæmia. He said that there was strong evidence that the lead given by British medicine in the realization of the great etiological importance of focal sepsis was being appreciated and followed in other countries. A point of the greatest importance was that just as dental sepsis was often latent and could only be demonstrated by radiological methods, so in nasal sinusitis the existence of the focus of infection was quite latent in a large number of cases and gave rise to no local symptoms. It was easy to overlook nasal sinusitis in a case of chronic disease such as arthritis or diabetes unless special search was made. Where no focus of infection was found, as a rule the explanation was that the investigation had not been sufficiently complete. In a considerable number of cases under his care where the disease had been obviously due to a chronic toxæmia a latent nasal sinus infection had been discovered. He was most strongly of opinion that in every case of this kind a systematic expert examination of the nasal sinuses was essential. It had to be remembered that often a nasal sinusitis was coexistent with another focus of infection, and the presence of dental sepsis, for example, should not preclude a systematic examination of the nasal sinuses. It was also necessary to remember that a clear serous effusion or an oedematous mucous membrane would exhibit some opacity to x rays but little to the light rays; in a number of cases of latent sinusitis under his care there had been a discrepancy between the radiographic opinion and expert opinion based on transillumination. The diagnosis of the presence of pus in an antrum could not be made with absolute certainty by radiographic examination alone, and rhinoscopic examination accompanied by puncture of the suspected sinus appeared to be the only certain method of diagnosis. Examination of the washings with a sterile saline solution would reveal the presence of pus or bacterial infection. Transillumination was a method of investigation which, with a little practice, could be performed by every practitioner, and in cases of toxæmia of obscure origin it was desirable that it should be carried out as a routine procedure. Sir William Wilcox gave the details of a number of cases arising from nasal sinusitis, including cases of acute and chronic toxæmia, pernicious anaemia, adenitis resembling lymphadenoma, arthritis, diabetes, and toxic neuritis.

The paper was discussed by Sir STCLAIR THOMSON, Mr. HERBERT TILLEY, Dr. P. WATSON-WILLIAMS, Dr. W. S. SYME, and Sir JAMES DUNDAS-GRANT, all of whom agreed that the only certain method of diagnosing antral disease was to puncture the antrum.

The Path of Infection in a Case of Leptomenigitis.

Dr. A. LOGAN TURNER read a joint paper by himself and Dr. F. E. REYNOLDS, illustrated by a series of excellent photomicrographs, on the path of infection in a fatal case of leptomenigitis following operation on the ethmoidal air cells. There was no break of the cribriform plate; and it was clearly demonstrated that the infection had spread up to the meninges along the perineural lymphatic spaces of branches of the olfactory nerve.

The Lymphatics in Laryngeal Disease.

Dr. JOHNSON HORNE gave an epidiascopic demonstration of the role of the lymphatics in laryngeal disease and the role of the larynx in lymphatic disease. He said that the factor determining the involvement of the adjacent lymphatic glands was whether the disease in the larynx was primary or secondary. If primary the glands became involved, if secondary the glands were not affected. In carcinoma of the larynx a gland sooner or later became palpable. That

"sooner" or "later" was governed by the disease being extrinsic or intrinsic, and if intrinsic by the disease originating in the part covered with columnar epithelium or in the part covered with squamous epithelium; whereas in syphilis and tuberculosis—taken as types of secondary disease—no matter how destructive the disease in the larynx the glands were not involved. Tuberculosis of the larynx was always secondary to chronic phthisis. In tuberculosis of the larynx secondary infection of the adjacent cervical glands never occurred. That "always" and that "never" sounded dogmatic, but it was justified by his pathological and clinical researches. A case in which the cervical glands became infected by the larynx some years after the disease in the lung had been cured was an exception which proved the rule he had laid down. It was noteworthy that a very small percentage of the subjects of tuberculous necks suffered from chronic phthisis. Therefore such subjects escaped laryngeal tuberculosis. Passing to the role of the larynx in lymphatic disease, Dr. Jobson Horne demonstrated a fold in the larynx passing downwards and forwards between the cartilages of Santorini and Wrisberg, to end at the posterior vocal process. That he described as the vulnerable spot in systemic infection through the larynx. Larynges were shown with ulceration or breach of surface or old scarring at that spot, removed post mortem from cases of Hodgkin's disease. The results of investigations led to the conclusion that in not a few cases Hodgkin's disease was tuberculosis, and that some cases of "sarcoma" should be placed amongst the granulomata.

Cases and Specimens.

A number of interesting cases and specimens were exhibited by Mr. H. BELL TAWSE, Mr. J. A. GINN, Dr. D. R. PATTERSON, Mr. HAROLD BARWELL, Mr. LAWSON WHALE, and Dr. DOUGLAS GUTHRIE. Mr. ALEX. TWEEDIE showed a combined tongue depressor and post-nasal mirror.

THE DISEASES OF MERCHANT SEAMEN IN 1924.

At a meeting of the Epidemiological Section of the Royal Society of Medicine, held on May 28th, Dr. E. W. GOONALL in the chair, Fleet Surgeon W. E. HORNE read a paper on the diseases of merchant seamen in 1924.

Fleet Surgeon HORNE said that the number of merchant seamen in 1924 had been stated to be 234,101, more men than were in the army, but of their health conditions there was no annual report. Probably 90 per cent. were employed continuously throughout the year—namely, 150,000 British seamen, 11,000 foreigners, and 50,000 lascars. Deaths occurring on board, or while the men were enrolled as belonging to ships, were stated in the annual return of the Board of Trade, but not any deaths during leave after the ships were paid off, or when the men were unemployed. In 1924, in the case of British seamen, there were 433 (2.89 per 1,000) deaths from accidents, 26 deaths due to alcohol, and 361 (1.88 per 1,000) from disease. Deaths from pneumonia in British seamen numbered 46, in lascars 49, though the total number of lascars employed was only one-third of the British, and the deaths from pulmonary tuberculosis numbered respectively 21 and 43. In twenty years all the death rates had improved, except those of lascars from pneumonia and tuberculosis. The lascar accommodation retained the same small statutory cubic space, 72 cubic feet, while the British seaman, for whom the cubic space had been increased by two-thirds, had had his pneumonia death rate reduced by 20 per cent., and the tuberculosis rate by 30 per cent. The Board of Trade received reports of the deaths of seamen, and published the annual statement of them, but without medical comment. By law, a ship must be provided with "proper accommodation" for the crew, and it was for the Board of Trade, as the competent authority, to determine what accommodation was "proper." It could not do this without the assistance of expert advice. Much port sanitary authorities and their experienced medical officers of health, but progress was deplorably slow. Dr. W. Collingridge, late medical officer to the Port of London,

had made certain recommendations in 1894, all of them admittedly reasonable, but even now, thirty years later, some of these recommendations had not been adopted. The Royal Sanitary Institute had asked that the care of seamen should be transferred to the Ministry of Health, and Fleet Surgeon HORNE hoped that this change would be effected in the near future.

Dr. ARNOLD CHAPLIN said that he refrained from expressing an opinion on the statistics presented, but suggested that "crew days" gave a better foundation for calculation of death rates than mere numbers; this was the method he had used. It was unprofitable to compare the death rates of Europeans and lascars in ships, because lascars had so high a tuberculosis mortality in their own homes. They had far less at sea, and he felt confident that to increase the cubic space would not materially reduce their death rate from this disease. It was easy to enforce inoculation in a disciplined service; impossible in the merchant marine.

Dr. W. M. WILLOUGHBY said that increased space for crews would not abolish phthisis. Instead of blaming the Board of Trade for so slowly adopting Dr. Collingridge's suggested reforms, Fleet Surgeon HORNE should have praised it for having brought them into being.

Dr. P. N. RANDALL, as a former sea-going physician, thought that Fleet Surgeon HORNE had steered his way with skill through the tangle of the statistics as they were presented.

Sir W. J. SIMPSON said it must be clear to all that the charge of the statistics about the deaths of seamen and the care of their health should be in the hands of the Ministry of Health.

Dr. T. CARNWATH said it was difficult to form any opinion on the significance of the death rates presented when the ages of the population concerned were not considered.

The CHAIRMAN observed that even in a fever hospital, where the risks were clearly calculable and could be demonstrated, it was difficult to get all the advisable protective inoculations performed. He thought the frequent newspaper stories of wireless consultations at sea on sailors sick in ships with no doctor must have impressed everyone with the large number of sailors there were in hardship, without doctors travelling in their ships.

Fleet Surgeon HORNE, in reply, said that the ordinary cubic space for lascars was 72 cubic feet, and their tuberculosis death rate 1.2, but he had once visited a P. and O. liner with Dr. Arnold Chaplin, who had stated the death rate of lascars in the employment of that company was 0.47, one-third of the ordinary rate. The lascars in that ship had 140 cubic feet each. They also had skilled care, but no one could doubt that the extra cubic space had something to do with the lowering of the death rate by 60 per cent. He knew that all the causes of death were not medically certified, but hoped that the errors from year to year were similar, since otherwise the statistics would be valueless. He had in a recent paper discussed the death rates of merchant seamen in relation to their ages, in an endeavour to obtain a standard death rate for seamen, and the point had not been overlooked in the preparation of his present paper. There was no scheme for teaching hygiene to merchant seamen, but officers now had to pass an examination in first aid. He was saddened by the want of supervision over seamen's health.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

A MEETING of the Medico-Chirurgical Society of Edinburgh was held in the Hall of the British Medical Association, 6, Drumshough Gardens, on June 2nd, Mr. ALEXANDER MILES, F.R.C.S., in the chair.

Two specimens of the intramural diverticula from the small intestine were shown by Mr. J. W. STRUTHERS. Dr. W. T. RITCHIE then read a communication on paroxysmal tachycardia, illustrated by tracings, based on a study of fourteen of his patients and on cases recorded in recent literature on the subject. Of the fourteen cases one was auricular, one nodal, eight ventricular, and four of undetermined origin. The longest paroxysm occurred in a case of ventricular origin in a man, aged 29, who had

been subject to paroxysms for fourteen years. A final paroxysm at a rate of 237 to 240 was terminated by death on the ninth day. The longest paroxysm on record, said Dr. Ritchie, was one of fifteen months' duration in a man aged 22. Paroxysms usually ended spontaneously. No method was known whereby paroxysms of nodal or ventricular origin could be arrested. Attempts to arrest auricular paroxysmal tachycardia met with more success, and such methods as deep breathing, holding the breath, drinking cold water, straining with closed glottis, or firm compression of the abdomen succeeded in some cases. All these measures, if successful, probably acted, like ocular compression, by reflex vagal stimulation. Direct compression of the right or left vagus in the neck was undoubtedly the most effective means of arresting auricular paroxysmal tachycardia. In diagnosis paroxysmal auricular fibrillation could readily be excluded. It was not so easy to exclude auricular flutter. If vagal compression caused transient slowing of the ventricles, and if this effect passed off rapidly after the vagal compression had been relaxed, the case was one of auricular flutter. If vagal compression caused the ventricular rate to fall suddenly to normal—for example, from 160-180 to 80—and the latter rate was maintained after withdrawal of pressure from the vagus, the attack was undoubtedly one of auricular paroxysmal tachycardia. Electro-cardiographic examination was, however, the most reliable means of establishing the diagnosis. The prognosis depended on the degree of integrity of the cardiac muscle and valves, rather than on the rate and duration of the tachycardia. The risk attending the administration of digitalis and strophanthus appeared to be greatest in paroxysmal tachycardia of ventricular origin. Quinine and quinidine were probably of little therapeutic value in arresting paroxysms.

In the discussion which followed Dr. LAMBIE said that he had tried pilocarpine, both hypodermically and orally, with success in the treatment of paroxysmal tachycardia of auricular origin. Dr. RAE GILCHRIST emphasized the danger of the use of the digitalis group, especially in the cases of ventricular origin.

Professor D. P. D. WILKIE read a communication entitled "Observations on the pathology of the biliary passages and their clinical bearing." He pointed out that it had come to be recognized that disease of the biliary passages might occur independently of any bacterial infection, and that even for calculus formation sepsis was not essential; also that infection might occur and even persist without leading inevitably to calculus formation. The work of Aschoff, Berg, Schmieden, and Westphal was referred to as shedding light from different angles on the primary stages of gall-bladder disease. Professor Wilkie showed lantern slides to demonstrate the minutest anatomy and physiology of the biliary system and the results produced by various experiments on animals. He then described two varieties of metabolic gall stones—the single radiate cholesterol stone and the rarer and usually multiple pure pigment stone. He said that the cholesterol in normal bile was held in colloid solution which was dependent on the presence of bile acids—not only the amount of bile acids but the relative proportion of each. Any excess of cholesterol or deficiency in quantity or quality of its solvent in the bile might lead to crystallization out of the cholesterol, and this would tend to occur where concentration of the bile occurred—in the gall bladder. In pregnancy, rapid loss of fat, and arterio-sclerosis there was an excess of cholesterol in the blood and sometimes in the bile, and in such cases cholesterol stone formation might occur. Such a stone might remain silent, but might become impacted, with afebrile attacks of colic separated by long intervals of perfect health. Certain organisms, such as typhoid and colon bacilli and certain strains of streptococci, found the gall bladder a habitat well suited to their needs. The streptococci usually produced an intramural infection, while the bile itself might be sterile or give a growth of the colon bacillus. Thus the infection might reach the gall bladder by the blood stream, as experimental evidence suggested in cases of primary cholecystitis. The portal of entry would appear to be frequently through the teeth or appendix. Disinfection by massive doses of urotropine might be possible

in some cases, but where there was an intramural infection removal of the gall bladder would appear to be essential. On the other hand, an aseptic stone might be the forerunner and exciting cause of gall-bladder infection. The stone might block the duct, and infection by way of the ducts or by the blood stream occur. A mucocele might result, or the stone might roll back and form a mixture of mucus, pus cells, bacteria, and epithelial debris which agglutinated into little masses on which cholesterol and bilirubin calcium were deposited. Primary cholecystitis was very apt to lead to calculus formation, little masses of organic matter forming the nuclei for concretions of cholesterol, pigment, and calcium. Professor Wilkie said that operations were sometimes undertaken for symptoms which had led to a diagnosis of gall stone, though neither stone nor sign of inflammation in the biliary passages was found. Experimentally it was shown that mild stimulation of the vagus caused the gall bladder to contract and the sphincter of Oddi to relax. Stronger stimulation caused spasm of both the neck of the gall bladder and the sphincter of Oddi. Stimulation of the sympathetic caused relaxation of the gall bladder. Thus a hyperkinetic stasis of the gall bladder might occur. This was found in the early stages of pregnancy, and it was found, further, that increased blood cholesterol induced it. The bile stasis of pregnancy was therefore dependent less on any gross mechanical pressure from the growing uterus than on disordered activity in the intrinsic biliary musculature. A tinge of jaundice and attacks of pain simulating biliary colic might occur when there was no stone present. Hypokinetic biliary stasis often occurred in the asthenic visceroprotic individual. The generous and intricate nerve supply accounted for various reflex phenomena in gall-bladder disease. Through the sympathetic a connexion was established with the seventh, eighth, and ninth thoracic segments of the cord, explaining the girdle pain and sense of constriction. Through the hepatic and phrenic plexuses a link was formed with the phrenic nerve, leading to arrest of diaphragmatic movement in an attack of biliary colic or acute cholecystitis and signs of congestion and oedema at the base of the right lung. The vagus and sympathetic connexions explained the gastric flatulence and distension. The slow insidious poisoning of heart muscle, of joints, and fascial planes which followed neglected cases made the gall bladder suspect when focal infection was in question. When a stone or stones had formed and were giving rise to recurring or persistent symptoms, the only satisfactory treatment was surgical. With a single cholesterol stone without secondary infection, an ideal cholecystotomy; followed by a regime designed to prevent cholesterinaemia and biliary stasis, would seem the logical treatment. Where multiple stones were found within a thin-walled functioning gall bladder, the removal of the stones with temporary drainage might be justified if the surgeon was satisfied that all stones had been removed. Where the walls of the gall bladder were thickened nothing short of cholecystectomy would give successful results. The recognition of the "stasis gall bladder" as a pathological entity must lead them to consider the removal of this organ in cases of biliary colic where at operation no stones or signs of inflammation were present.

A short discussion followed, and Professor WILKIE replied to questions.

CARCINOMA CERVICIS FOLLOWING POSTERIOR DIVISION.

A MEETING of the Section of Obstetrics of the Royal Academy of Medicine in Ireland was held in the Royal College of Physicians on May 28th, when Sir WILLIAM SMYLY, in the absence of the President, took the chair.

Dr. BETHEL SOLOMONS showed a specimen of carcinoma of the cervix following posterior division, and a uterus he had removed by Wertheim's method from a woman, aged 46, married twenty-six years, sterile. For the past year, and a half the menstruation was irregular, but her general health was good. Posterior division of the cervix had been done some years previously. Dr. Solomon said he had condemned this operation in any form for many years,

but it was still largely practised. Pregnancy might result after it, but the same would occur with a properly done dilatation. In scores of cases of uncured sterility the result was a wound pouring leucorrhoea, usually accompanied by erosion; many of these patients were suffering also from backward displacement, fibroids, and especially salpingitis. The case he now showed was rare, and he brought it forward as another example of the possible ill results of the operation, for it was a well established fact that injury to the cervix was the predisposing factor in carcinoma. Dr. Lait's report was:

"The posterior lip is involved in the main mass of the tumour, which is a spheroidal cell carcinoma originating from the squamous epithelium. It shows an ulcerated surface with many vessels. Cell nests, or masses of epithelium with central keratinous degeneration, are present. The tumour deeply invades the cervical tissue, and extends into the posterior vaginal wall. One part shows a calcified patch, presumably around a buried suture in the previous operation of posterior division. The section of the anterior lip shows that it is also involved in the region of the external os, but there is not the same infiltration of tissue which is present in the previous section. The right ovary is the size of a walnut, and contains inspissated pus. The tube shows chronic salpingitis. There is no evidence of tuberculosis."

The CHAIRMAN said that this was the first case he had ever seen of carcinoma of the cervix following posterior division. He came across many cases of carcinoma of the cervix where no divisions at all had been done. He thought that in Dr. Solomons's case, however, carcinoma was very probably the result of the division of the cervix, because it was well known that tearing of the cervix and granular erosion at childbirth predisposed to carcinoma. He thought there were cases in which posterior division of the cervix was a very good operation, however, and he would always do posterior division in cases where the conical cervix was turned forwards, as when the cervix was twisted forward it was a less favourable position for impregnation than the normal position. Of all forms of treatment for sterility posterior division of the cervix was, in his experience, the most successful. Sterility, he thought, was more often the result of blocking of the cervix than of blocking of the tubes. He thought Dudley's operation a very bad one.

Dr. G. FITZGIBBON said that he formerly had done posterior division of the cervix in cases of sterility, but he had now given it up, as he thought it unnecessary if sufficient dilatation was carried out to cause a certain amount of splitting of the internal os. The cancer in Dr. Solomons's patient had extended a good deal through the cervix, but the patient had arrived at the very definite cancerous period of her life, and he thought that if posterior division of the cervix had caused cancer in this case it would have occurred earlier in her life. He had had some extremely good results following posterior division; but he had had equally good results following full dilatation of the tubes.

Dr. D. J. CANNON asked what the pre-cancerous condition of the patient in this case was, and if Dr. Solomons had ever met cases in which it had been impossible to dilate the cervix. He had seen a few such cases, and in them the only possible thing which could be done was a posterior division of the cervix.

Dr. J. S. QUIX asked if Dr. Solomons had seen many cases of carcinoma of the cervix in nulliparae. He himself had never seen one, but he knew that such cases did occur. Posterior division of the cervix was an extremely difficult operation to do properly, and he did not see what the advantage of it was over full dilatation of the tubes.

Dr. Solomons, in reply, reiterated the point that he did not draw any conclusion from this isolated case. There were rare occasions on which it was impossible to pass a sound; then the cervix must be split to find the way, but after dilatation it should be sewn up again. He had never seen cancer of the cervix in any other nullipara. The operation of posterior division of the cervix was so easy to attempt that many tried it, but it was well nigh impossible to attain a really satisfactory result.

Dr. L. L. CANNON (Master of the Coombe Hospital) read the annual report of the Coombe Lying-in Hospital for 1925, and this was discussed in some detail by the CHAIRMAN, Dr. FITZGIBBON, Dr. SOLOMONS, Dr. A. H. DAVIDSON, and Dr. CANNON.

MIDDLE-EAR DEAFNESS.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland held on May 21st, with the President, Mr. R. C. B. MAUNSELL, in the chair, Mr. W. C. STEVENSON and Mr. T. G. WILSON read a paper on the rationale of radium treatment of middle-ear deafness, and submitted a preliminary report on its effect on chronic hyperplastic otitis media.

Mr. STEVENSON said that since 1917 the army and later the pensions authorities had recognized the radium treatment of scars and gunshot injuries on the recommendation of Sir Robert Jones, who had investigated the results obtained by him by this method of acting on scar tissue at Alderhay Hospital, Liverpool. During 1925, 24 pensioners were so treated for the Ministry of Pensions. It had been proved beyond question that when the routine treatment in the massage department failed to benefit a limb crippled by scar tissue, improvement in its function resulted after radiation, especially when the adhesions or fibrous tissue softened by radium treatment were stretched by subsequent re-educational exercises. If deafness was due to fibrous tissue binding together the ossicles which transmitted the vibrations of the drum to the auditory receptive apparatus, it was reasonable to expect that improvement in hearing would result if these adhesions were softened and stretched, and dealt with on orthopaedic principles.

Mr. WILSON recorded three cases—two of chronic hyperplastic otitis media and one of oto-sclerosis. He pointed out that these conditions were fully discussed at last year's British Medical Association meeting at Bath, when the treatment was universally admitted to be most unsatisfactory. In the two former cases marked improvement was found after radiation, the hearing power for the conversational voice in each case being increased from about two feet to from ten to fifteen, and a corresponding improvement being found for the other hearing tests. Hearing in the case of oto-sclerosis was not improved, but it was important to note that tinnitus was considerably diminished.

Both authors laid stress on the importance of re-education of the cortical auditory centres, and of continued routine treatment to prevent the progress of the disease, in order that the patients should obtain the full benefit of the increased functioning power of conducting mechanism following radium treatment.

The PRESIDENT said that this was quite a new form of treatment for a very intractable ailment of the ear.

Dr. HORACE LAW thought the only difficulty about this treatment would be choosing the cases, and keeping clear of cases of oto-sclerosis. The patients treated by Mr. Wilson and Mr. Stevenson had all been very young, and in cases where the deafness was very marked, in patients who were little more than children, oto-sclerosis was more dangerous, more complete, and more likely to lead to complete deafness. He felt that Mr. Wilson should remember to try to keep otitis media and oto-sclerosis separate, and also remember that those two conditions very often overlapped, though this occurred more frequently in cases at a more mature age than those that Mr. Wilson had treated. Mr. Wilson should follow up his cases, as it was too soon yet to know how far the improvement produced was going to be permanent. If benefit could be produced in cases of deafness of this character, the patients might remain all right for a very long time provided other things did not supervene. He thought that the patients who had been treated should be given another dose of radium in a short time, and felt that they would require other treatment also, such as massage. In patients who were very deaf the thing to remember was that what was needed was for them to hear the human voice. Mr. Wilson was to be congratulated on the success of his initial dose in these cases, as it was not easy to choose a dose that would produce an effect on the injured tissues, without too much reaction. Deafness in these cases was due to two things—namely, a definite laying down and thickening of the tissues of the ear, and a thinning out of the tissues of the ear afterwards; and so radium might have a twofold action.

Mr. STEVENSON, in reply, said that the patients treated had been young, but they were not chosen cases; they were just the first that had turned up at the hospital. He

thought that if the patients had been a good deal older they would not have got such quick results from the treatment.

Mr. Wilson thought that if radium treatment of the ears was put on a secure basis the actual fact that improvement was got would help in diagnosing between otitis media and oto-sclerosis. If radium treatment should be proved valuable after a time, then the functioning power of the ears could be improved by it, and the centres of the ears improved by treatment following radium. On the whole, he had found that better results were obtained from radium treatment in cases without much atrophic change.

Reviews.

A TEXTBOOK OF PSYCHIATRY.

THE fourth edition of Craig's well known textbook entitled *Psychological Medicine*¹ has been almost entirely rewritten, and is issued under the joint authorship of Sir MAURICE CRAIG and Dr. THOMAS BEATON. It is the authors' aim to present a modern view of mental disorders from both the physiological and psychological standpoints, and an endeavour has been made throughout the book to link up psychiatry with general medicine.

It is evident that much thought and care have been expended in the preparation of the volume. The introductory chapters, in which the student is given a biological conception of mind and its disorders, create a favourable impression at the outset, and the book as a whole may be described as a solid, well balanced, and useful contribution to psychiatry. In the preliminary pages such difficult subjects as the function of consciousness, the nature of desire and purpose, the unity and individuality of the organism, the evolution of structure, and the relation of mental processes to neurological mechanisms, are very clearly and smoothly discussed. A useful chapter deals with laboratory methods of investigation in mental disorders, and it is pointed out that our definite knowledge of the intimate relationship between mental and physiological function rests on an ever-growing foundation of practical proof. It is recognized, however, that the utmost refinements of laboratory investigation have not yet indicated a physiological explanation for many mental processes, and that psychological methods of approach are essential for the understanding and treatment of mental cases. In the widest sense of the term, psychological treatment is probably the most effective means of bringing about a change for the better in the reactions of mental patients, and in no psychosis or neurosis can formal or informal psychotherapy be excluded as an element in their amelioration or cure. The authors write with considerable psychological insight and much common sense, and do not ignore the fact that the psychiatrist has to treat a personality and not merely a physical organism. An interesting and original chapter is that dealing with the nature, causation, and treatment of hysteria—a malady the manifestations of which are here aptly described as differing from all other morbid mental phenomena in depending on the compassionate impulses which arise in social relationships.

The contents of the volume are divided into sections with the following headings: biology; causation, classification, and symptomatology; the biogenetic psychoses; the psychoses of toxic origin; insanity and epilepsy; the minor mental disorders or psychoneuroses, with their allied psychoses; insanity and physical disease; and mental deficiency. Sleeplessness, malingering, treatment, case-taking, laboratory work, and the relationship of insanity with law, are the subjects considered in a miscellaneous section. We note the absence of any account of the Binet-Simon or other mental tests—an omission which might easily be remedied in a future edition.

The aims and tendencies of modern psychiatry are admirably expressed in the volume, and we can thoroughly recommend it to the student and practitioner as a sound and trustworthy textbook.

¹ *Psychological Medicine: A Manual of Mental Diseases for Practitioners and Students*. By Sir Maurice Craig, C.B.E., M.A., M.D. Cantab., F.R.C.P. Lond., and Thomas Beaton, O.B.E., M.D. Lond., M.R.C.P. Lond. Fourth edition. London: J. and A. Churchill, 1926. (Demy 8vo, Pp. xiii + 437; 25 plates. 21s. net.)

PRACTICAL PHYSIOLOGICAL CHEMISTRY.

LABORATORY courses in physiological chemistry were modest affairs when Mr. S. W. COLE's textbook first appeared twenty odd years ago. The book has now reached a seventh edition,² and the comprehensive character and diversity of the technique in the exercises are significant of the growth of chemistry in biological and medical curricula during these years.

Mr. Cole has very definite—and very satisfactory—ideas of the functions and responsibilities of a teacher. His book is not merely one man's harvest of the technique of many. Rather is it the fruit of a long personal experience in the guidance of students in the first of British biochemical schools. We are allowed to share all the simplifications of technique, all the tricks of the trade, which have grown out of the difficulties and distresses of the teacher and his students.

The publishers are justified in their claim that the seventh edition is completely revised and enlarged. Nothing is missing that was good in previous editions, and there was little that was not good. The opening chapter, on the properties of aqueous solutions, now includes a valuable outline of the theory of electrolytic dissociation with simple instruction in electrometric methods for the determination of that mystic symbol, pH. A new chapter, largely theoretical, treats of the mechanism of biological oxidation and reduction. We do not know of any more satisfactory synopsis of the recent progress in the simplification of what has been an ill co-ordinated problem. A new method, devised by the author, for the determination of sugar has been added since it has found favour in his own classes, and a few methods of blood analysis have been introduced in deference to the growing clinical importance of chemical studies of the blood. The chapter on the blood pigments has been revised to comprehend recent views of the haemoglobin molecule.

Physiology owes much to the Cambridge school of biochemistry under Sir F. Gowland Hopkins. This book is not the least of the contributions of that school.

THE SOIL IN HEREDITARY SYPHILIS.

"THE Soil in Hereditary Syphilis" may not be the exact translation of Professor HUTINEL's *Le Terrain Hérédosyphilitique*,³ but it conveys what the author considers an important part of his exposition, that hereditary syphilis has indirect as well as direct effects, and both must be included in any complete account of the subject. The disturbances produced in the human body by the poison of syphilis are more varied and widespread than those of any other infective disease; and if this infection, which is always a blood infection, occurs in the body of the foetus, and runs its course in the infant and child where metabolism is specially active, and all tissues and organs are in the process of growth, the range and variability of its effects are inevitably greater than in the more stable body of the adult. The direct manifestations of hereditary syphilis are described by Dr. Hutinel under the two stages of septicaemia, and later localizations; but he then proceeds to deal with clinical phenomena which are indirect results of syphilis and due to interference with growth or to a disturbed action of glands of internal secretion. Thus we have chapters devoted to the dystrophies of hereditary syphilis, in which the word "dystrophy" is interpreted in a most liberal way to cover overgrowth and wasting of the whole body or of any of its parts, and on the disorders of internal secretion, and an interesting discussion of diathesis in relation to hereditary syphilis. The book concludes with chapters on the stigmata and clinical signs, and on treatment.

Professor Hutinel is a well known authority on congenital syphilis, and in another book on the dystrophies of adolescence he has already detailed his ideas as to the indirect effects of syphilis both on the glands of internal secretion and on general metabolism. This part of the subject is now included in a complete and general survey

² *Practical Physiological Chemistry*. By Sydney W. Cole, M.A. Seventh edition. Cambridge: W. Heffer and Sons, Ltd. 1926. (Demy 8vo, Pp. xii + 479; 65 figures. 16s. net.)

³ *Le Terrain Hérédosyphilitique*. Par V. Hutinel. Paris: Masson et Cie. 1926. (Med. 8vo, pp. 455. 30 fr.)

of the whole wide subject. It is written by a master of the subject, one with extensive clinical experience of the disease and familiar with the literature; the style is always clear, if sometimes rather copious and a little rhetorical. It is not meant to be a clinical textbook of the disease, but rather an essay from the standpoint of general pathology. As a general discussion of this intricate disease it is admirable in its arrangement and in its clear and thoughtful exposition.

THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE LIVER.

A NEW volume, the sixteenth, has been added this year to the series of monographs which are being edited by Professor SCHWABE of Berlin on errors in diagnosis and treatment and their prevention.⁴ It deals with diseases of the liver, including hepato-splenic affections, and has been written by Professor ERPPINGER and Dr. WALZEL of Vienna. It is in two parts—the first on the prevention of errors in diagnosis, and the second on the prevention of errors in treatment. The first part contains a general and detailed description of jaundice, followed by a consideration of the diagnostic symptoms of diseases of the liver and spleen. The authors, in introducing the subject of their monograph, point out the mistakes that arise from ascribing to one organ alone all the symptoms of the so-called affections of the liver, whereas in fact they are not all due to diseases of the parenchyma of that organ, but are more of the nature of disturbances of a whole system, and indicate a pathological condition of more than one organ. The liver, which is the largest organ of the body, occupies a central position in the process of metabolism, and exercises a continuous control over the blood stream, not only mechanically, but also chemically. Yet scarcely any changes in metabolism are brought about even in livers which may be severely damaged in an anatomical sense.

It has been customary to attribute to the liver the origin of all disorders in which jaundice is the prevailing symptom. It is this doctrine which the authors set themselves out to combat in discussing jaundice both in general terms and in detail.

They recognize three distinct classes of icterus: the mechanical, due to obstruction in the flow of bile into the intestine; the haemolytic, due primarily to an excessive escape of bile and its elimination under abnormal conditions; and the icterus due to actual disease of the parenchyma of the liver. The detailed descriptions of these three forms of jaundice include, under the heading of mechanical jaundice, an account of the various causes of obstruction to the flow of the bile, such as cholelithiasis, carcinoma, chronic pancreatitis, duodenal ulcer, and some less common causes, such as echinococcus affection of the gall bladder. A critical analysis of the means for making a differential diagnosis of these conditions is an important feature in this section of the book. Haemolytic jaundice is most commonly a symptom in other diseases, such as pernicious anaemia, malaria, and poisoning by certain drugs, and stress is laid on the importance of distinguishing these forms of icterus from congenital haemolytic jaundice, which is inherited and does not indicate any actual disease. It is more difficult, however, to distinguish between it and icterus associated with enlarged spleen and cirrhosis of the liver. The differential diagnosis depends on tests for bile acids in the urine, which are not found in the congenital type.

In dealing with the type of jaundice due to affections of the parenchyma of the liver, the authors enter into an exhaustive discussion of what is called "catarrh of the liver." They regard as essential the recognition of the fact that a catarrhal jaundice is not necessarily a catarrh of the bile duct dependent on a gastro-duodenal catarrh, but may be due to a general hepatitis, and in its most acute forms may resemble the jaundice of acute atrophy of the liver. In this section reference is made to the liver

and spleen conditions found in Banti's disease; and the authors are sceptical regarding the existence of this disease as distinct from the pathological conditions caused by malaria. They come to the conclusion, at any rate, that true Banti's disease does not occur in Austria or Germany, although possibly it may do so in countries bordering on the Mediterranean. They consider that further investigations are called for in connexion with this disease.

In the section dealing with the diagnostic symptoms of diseases of the liver, of special interest are the descriptions of associated enlargements of the liver and spleen, and of the conditions in which the dominant symptom is a tumour of the latter, and here again the authors enter into a full discussion of Banti's disease. Other subjects dealt with in this section are the symptoms of obstruction in the portal vessels, lesions of the pancreas, tumours of the gall bladder, pain in the region of the gall bladder, in addition to the various tumours and other conditions causing liver enlargement. An account of the various methods of diagnosis by laboratory investigations concludes this section of the volume.

The part dealing with errors in treatment is of special interest, and contains some important suggestions, especially with regard to the treatment of cholelithiasis, differentiating between the quiescent and painless conditions and those in which there is acute suffering. In the latter cases the physician is advised to prescribe dietetic, medical, and mechanical methods of treatment, all of which are considered in detail, as well as the indications for and against surgical operation. Reference is made to the recent use of pituitrin in removing gall stones from the bile duct on account of its action in exciting intensive peristalsis. The authors consider it well worthy of trial. The treatment of other liver affections contains nothing of special importance or interest; but in concluding this review we may say that those medical practitioners who are able to read German will find that the monograph contains much wise guidance both in diagnosis and in treatment.

HOPE'S "PUBLIC HEALTH."

THE wide experience of Professor E. W. HOPE, alike as a teacher, and, till lately, an administrative exponent of the principles and practice of hygiene, has happily found expression in his *Text-book of Public Health*. In the ninth edition,⁵ which has recently been issued, the name of Dr. C. O. STALLYBRASS is associated with his. The eighth edition, by Professor Hope alone, was published in 1915, and the progress of sanitary science since that date is reflected in the increased dimensions of its successor.

In the new edition the chapter on public health legislation is transferred to the opening pages. It is necessarily a summary, but is nevertheless readable, being compact without obscurity, though the Act referred to in line 11 of the text of page 23 can only be identified by collating the parent passage in the eighth edition. In the section on meteorology there are some flaws. The black bulb in racuo thermometer should not have been figured in the position of a grass minimum instrument. No reference appears to the Kew pattern barometer, the type now favoured by the Meteorological Office. No explanation of the millibar is afforded, though a pressure in millibars is quoted. The name of the physicist J. F. Daniell is as here printed. Under lighting, air, and ventilation there are informative additions on the uses of ultra-violet rays and on smoke prevention. Under food, the article on vitamins is new. So also is the account of endemic goitre and its prophylaxis by iodization. Under sanitation of buildings a figure survives from the eighth edition showing double-trapping of waste-pipes, an elaboration which modern practice is tending to abandon.

It is matter for regret that the authors have not been more communicative on town-planning, a subject on which they are so well qualified to speak, but what they have written is eminently lucid, and is aided by views of a reconstruction and the lay-out of arterial roads. The

⁴ Die Krankheiten der Leber mit Einschluss der hepato-splenicen Affektionen. By Professor Dr. H. Erppinger and Dozent Dr. P. Walzel. Diagnostische und therapeutische Irrtümer und deren Verhütung. Innere Medizin. Edited by Prof. Dr. J. Schwabe. Heft 16. Leipzig: Georg Thieme, 1925. (Roy. 8vo, Pp. 134; 10 figures. Paper cover, R.M.5.70; bound, R.M.7.20.)

⁵ *Text-book of Public Health*. By E. W. Hope, O.B.E., M.D., D.Sc., and C. O. Stallybrass, M.D. (State Medicine), D.P.H. Ninth edition, revised and enlarged. Edinburgh: E. and S. Livingstone, 1925. (Demy 8vo, Pp. x + 340; 71 figures. 15s. net; postage 5d.)

section on vital statistics is useful, though in parts severely compressed. The chapter on general epidemiology includes material on insect vectors from the eighth edition, but is otherwise new; it deals with immunity and disease transmission in an interesting manner. The section on infectious disease is greatly expanded and new work recorded. The welfare of motherhood and infancy, the health of the school child, and occupational disease are effectively set forth. There are also articles, as in the eighth edition, on marine and military hygiene.

The book is strong on the practical side, but at the same time it keeps general principles clearly in view. It is comprehensive, and covers the field well. It will amply suffice for the medical student, and in many of its topics will meet the requirements of the candidate for a diploma. To both of these it may be cordially recommended.

"BRAIN."

IN the issue of *Brain*⁶ for April (Part 1 of vol. 49) Professors Brouwer and Zeeman of Amsterdam describe their experiments on monkeys' on the projection of the retina in the primary optic neurones, and arrive at some conclusions which are new and important. They followed by the Marchi method the degenerations produced after localized injuries to different parts of the retina: nearly all the degenerated fibres ended in the external geniculate body on one or other side, a few in the superior colliculus and none in the pulvinar of the optic thalamus. There is a definite localization in the external geniculate body of fibres from the retina: the macular fibres occupy a large area, and the authors consider it probable that these fibres also occupy a wide area of the optic radiations and calcarine cortex, and are not limited to the occipital pole. Dr. H. H. Woollard contributes a lengthy paper on the retina and lateral geniculate body in tupaia, tarsius, nycticebus, and hapale, tracing the development of the macula and geniculate body in this series of closely related animals.

Drs. Stanley Barnes and E. Weston Hurst contribute a further note on hepato-⁷ including the detailed post-mortem fourth case in the family previously described by them. In addition to changes in the basal ganglia a remarkable necrotic condition was found in the frontal lobes in this case. The Kayser-Fleischer zone of pigment in the cornea was present, and its nature is discussed fully. Dr. W. Russell Brain deals with the mechanism and clinical significance of the rotated or "cerebellar" posture of the head, and concludes that the term "cerebellar" is a misnomer, as the attitude is not assumed in pure cerebellar lesions. He considers it to be due to interference with impulses from the labyrinths concerned with the maintenance of postural tone in the neck muscles.

Professor S. E. Henschen of Stockholm contributes a very interesting article on the function of the right hemisphere of the brain in relation to the left in speech, music, and calculation. Dr. James Taylor, in an article on prognosis in disseminated sclerosis, relates a number of cases from his long experience illustrating the remarkable remissions which occur in this disease, and the great difficulties in prognosis. He lays stress on the importance of rest in the early stages.

This number contains also the report of an important discussion in the Section of Neurology of the Royal Society of Medicine on the sympathetic innervation of voluntary muscle.

NOTES ON BOOKS.

THE volume on the treatment of infectious diseases in private practice,⁷ by Professor J. RIEUX and Dr. C. ZOELLER, is a recent contribution to a series of small books edited by Dr. C. Fiessinger, and is divided into two parts. First there are

⁶ Published in London by Macmillan and Co., and in New York by the Macmillan Company. Yearly subscription in this country 24s., to be sent to Messrs. Macmillan, St. Martin's Street, London, W.C.2. Price of this part 6s. net.

⁷ *Traitément des maladies infectieuses en clientèle*. Par J. Rieux et C. Zoeller. Comment guérir? Bibliothèque des Praticiens. Paris: A. Maloine, 1926. (54 x 72, pp. 11 + 246; 28 figures. 18 fr.)

four chapters on the treatment of infectious diseases in general, dealing respectively with general considerations, pathogenic medication (which includes treatment by serum and vaccines, shock therapy, and chemotherapy), symptomatic treatment, and regimen (which comprises personal hygiene, diet, and disinfection). The remainder of the volume is concerned with the treatment of special diseases, and the whole affords a clear and concise account of French practice in the management of infectious diseases. Another volume in this series is by Dr. F. NIDERGANG. It is on diseases of the mouth in private practice,⁸ and contains a concise and practical account of the medical and surgical diseases of the mouth, including the lips, gums, jaws, tongue, cheeks, palate, and pharynx. Morbid anatomy is excluded, and special attention is devoted to treatment. The arrangement of the subject-matter is good, and the description of the various morbid conditions clear and complete, so that the book may be warmly recommended both to practitioners and students familiar with the French language.

*Bergey's Manual of Determinative Bacteriology*⁹ is, as we pointed out when reviewing the first edition, a dictionary or guide-book to the classification of microbes, or (to quote its supplementary title) "a key for the identification of organisms of the class schizomycetes." Dr. BERGEY has been assisted in the compilation by a committee of the Society of American Bacteriologists, and the book may be regarded as one of the official publications of this society. There is no doubt that a service has been rendered to bacteriology by the preparation of this book, which has already brought a semblance of order to bacteriological nomenclature. A few mistakes made in the first edition have been rectified, otherwise the second edition does not differ much from the first. One change we are very pleased to notice. The staphylococcus now comes to rest amongst its kindred of the tribe micrococceae. It was never easy to understand why the American Committee on Classification and Nomenclature, in its reports of 1917 and 1920, placed the staphylococcus amongst the streptococceae. This unnatural partnership has now been dissolved.

The object of the little work on quinine in therapeutics¹⁰ by Dr. L. DESTOUCHES is to keep a *via media* between those who would regard quinine as a panacea and those who would confine its use to the treatment of malaria. The book is in four parts, preceded by a brief sketch of the history of quinine. The first part is devoted to a chemical study of the drug, the second to its physiological action, the third to its therapeutic properties, and the fourth to the administration of its salts. The reader will be well advised to bear in mind what we said (*JOURNAL*, January 23rd, 1926, p. 154) about the booming of quinine to the exclusion of the other alkaloids of cinchona, which form quite efficient substitutes.

In his essay on *Thomas Sydenham*,¹¹ the tercentenary of whose birth was recently commemorated in the *JOURNAL* (November 15th, 1924, p. 917), Dr. DAVID RIESMAN, professor of clinical medicine in the University of Pennsylvania, has given a brief but sympathetic outline of the life and achievements of the English Hippocrates. A portrait of Sydenham faces the title-page, and a bibliography of his works, with a facsimile of the first English edition, is appended.

PREPARATIONS AND APPLIANCES.

"Methyl-Aspirodine."

METHYL-ASPIRODINE is a new synthetic compound prepared by Mr. W. H. Martindale, Ph.D. The chemical name of the compound is methyl iodo-aspirinate, or methyl acetyl-iodo-salicylate. It contains 39.7 per cent. of iodine and the equivalent of 56.3 per cent. of aspirin. The compound is a white crystalline powder, which melts at 40°C. It is insoluble in water but freely soluble in oil. The powder can be rubbed into the skin, and is rapidly absorbed. It is non-greasy, and practically odourless. Theoretical considerations make it probable that this compound will prove useful for local application byunction for the relief of rheumatic pains. Its action may be expected to be similar to that of methyl salicylate (oil of wintergreen), and it has the great advantage of being odourless. It has a mild rubefacient action.

JUNE 26, 1925]

British Medical Journal.

SATURDAY, JUNE 26TH, 1925.

THE ASSOCIATION IN SOUTH AFRICA.

THE recent visit of the Medical Secretary to South Africa is an important event in the history of the British Medical Association. In August last year the South African Committee, the central body of the Association in South Africa, requested that such a visit should be paid, and at its meeting in October the Council acceded to the request that the Medical Secretary should proceed "on an organizing tour," and instructed him to convey to the South African Committee its best wishes "for the success of efforts to promote the solidarity of the profession in South Africa." We publish in this issue, as an appendix to the Supplementary Report of Council (SUPPLEMENT, p. 235), the account of the progress and results of his mission which Dr. Cox has presented to the Council. The interest and value of this report correspond to the importance of the occasion. Its consideration and the action to be taken thereupon will no doubt be one of the chief features of the meeting of the Representative Body at Nottingham. There, as at the Council meeting, the extraordinary tact and ability with which Dr. Cox conducted delicate negotiations, and the remarkable and gratifying success achieved, will be appreciated, acknowledged, and confirmed.

The situation with which the Association and the profession have been confronted for some years in South Africa, and with which the Medical Secretary was faced on his arrival there, was a serious one. In a country where distances and difficulties of travel and communication are very great, where races are diverse, and where political influences and opinions are strong, active, and antagonistic, the medical profession, relatively small in numbers, was ranged in two camps—the larger, more widely spread, and more generally active being the Branches of the British Medical Association, with the South African Committee as its central representative body; the smaller, strong on the Rand, calling itself the South African Medical Association, which had at its formation in 1918 based itself on the use of trade unionist methods, but which had latterly stood rather as emphasizing its independence of all associations and influences other than those which were purely South African. Outside both organizations were a number of practitioners who, from indifference or from weariness with professional divisions, remained isolated individuals. The profession, so organized or unorganized, was threatened by the Union Government with action which, if carried through, would seriously affect its interests and traditions, either as a whole or in various localities, and was handicapped in making its opinions and wishes known and respected by divided counsels, by rival deputations, and by dissipated forces. Clearly this was not a position in which the prime movement and object should be by active propaganda to endeavour to secure the absolute predominance of one or other organization, but rather one in which the wise course was to secure unity by some form of effective compromise. Fortunately, influential men at the head of both Associations were statesmanlike enough to realize this, and disinterested enough to take active steps in the right

direction. Naturally there were differences of opinion as to what was the most desirable and effective line of action.

At first sight the method of "affiliation" seemed attractive. By this method, though individual members of the British Medical Association might continue to exist in South Africa, the whole organized machinery of the Association there would cease to be, and organization of the profession within an entirely independent association would be developed, though by the use of the phrase "affiliated to the British Medical Association" it was intended to emphasize the fact that the relationship of the two Associations would be intimate and friendly. Two circumstances lent weight to this suggestion. One was that in 1923 a referendum of the whole profession in South Africa, and of the members of the British Medical Association there, had been taken, with the result that in a large vote there had been a definite majority in favour of this course. This, however, could not be taken as decisive, because no fewer than seven of the ten Branches of the British Medical Association, on a subsequent referendum as to the desirability of dissolving the Branches as a first step towards affiliation, had a majority against the proposal, and therefore could not very well be dissolved; and also because it appeared that many who voted in the majority had believed that the relationship of "affiliation" was more close than it actually is—that, indeed, it involved organic connexion, with effective membership of the older association. The second circumstance which seemed to point to the "affiliation" solution was that this had recently been adopted in respect of Canada. But the position in the two countries was very different: the opportunity for any alternative solution in Canada had passed many years ago. In that dominion there was an active Canadian Medical Association, large, powerful, effective, and without rival, whereas the surviving Branches of the British Medical Association there existed merely on paper. Dr. Cox and Sir Jenner Verrall, in their mission to Canada in 1924, had to do the best that was possible in the circumstances, and the result is a cordial working agreement between two independent associations.

That, in the circumstances described, a much more satisfactory result has been obtained in South Africa is a matter on which the Association and all concerned are to be congratulated, and for which the Medical Secretary and those who worked with him—Dr. Orenstein, Sir Spencer Lister, Dr. Max Greenberg, Dr. Francis Napier, and others—are greatly to be thanked. The solution adopted completely unifies the organization of the profession in South Africa, retains for all an integral membership of the British Medical Association, and under the name of the "Medical Association of South Africa (British Medical Association)" establishes an organization which, while practically autonomous as far as South Africa is concerned, will not only be entitled to the full support of the Association in all other parts of the Empire, but will be enabled—and expected—to carry its full weight in the affairs of the Association as a whole, and to contribute whatever it can to the furtherance of the interests and maintenance of the honour of a united profession. Thus the ideal of the British Medical Association as an Empire organization is safeguarded, each part standing on the same footing as the rest, and all mutually helpful. With this constitution and under this name the future of the Association in South Africa appears assured. Already there is an accession of membership, and there are signs of increasing vitality.

Union here, as elsewhere, brings strength, not only in professional work, but in dealing with the proposals of the Government and of local authorities.

The subsidiary parts of Dr. Cox's report are deserving of notice. To have revived the Natal Coastal Branch, which has been and should be one of the strongest Branches in South Africa, but which from various causes had fallen on evil days, was a considerable achievement. The formation of a new Branch in the Mandated Territory of South-West Africa is a very interesting event, in some respects unique. The visits to the Branches in Southern and Northern Rhodesia were evidently timely and useful. These colonies do not, of course, come within the Union of South Africa, and it is probable that Northern Rhodesia will become more and more closely associated with the group of East African Colonies and have to deal with problems similar to theirs.

It is to be remembered that a considerable proportion of the membership of the Association is overseas, and such visits as those recently undertaken by the Medical Secretary and by prominent members of the Association demonstrate, not only that the Association has the interests of such members fully in mind, but that a closer personal intercourse, whether here or in the Colonies and Dominions, is to the great advantage of almost all the Association's activities. The visit of Dr. J. A. Macdonald to South Africa in 1920-21 was greatly appreciated, and had paved the way for the results which may be expected from the subsequent visit of Dr. Cox.

THYROXINE.

WHEN the student first acquires a textbook of physiology his earliest reconnaissance is likely to be among the illustrations to the text. One of these which will surely capture his interest will be that of the contrasting photographs of a ecretin before and after a course of thyroid feeding. The visual evidences, indeed, of abnormal endocrine function are often so striking that the subject of the chemical control of bodily functions by the ductless glands has long been popular in both laboratory and classroom, while it is the branch of medical science in which the lay public is to-day better instructed than in any other. So frequently does the word "hormone" come to the lips as a facile explanation of the function of a gland that we need still to be reminded that insulin, pituitrin, and other common therapeutic preparations of endocrine organs are only crude extracts of glands whose active principles have so far defied isolation in the pure state, though we may hope that the crystalline substance which Abel has this year isolated from insulin preparations is indeed the pancreatic hormone. Until recent years adrenaline was the only complete victory which the chemist could claim in this field, since the isolation and the identification of this substance were crowned by its synthesis in the laboratory.

About ten years ago E. C. Kendall separated from the thyroid gland a crystalline material, containing 65 per cent. of iodine, which was shown to have the physiological effects of the whole gland, and was, indubitably, one of the hormones of this gland. A chemical structure for this compound was later advanced, and the claim made that a substance of this structure had been successfully synthesized, though no details of the method have yet been vouchsafed. The chemical constitution proposed presented

certain inherent chemical improbabilities, and biochemists, in this continent at any rate, were inclined to defer acceptance until the crucial proof of synthesis should be supported by experimental detail. Nevertheless, in the material which Kendall had isolated there became available a substance with undoubted physiological function, and it may seem strange that no other laboratory has, during the past decade, attempted to confirm or to correct the contentions of Kendall.

In two papers by Dr. C. R. Harington in the last number of the *Biochemical Journal*¹ will be found at once the explanation for the timidity of chemists to undertake this problem and the justification of their scepticism. There will be found, moreover, one of the prettiest examples of the application of the classical methods of organic chemistry to a definite biochemical problem, one of the most lucid arguments in analysis and synthesis, and one of the big contributions of the present century to biochemistry. There will be found, in brief, a method for the isolation of the thyroid hormone some twenty-five times as productive as that of Kendall, and a definition of the structure of this substance so precise as almost to command acceptance.

The name of Kendall will remain associated with the first successful preparation of thyroxine, but his method, which produced only 11 grams from a ton of fresh glands, must now give place to one which, by what now appear to be simple modifications, gives 270 grams from the same amount of material. Dr. Harington records that the British Drug Houses, Ltd., have co-operated with him in the large-scale application of the method, and have successfully prepared considerable quantities of the crystalline material. With so greatly improved a source of thyroxine Dr. Harington was ready to tackle the problem of its chemical constitution. He parts company with Kendall at the outset, for he asserts that the latter's analysis of his product was wrong. Much may hang upon the correctness of a single analytical figure. Whereas Harington ascribes to thyroxine the composition $C_{15}H_{11}O_4NI_2$, Kendall gave to it the formula $C_{14}H_{10}O_3NI_2$. He was led thence to the facile acceptance of very debatable evidence for the chemical nature of the molecule, and so to a mass of synthetic experiment and physiological speculation which, in the light of the present work, becomes almost impossible to appraise.

The argument of Harington's work deserves brief summary. The crystalline thyroxine was first deprived of its iodine. Analytical methods indicated that the desiodothyroxine was a phenolic amino-acid containing two benzene rings, a three carbon side chain, and an oxygen atom probably linking together the two benzene rings. "At this point," says the author, "it was decided to attempt to meet degradation by synthesis." The attempt was completely successful. Two independent methods each gave a product chemically identical with desiodothyroxine. One link only appears to be missing. The iodine atoms must be introduced into the synthetic product in such a way as to produce a substance having the physiological as well as the chemical properties of thyroxine. It is to be hoped that we shall not have long to wait for this final achievement. The structure proposed by Harington is represented by the formula

¹ Harington, C. R.: *Biochem. Journal*, 1926, 20, 293-299, 300-311.

wherein the only point of doubt is the situation of the four iodine atoms. The formula proposed by Kendall was

It has been necessary to emphasize the disparity between the views of these two workers because Kendall has built upon his conclusions theories of the function of the thyroid and other hormones which, in America at least, have found such favour as to earn for their author (who is professor of biological chemistry in the Mayo Foundation of the University of Minnesota) the Chandler Medal of Columbia University. A summary of these views will be found in the lecture delivered by him on the occasion of the bestowal of this medal.² Kendall's contention is that thyroxine acts as a catalyst of metabolic processes by virtue of its ability to behave, under defined conditions, as what we interpret to be an oxygen "activator." This may well be so, but it must be emphasized that the argument is based not upon the chemistry of thyroxine, but upon that of synthetic compounds having structures similar to that attributed by Kendall to thyroxine. The evidence involves some liberties with conventional structural organic chemistry, some unjustifiable employment of the blessed phrase "oxidation-reduction potentials," and some *ad hoc* applications beyond the immediate problem to the behaviour of adrenaline and "bios." Wide generalizations are always attractive, but only breed general scepticism when an element of doubt creeps into the premisses from which they derive. If the work of Harington is accepted it must be conceded that the physiological behaviour of the synthetic compounds of Kendall can have no relation to the function of thyroxine, and, that being so, it would seem that the whole argument surrounding this work must be recast.

The isolation of thyroxine, though a big laboratory success, does not make to medicine so immediate a contribution as have discoveries—chemically incomplete—such as that of insulin. Therapeutically there is no impediment to the oral administration of the whole gland or simple extracts of it. As a matter of economics it is cheaper to give the gland to be swallowed than to administer a pure product separated at considerable expense or synthesized at still greater cost. On the other hand, to physiology the offering is immediate and important. There is offered the opportunity for the quantitative study of the effects of the hormone such as is not permitted with gland preparations whose content in hormone has not been determined. In desiodothyroxine, again, there is a substance whose physiology demands investigation.

Boothby and Sandiford³ have recently summarized a large amount of work done upon the quantitative effects of thyroxine on basal metabolism using the commercial substance prepared by Kendall's method. A relation has been shown to exist between the amount of thyroxine in the circulation and the increase in metabolic rate such that 1 mg. raises the basal metabolic rate 2.8 per cent. In myxoedema the rate is some 40 per cent. below the normal, so that, if this is to be attributed to lack of thyroid secretion, 14 mg.

of thyroxine should restore the patient to a normal metabolic rate, and this it does. Moreover, the study of the rate of decay of the action of thyroxine indicates that this is of an order suggesting a daily loss from the circulation of 0.4 mg. Consequently the daily injection of this amount should maintain a normal rate in this condition. This conclusion also has been entirely justified by experiment. In respect of hyperfunction of the thyroid we need note only that the clinical picture of adenomatous goitre with hyperthyroidism may be produced by persistent overdosage with thyroxine. This is not so with exophthalmic goitre, again agreeing with the clinical differentiation of these two conditions. It is suggested that in the latter condition there is not only an increased secretion by the gland but also a defective synthesis, so that modified substances having special physiological effects are thrown into the circulation. Remembering the success of Plummer in reducing the metabolic rate in cases of exophthalmic goitre by massive doses of iodine, we see a direct clinical interest in studies of the physiology of desiodothyroxine.

We are glad to add our voice to the chorus of congratulation which the work of Dr. Harington has evoked. The proper guardian of knowledge is power. Medicine looks to the co-operation of physiology for the full reward of the accession of knowledge.

REORGANIZATION OF THE UNIVERSITY OF LONDON.

A BILL to carry out the recommendations of the departmental committee, of which a full account was given in our issue of May 22nd (p. 875), was introduced into the House of Lords on June 15th by the Earl of Balfour, Lord President of the Privy Council. The bill sets up a body of University of London Commissioners, and prescribes what they are to do. The members of the Commission are Mr. Justice Tomlin, M.A.Oxon.; Sir Lewis Selby-Bigge, Bt., K.C.B., M.A.Oxon., lately Secretary of the Board of Education; Sir Cyril S. Cobb, K.B.E., M.A.Oxon., late Chairman, London County Council; Sir Josiah Stamp, G.B.E., D.Sc.Lond.; Sir E. Cooper Perry, M.A., M.D. Cantab., lately Principal of the University of London; Mr. A. D. Lindsay, M.A.Oxon., Master of Balliol College, Oxford; Miss Bertha S. Phillpotts, Litt.D.Dublin., formerly Mistress of Girton College, Cambridge; and Professor T. Perry Nunn, D.Sc.Lond., Principal of the London Day Training College. The Commissioners are to make statutes for the University of London in general accordance with the recommendations of the report of the departmental committee, but subject to any modifications they may deem expedient, and to carry out this duty may make statutes also for any school of the University, or for any other college, school, or institution, in order to enable it to become a school of the University. Such statutes, however, must be made with the consent of the several governing bodies. The Commissioners must consider any representations made to them by any of these bodies, or by the Senate or Convocation, or by any fifty graduates of the University. After the Commission has expired the University is to have power to alter or supplement statutes, under certain conditions. The Commission is not to have power to alter the incorporation in the University of University College or King's College. Judged by the letters the member for the University has addressed to us, the bill will be strenuously opposed when it gets to the House of Commons. Our readers, we are sure, feel deeply indebted to Dr. Graham Little for the trouble he has been at to explain to them why he and those who think with him are so vehemently and vociferously opposed to the proposals of the departmental committee, which were designed to make the Univer-

³ Boothby and Sandiford: *Physiol. Reviews*, 4, 69 (1924).

sity an efficient educational institution, but we fear that he has not wholly succeeded. They perceive that he is very angry, and are almost reduced to believing that his only friends are the Duke of Bedford's trustees, who have taken back the gift of the Bloomsbury site the University contumeliously rejected. One of his arguments, if we understand him aright—and there must always be some doubt about this until he grows calmer—is that the University should be left to manage its own affairs. Upon this it seems just to make two observations. First, that the University has been managing its own affairs, with the occasional assistance of Royal Commissions, for fifty years or more, and has got them into the present muddle; and, secondly, that other universities possessing probably as many teachers and perhaps more graduates, such as Oxford and Cambridge, have on several occasions submitted to reorganization at the instance of Parliament and outside commissioners.

THE NATIONAL PHYSICAL LABORATORY.

ON June 22nd the President of the Royal Society, Sir Ernest Rutherford, entertained at the National Physical Laboratory; Teddington, a large number of guests who had been invited to meet the General Board of the laboratory, of which he is chairman. He was accompanied by Sir Richard Glazebrook, a former director, and by the director, Sir Joseph E. Petavel. The laboratory, which consists of a large number of separate buildings, covers a wide area on the outskirts of Bushy Park. In every department there are abundant evidences of activity, and a number of interesting experiments and apparatus were shown. Thus experiments in aerodynamics were in progress in wind tunnels of various dimensions, and in the wireless department it was found that problems of the constitution of the atmosphere were being attacked from an entirely different direction. In this way knowledge was being obtained about parts of the upper atmosphere beyond the reach of the direct observations employed in meteorology. In the engineering department tests of endurance and fatigue were being conducted on big-end bearings, springs, nuts, and gears. Apparatus for measuring the speed, screw thrust, revolutions, and the power required for the propulsion of a single-screw steamer were demonstrated in the William Froude National Tank. There were few exhibits of purely medical interest; but the department for testing clinical thermometers was open to inspection, and there was an exhibition of x-ray apparatus in the physics department. Amongst the latter there were Laue photographs of diamonds and single crystals showing their structure. In the metallurgy department researches were being made on the amalgams used by dentists.

PROFESSOR AUGUST KROGH.

THE colleagues of the well known Danish physiologist Professor August Krogh have made his fiftieth birthday the occasion for offering to him their felicitations and homage in the form of a volume entitled *Physiological Papers*.¹ Adding interest to the personal intimacy of this birthday present is the fact that it is probably the swansong of the old laboratory of which Professor Krogh has been the inspiration. The Rockefeller Foundation having added to its multitudinous benefactions the recognition of the eminence of this Danish school of physiology, the cramped quarters of the old laboratory are shortly to be abandoned for the spaciousness of a new and well equipped building. To this volume twenty-two fellow workers and one-time students of Professor Krogh have contributed papers touching many fields of physiological inquiry, the

majority of the contributions being in our own tongue, whilst the remainder are written either in German or French. To give a précis of the table of contents would be an unsatisfactory escape from the difficulty of reviewing a book such as this. We must be content to note only a few papers which appear to be of most direct clinical interest. In the first place, teachers of medicine will be interested in the description by a late student of Professor Krogh of an attempt to maintain in his clinical teaching in a large American hospital an interest in and use for the physiological training of the early years of the students' curriculum. Professor Hagedorn, in a continuation of his studies on the sugar of the blood, discusses the question of alimentary glycosuria; he concludes that its course is best explained by the view that the immediate storage of sugar in the liver is followed, after the completion of absorption, by a redistribution of the carbohydrate stores between liver and peripheral tissues. Certain implications in respect of the diabetic condition are indicated. Two other papers on blood chemistry bespeak the part Professor Hagedorn has taken in the direction of work in this laboratory. In a paper by L. T. Poullson is described an investigation of the antagonism between histamine and pituitrin, and it is reported that hopeful clinical tests have been made with pituitrin in cases of shock. Dr. E. Lindberg discusses the relation of the pancreas and thyroid, and finds in the records of some cases of Graves's disease treated with insulin evidence of a hitherto unrecognized function of the pancreas. A paper of pharmacological interest concerns the use of the white mouse and the frog's heart for the biological assay of digitalis substances, and another reports a continuation by Professor Widmark of his study of the physiology of alcohol. The rates of accumulation and disposal of alcohol by the body are discussed. Among the papers of general physiological interest we must be content to note only the direct influence of the work of Professor Krogh in four different papers dealing with varied aspects of the problem of respiration, and two others concerned with the factors involved in the circulation of the blood. One other contribution only will be referred to—the important essay from Professor Lindhardt on the relation of muscle structure to the mechanism of muscular activity. The plea is cogent that, in the success which has attended the chemical and physical analysis of the activity of the isolated muscle, we should not ignore the mechanical restrictions which are imposed by the intimate structure of the bundle of fibres which we call a muscle. In welcoming this tribute of a notable school to its master we would like to add our homage to theirs, and offer to him and to them our congratulations on the promise of the wider opportunity which the new laboratory will offer.

THE PHARMACOLOGICAL TESTING OF DRUGS.

A BRIEF account was given in our last issue of the opening by the Minister of Health of the new pharmacological laboratories of the Pharmacological Society of Great Britain in which some of the testing contemplated under the Therapeutic Substances Act can be carried out. The laboratories, which are intended for the threefold use of research work on the pharmacological testing of drugs, the training of pharmacists in the methods of pharmacological assay, and the commercial testing of drugs for manufacturers, particularly those who are unable to set up their own laboratories for testing their products, consist of four large well lighted rooms above the society's examination hall in Bloomsbury Square. The first room is at present used for the testing of digitalis, strophanthus, and squill; the second room contains, among other apparatus, that which is needed for testing the strength of pituitary extract and all the various preparations of ergot. At the moment the laboratories are prepared only to test members of the digitalis

¹ *Physiological Papers*. Dedicated to Prof. August Krogh, Ph.D., LL.D. London: W. Heinemann (Medical Books) Ltd. 1926. (7½ x 7½, pp. xvi + 355; illustrated, 30s. net.)

series, pituitary extract, and ergot, but the council of the society has approved the setting up of a department, which will occupy another of the rooms, for testing the vitamin content of various products. Not only are medicinal preparations, such as cod-liver oil, to be tested, but also preparations on the border-line between drugs and food, such as fruit juices and invalid foods. The approval of the Accessory Food Factors Committee of the Medical Research Council and the Lister Institute has been secured for this project, and the Accessory Food Factors Committee will take the responsibility of laying down the standards and tests to be applied. The routine testing of vitamin-containing products will be undertaken should vitamin preparations be scheduled in the future. The last of the four rooms is for the housing of animals, which are kept under conditions approved by the Home Office, by whom the laboratories have been licensed for physiological purposes. There are also additional rooms, which will be available as the work develops. Dr. J. H. Burn, the director of the laboratories, fully recognizes that a most important field of research for laboratories of this kind is the investigation of the properties and extracts of animal glands, and this it is proposed to develop as opportunities arise.

HARVEIAN SOCIETY OF LONDON.

THE annual dinner of the Harveian Society of London was held at the Connaught Rooms on June 17th. In proposing the health of the society Sir Archibald Garrod said that his first knowledge of the society arose from reading the Harveian Lectures of Dr. Chendle, one of the finest pieces of medical writing. Until comparatively recent times no one could learn science except in medical schools; and it was still the duty of medicine to teach people to criticize in a scientific manner. He hoped clinical medicine and surgery would continue to be regarded as sciences. Although the medical man was expected to give a diagnosis at once, no sound physician, said Sir Archibald, made a diagnosis under a fortnight. The president, Mr. E. Laming Evans, in reply, referred to the successful existence of the society for ninety-five years. He then said that next autumn would see the first award of the Buckston Browne prize—a medal and the sum of £50. The prize was to be awarded biennially for the best essay on a selected subject. This year the subject was "The etiology of high blood pressure and of the respiratory phenomena associated with high blood pressure and chronic nephritis." He went on to recall the fact that when Harvey was appointed physician to Charles I one of the perquisites of his office was "a diet of three dishes of meat, a meal, with all incidents thereunto belonging." Harvey died a martyr to gout and high blood pressure! Dr. Walter Jagger proposed the health of the visitors in a humorous speech. In reply Sir Laming Worthington-Evans, M.P., explained to Dr. Jagger the origin of the name he shared with his brother, the president; made observations on the relationship of his profession to that of medicine; and said that he would have liked to offer himself as assessor for awarding the Buckston Browne prize, observation being fitting for politicians; but he feared that induction required higher qualifications. Sir John Rose Bradford recalled that Harvey had said that it was good for people to meet together at feasts. Unfortunately, owing to alteration in currency, the feast of Harvey at the Royal College of Physicians had become reduced to a bag of macaroons. Therefore the President of the College was naturally grateful for the opportunity of dining with the Harveian Society. Sir Oscar Warburg described the advantage of combining the omniscience of the administrator with the infallibility of the clinician. Sanitary science was older than Harvey, dating back perhaps to Chiron the centaur. But Chiron was an unqualified person; and Hippocrates was probably the first person allowed by

the British Medical Association of the day to practise. Sir Oscar Warburg attributed the reduction in infantile mortality and of deaths from tuberculosis to co-operation between administrators and the medical profession. But he regretted that medical men did not always give clear guidance on important subjects, such as birth control, prophylaxis in venereal disease, sunlight treatment, and so on. In conclusion the speaker deplored the loss to the London County Council, no less than to the medical profession, caused by the death of Sir Frederick Mott. Among other distinguished guests present were Sir Richard Glazebrook, Sir St. Clair Thomson, Sir Holburt Waring, Sir Frederick Butler, Sir John Lithiby, the Master of the Apothecaries' Society (Dr. Vincent Dickinson), Mr. Mortimer Woolf, the Mayor of Paddington (Mr. Snell), and the presidents of the West London Medico-Chirurgical and the Chelsea Clinical Societies (Drs. H. W. Armstead and Seymour Price).

CINEMATOGRAPHIC OBSERVATION OF HUMAN CAPILLARIES.

THE power of the capillaries to contract on mechanical, electrical, or chemical stimulation has been well established by experimental observation, and the work of Krogh and others has shown that the areas and conditions of the capillary circulation are constantly changing. But two questions remain to be settled: (1) whether or not these variations in the capillary bed are due to contractility independent of such stimuli on the part of the capillaries, or to alterations in the tonicity of the corresponding arterioles supplying these areas; and (2) whether or not, if such independent contraction of the capillaries does occur, it is (a) a peristaltic wave forward, like that of the heart ("the peripheral heart"), or (b) a local rhythmic contraction. To elucidate these problems J. Hamilton Crawford, assisted by H. Rosenberger,¹ of the Hospital of the Rockefeller Institute for Medical Research, has investigated by means of a cinematographic apparatus the conditions of the capillaries in the human nailfold of eight normal subjects and seven patients with auricular fibrillation. These two groups are discussed in two successive papers, and the cinematographic apparatus is described in another; it consists of five parts—namely, a bed for the subject and a support for the arm, a lighting system, a microscope, a stand for holding and adjusting the finger, and a camera. The photographic films thus obtained gave a magnification of 14.4, which could be enlarged by means of a projectoscope to any desired degree (350 times was that employed) so as to reduce the possibility of error. The films were taken at intervals of one-sixteenth of a second, and the diameters of the arterial and venous limbs of the capillaries were carefully measured at a constant distance from a base line, the venous limb being slightly the larger. The observations show that the capillaries are constantly changing in diameter, but no evidence was found that the changes were due to a peristaltic wave of contraction, a contractile motion like that of the heart, or a pulsatile motion conveyed from the heart. The mechanism of the changes is left uncertain. Curious gaps, probably due to an empty rather than a contracted condition of the capillaries, are occasionally seen, and possibly these are due to a momentary stoppage of the circulation caused by agglutination of the corpuscles. In the cases of auricular fibrillation the same variations, only greater in cardiac failure, were seen, but no evidence was obtained that cardiac failure provides a stimulus to capillary contraction. In well marked cardiac failure there was stasis of blood, which was relieved when the condition of the heart improved under the influence of digitalis.

BORDER COUNTIES BRANCH.

COMMEMORATION OF THOMAS ADDISON.

A MEETING commemorative of Thomas Addison, M.D., was held by the Border Counties Branch of the British Medical Association on Saturday, June 19th, at Lanercost Priory, where Thomas Addison is buried. The President of the Branch, Mr. Norman MacLaren, F.R.C.S., of Carlisle, presided over a large company of members of the Association and their friends, who filled the Dacre Hall. Among those present were Sir William Hale-White (London), Dr. G. T. Willan (Carlisle), Professor W. E. Humo (Newcastle), Dr. J. A. Ross (Carlisle), Dr. Joseph Hunter (Dumfries), Dr. G. B. Muriel (Whitehaven); and Professor Lorrain Smith, Dr. J. R. Drever, Dr. A. Goodall, Dr. James Davidson, and Dr. John D. Comrie (Edinburgh). The party were received in the Priory by the Rev. A. P. Durrant, who gave an address of welcome and a short description of the Priory. At the close of the meeting members visited Addison's grave, which is situated in a quiet sequestered spot under an old yew tree in the Priory churchyard, surrounded by rows of tombstones erected to Addisons and Addysons of bygone times. The party also had an opportunity of visiting Banks House, the home of Addison's forefathers, the Roman wall and camp at Birdoswald, and the neighbouring castle of Naworth, the seat of the Earl of Carlisle.

President's Address.

The President of the Branch, in opening the commemorative proceedings, referred to the fact that Dr. Thomas Addison sprang from a family of yeomen in Cumberland which had resided at Banks House in the parish of Lanercost since the time of the Commonwealth. Joseph Addison, the father of the physician, had traded as a grocer at Long Benton near Newcastle-on-Tyne, married Miss Sarah Shaw, and had two sons, John and Thomas, the latter of whom they were met that day to honour. Thomas Addison had been born at Long Benton in 1795 (not 1793 as generally stated), and although designed by his father for the law had himself chosen medicine as a profession. At Newcastle Grammar School he had obtained a masterly knowledge of Latin, which he spoke and wrote fluently. He had not followed the ordinary usage of the day in being apprenticed to a surgeon-apothecary, but had gone direct to Edinburgh to commence his medical studies. Mr. MacLaren referred also to Addison's marriage in 1847 at Lanercost Church to Elizabeth Catherine, widow of Mr. H. W. Hauxwell, to his death at Brighton on June 29th, 1860, and his burial on July 5th at Lanercost Priory, which had been associated for seven and a half centuries with the names of Robert de Vallibus, the founder, with Belted Will Howard, and with other warrior knights, abbots, and yeomen of the borders, and which Addison had loved so well.

Edinburgh Studies.

Dr. John D. Comrie followed with a description of the medical school as it existed at Edinburgh in the years 1812-15, when Addison was a medical student there. He referred to the fact that Addison had been a fellow student of Richard Bright, with whom he was in later life associated as physician to Guy's Hospital and as writer of an important textbook on medicine. During his first session at the university, Addison had taken the classes of chemistry and midwifery, and had apparently studied anatomy under one of the extramural teachers who were successfully competing against *Monro Tertius* in his declining years. In his second year Addison worked with extraordinary assiduity, attending no fewer than eight classes—those of *materia medica*, practice of medicine, institutes of medicine, anatomy, botany, clinical medicine, clinical surgery, and obstetrics. In addition to this, he

had been a member of the Royal Medical Society, but he had not reached the presidential chair, as had been commonly stated in his biographies. In his final year, 1814-15, the number of classes which he attended was more reasonable, these being clinical medicine, practical anatomy, chemistry for a second time, and *materia medica* for a second time. It was interesting to notice that he had twice over attended the *materia medica* class, taught by Professor James Home, who had been a very popular lecturer and from whom Addison had learned those principles which he later taught with great success as lecturer in *materia medica* at Guy's Hospital. Dr. Comrie described the personal characteristics of several of Addison's professors, who had apparently done much to mould his character, in particular Professor James Gregory, from whom he had learned medicine and who had attended Addison through a serious illness. Addison graduated M.D. in August, 1815, with a thesis, "*De Syphilide et Hydrargyro*."

Tribute by Sir William Hale-White.

Sir William Hale-White continued the story of Addison's life by describing the discoveries he had made at Guy's Hospital. He had entered as a perpetual physician's pupil at Guy's in 1817, held an appointment as house-surgeon to the Lock Hospital, and had been a pupil and physician at the General Dispensary, under the celebrated Dr. Bateman. What kind of a man had Addison been? the lecturer asked. The two persons best able to answer this had been Wilks, who was his pupil, and Lonsdale, his doctor friend in Cumberland. Wilks had attributed Addison's success to a personal power much superior to what Bright could ever claim, and equal to, if not greater than, that of Sir Astley Cooper. The students had worshipped him, but feared rather than loved him. He had been melancholy and liable to fits of depression and at times appeared haughty, unapproachable, and even rude, a failing which Addison realized and attributed to nervousness. Sir Samuel Wilks had given the following description of Addison's personality:

THOMAS ADDISON, M.D.

"He was dogmatic in his teaching and thus the pupils accepted as pure gospel every word which flowed from his lips. The force of his words was enhanced by his mode of delivery and by the presence of the man himself. Addison was of good height and well made, stood erect, with coat buttoned up very high, over which hung his guard and eyeglass. He wore a black stock with scarcely visible shirt collar, and this further elevated his head. He had a well proportioned good head, with dark hair and side whiskers, large bushy eyebrows, and smallish dark eyes, nose thick, as were also his lips, which enclosed his firmly knit mouth. His features were not refined, but belonged to a powerful mind, and showed no trace of any kind of sentiment. His penetrating glance seemed to look through you, and his whole demeanour was that of a leader of men, enhanced by his somewhat martial attitude."

Lonsdale had recorded that Addison loathed advertisement, indignantly refusing to write what he called "puffery," that he was musical, in politics a Tory, and he had considered that Addison would have risen to the top of any profession he had entered. Great as had been Addison's reputation among those of his own profession who knew him, he had not been successful in building up a large practice, and he had been almost unknown to the general public. He had thus been left free to teach and to make his discoveries. Now, however, his fame was world-wide, not only because he had been a great personality, a brilliant teacher, and an exceptionally successful diagnostician, but because he had made several fundamental discoveries in various departments of medicine. Sir William Hale-White mentioned seven points which had especially established Addison's reputation. It was difficult

to estimate the relative importance of these, but, taking them in the order in which Addison had published them, they had been the following. He had been the first to teach the clinical signs presented by a patient with a fatty liver. He had been the first to give an account of the symptoms and post-mortem appearances of appendicitis, and although this fact had long been forgotten the description of appendicitis given by him in *The Elements of Practical Medicine*, published in 1839, left very little to be added at the present day. He had demonstrated that pneumonia was not an inflammation of the tissue of the lung, but an inflammatory exudate into the air cells, and this process was now so completely recognized that it was difficult to realize that it had once required to be discovered. He had demonstrated that tubercles were not the sole cause of the change in the lung in phthisis, but that ordinary inflammation contributed, or, in present-day language, that phthisis was a mixed infection. He had pointed out that xanthoma, or, as he called it, vitiliginoid, of which he gave the original description, was associated with jaundice. He had discovered the existence of the severe anaemia often called pernicious anaemia, but better named Addison's anaemia, and he had given a perfect clinical description of it. He had discovered the existence of a disease due to destruction of the suprarenal capsules, which was now called Addison's disease, had given a complete clinical description of it, and had thus laid the foundation of modern endocrinology. Sir William Hale-White considered that Addison's greatest contributions to the advance of medicine had been those associated with diseases of the lungs. He had given an admirable and detailed description of the phenomena of pneumonia based upon careful pathological examinations. He had demonstrated also that the condition described by Laënnec as "earnification" was due to compression of the lung by fluid in which inflammation played no part. As regarded the pathology of phthisis, he had enunciated that "inflammation constitutes the great instrument of destruction in every form of phthisis," and he had added, "I very much question whether there ever was a single instance of tubercular disease of the lung proving fatal, in which symptoms of this pneumonic change might not have been distinctly recognized if the prevailing notions respecting tubercular infiltration had not obscured the perception of the beholder." This view, in opposition to the teaching of the great Laënnec, had afterwards been accepted by Reinhardt, Virchow, and other modern observers. It was curious that, although Addison was greatly honoured abroad, and although no man had ever been held in greater esteem at Guy's Hospital than Addison, the medical public in England paid little attention to him or to his discoveries during his lifetime. Only one medical paper, the *Medical Times and Gazette*, thought it worth while to notice the great man's death, while the Royal Society and the universities had passed him by in the honours they had to give, and he had held no court appointment. He had not been a member of the newly formed Pathological Society, and the Royal Medico-Chirurgical Society had refused to publish some of his papers, even after he had been president of it.

The meeting concluded with a vote of thanks to the lecturers who had come from London and Edinburgh for the commemoration.

THE HEALTH OF THE ARMY.

ANNUAL REPORT FOR 1924.

THE Report on the Health of the Army for 1924¹ has appeared within four months of the report for 1923. The expediting of these reports, as well as certain marked improvements in their character and arrangement (commenced in 1923), must be regarded as evidence of the earnest endeavour of the War Office to meet the frequently expressed desire for less delay in their issue. A record of the health of the Woolwich and Sandhurst cadets, and of the boys at the Technical School, Beachley, has been added to the 1924 report.

¹ Report on the Health of the Army for the Year 1924. Vol. 15. London: H.M. Stationery Office. (8vo, pp. iv + 146, with 75 statistical tables and 2 charts. Price 3s 6d. net.)

In an average strength of 10,231 officers the admission and death rates were 284.4 and 5.86 per 1,000 respectively, as compared with 286.9 and 3.93 in 1923, 298.3 and 4.48 in 1922, and 374.2 and 5.90 in 1921. Among other ranks, with an average strength of 192,283, the admission rate was 484.7 per 1,000, as compared with 484 in 1923 and 515.8 in 1922; while the death rate was 2.80, against 2.84 and 3.22 in the two previous years. In the year before the war the admission rate was 437.7 and the death rate 2.81. Although these rates do not indicate a higher degree of health in 1924 than in 1923, the ratio of invaliding from overseas fell from 8.65 per 1,000 of strength to 7.12, and of finally discharged as unfit for further service from 14.50 to 13. A much more favourable result would have been recorded but for the high incidence in the final discharge of invalids from India, which rose to 14.74 per 1,000, as compared with 8.47 in 1923. The constantly sick rate for the whole army also showed a slight decrease—from 28.54 to 27.11 per 1,000.

The chief causes of admission to hospital were malaria (13,644 cases), venereal diseases (9,193), influenza (6,654), tonsillitis (5,248), inflammation of areolar tissue (4,322), bronchitis (3,509), sandfly fever (3,005), and sprains (2,245). Influenza was widely prevalent during the year, the admission rate being 34.6, as compared with 7.6 per 1,000 in 1923. Malaria and bronchitis showed a slight increase in the admission rate, but there was decrease in the incidence of sandfly fever, venereal diseases, dysentery, and most of the other diseases. Only 14 cases of alcoholism were admitted throughout the whole army.

The highest ratios of inefficiency from sickness occurred in Iraq, West Africa, and China, and the lowest in Bermuda, Mauritius, the home commands, and Gibraltar. A marked improvement is shown in the health of the army on the Rhine, the constantly sick rate falling from 42.33 in 1923 and 64.49 in 1922 to 27.31 in 1924. This good result is attributed to a remarkable decrease in venereal diseases, the admission rate for which was only 38.4 per 1,000, as compared with 136.3 in 1923. Venereal diseases, both in the army as a whole and in individual commands, is gradually being reduced by a *cordon sanitaire* of moral and medical education, recreational and medicinal prophylaxis, notification and treatment.

In the summary of diseases and disabilities a short note on dysentery is important in view of the controversy that arose in connexion with the record of amoebic dysentery in 1923. The report for 1924 gives no information regarding the commands in which this form of dysentery occurred, but states that, of a total of 810 admissions, 707 were diagnosed as amoebic, 48 as bacillary, 54 as unclassified, and 1 as a carrier. As 669 of the cases occurred in India and 39 in Iraq, it may be assumed that the majority of the cases diagnosed as amoebic were geographically east of Suez, a fact which again corresponds with previous official returns. Doubts are, however, being thrown on the accuracy of the diagnosis, and investigations are now proceeding to determine whether, as has been suggested, bacillary dysentery is not more prevalent than the records disclose.

Enteric fevers were, as usual, more prevalent in India than in other commands, the ratio of admissions being 3.1, as compared with 2.3 in 1923; but for the whole army the ratio (1.1 per 1,000 of strength) is exactly the same as in the previous year. Several of the cases in India were traced to carriers employed in connexion with food or drink. Although over 95 per cent. of the troops in India were inoculated against enteric the report does not tell us how many of the 181 cases had been so protected. In this connexion the printer has allowed a mysterious parenthetical note—" (Para. omitted. See p. 143 of draft) "—to appear. Page 143 of the report, however, has no reference to the matter; it is a table of Iraq statistics, and the substance of the omitted paragraph must therefore be left to conjecture.

An interesting account is given of the occurrence of six cases of typhus in Malaya, although these are not shown in the statistical tables either of the whole army or of the Malaya garrison. The cases occurred among men in camp, near Kuala Lumpur, on ground over which native herdsmen, who suffer sporadically from the disease, had grazed their cattle. There was no evidence of infectivity by the agency of lice, and ticks are suggested as the vectors.

In the report on the activities of the special departments the value of the drug "von Heyden 471" in the treatment of kala-azar and Oriental sores, and the use of stovarsol in place of emetine in amoebic dysentery, are noted. The report on surgery is evidence of thoroughly up-to-date work on the part of the army surgical specialists.

In the section on hygiene many sanitary improvements are noted, including provision of child welfare centres. A new emergency ration of 1,700 calorie value, weighing 21 oz., is being tried in place of the existing ration of 2,800 calories and 38 oz.; and experiments are being conducted for better distribution of the load carried by the soldier, and for sterilizing water

by compounds of ammonia and chlorine. In the pathological department the more important researches dealt with were the production of an antidyenteric vaccine, investigating values of various serological tests for syphilis, serological work, in connexion with the food poisoning group of bacilli, and the relation of diphtheroid bacilli to skin ulceration. Recruiting is included in the work of the special departments; 57,066 candidates for enlistment were examined; 363.75 per 1,000 were rejected and 29.74 per 1,000 within six months after enlistment. In 1923 these ratios were 376.64 and 40.09 respectively. The marked decrease is attributed to better co-ordination of the medical recruiting methods. The greatest proportion of rejections were from Scotland—namely, 434.53 per 1,000, as compared with 360.89 from England and Wales and 309.99 from Northern Ireland. Diseases of the middle ear, defective vision, defects of lower extremities, loss or decay of teeth, and heart diseases were the chief causes of rejection. The remainder of the report, consisting of statistical tables, calls for no special mention, but it is to be noted that the table of tuberculosis incidence, according to age and length of service, which was open to criticism in the report for 1923, has been omitted.

THE MUSEUM OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ANNUAL REPORT OF THE CONSERVATOR.

IN his annual report for the year ending in June, 1926, the Conservator of the Museum of the Royal College of Surgeons of England refers to the changes which have occurred in the staff, to the work of the different departments of the Museum, to the research work undertaken at the College, and to the publications which have been issued and the lectures and demonstrations held in connexion with the Museum. Lists of gifts made during the year to the several collections are inserted, with comments on the specimens of special interest; and separate reports of the pathological and physiological curators, relating to their respective departments, are included in the main report. The post of pathological curator, left vacant by the lamented death of Professor S. G. Shattock, has been filled by the appointment of Mr. C. F. Beadles, who had long been connected with the Museum, assisted Professor Shattock in the formation of the great collection illustrating general pathology, and was mainly instrumental in the formation of the war collection which is at present housed in the basement of the building. With the exception of a certain number of dry specimens, the whole of the latter collection has been arranged and catalogued, and may be considered to be complete. Mr. Beadles is now engaged on the series of special pathology, and the revision and rearrangement of this collection, commenced by Professor Shattock, has made considerable progress, embracing the specimens of the cutaneous, locomotor, and nervous systems, and those of the heart and pericardium. The council of the College has been fortunate in obtaining the services of Mr. T. W. P. Lawrence, F.R.C.S., to advise in the diagnosis and description of all pathological specimens.

Among the additions to the pathological and teratological collections several are of unusual interest. One, the heart of a new-born child, shows complete obliteration of the aortic orifice, the sole communication between the left ventricle and the aorta being through a greatly enlarged anterior descending coronary artery, which at its lower end expands into a cyst communicating with the apex of the ventricular cavity. A second, almost identical, abnormality of the coronary artery is from an ox; in this case, however, the orifice of the aorta is normal. An equally remarkable specimen exhibits a general dilatation of the oesophagus of a dog, above a tight stricture due to compression in a ring formed on the one side by a right aortic arch and on the other by the normally placed pulmonary artery and ligamentum arteriosum. Among the specimens of more direct surgical interest is an uncommon form of tumour removed from the pleura, which has received the name of lipo-fibro-sarcoma or lipo-plastic sarcoma. It is characterized by the presence of extensive tracts of fat cells of the embryonic type, and when stained with Sudan forms a very striking object. Another interesting specimen has all the appearances of an ordinary ileo-caecal intussusception, but on closer examination

proves to be an invagination of the wall of the ileum, due to the presence of a submucous lipoma, and its prolapse through the valve in a form exactly resembling the bent sausage-shape of an intussusceptum. A very similar appearance, in another specimen, is produced by a large cylindrical cyst, six inches in length, of the type which is lined with intestinal mucosa and is recognized as liable to occur in the ileo-caecal region.

In the Physiological Department, among the additions to the collection are a number of specimens completing the series designed to illustrate the comparative anatomy of the ductless glands. The most interesting work in this department, however, is that of Mr. Burne, the curator, on the intimate relation of the thyroid gland to the lymphatic system. The results of his observations have been published in the *Philosophical Transactions*, and lend support to the conclusions drawn by Dr. Scott Williamson and Dr. Innes Pearce from the researches they are conducting at the College on the finer anatomy of the thyroid gland, details of which have already appeared in the *British Journal of Surgery*. The series of human osteology has had a notable addition this year in the form of a cast of the "Galileo" skull. The original specimen, which is the property of the Government of Palestine, and was sent to Sir Arthur Keith for examination and report, was excavated from a cave situated near the Sea of Galilee; it is of the Neanderthal type, and has the additional interest that it is the first example of that type found outside the limits of Europe. Another important addition is a cast of the "London" or "Lloyd's" skull, recently excavated in the City, and considered by Sir Arthur Keith to be the oldest trace of the human body yet discovered in the valley of the Thames. The Conservator has also had the opportunity of examining numerous other human remains excavated in this country, some of which have been added to the Museum, and has thus made progress in the accumulation of data bearing on the physical history of the English people. During the past year Miss Tildesley has been occupied in verifying the histories of the native Indian and Cingalese skeletons in the Museum, and more particularly in establishing the genuineness of the Vedda specimens—a point of importance, since that race is now ceasing to exist in its original purity. An interesting gift from the President, Sir John Bland-Sutton, deserves special mention. This is a fine specimen of the Mexican ligature ant (*Eciton hamatum*). The animal is used by the natives as a kind of animated Michel's clip in the suturing of wounds; it possesses two powerful mandibles with curved, sharply pointed extremities, and these, when the living animal is applied to the wound, grip its edges. The body is then cut away, leaving the head *in situ*; the prolonged contraction of the mandibular muscles effects a permanent closure of the wound.

The number of visitors to the Museum during the year was 11,168, many of them students. The new specimens will be on view in Room I from Thursday, July 1st, until Saturday, July 17th. The additions on the pathological side number as many as 140; this seems to indicate that members of the profession recognize the claim that the Museum has upon them, and their determination to maintain its position as the finest pathological museum in the world.

England and Wales.

ST. THOMAS'S HOSPITAL MEDICAL SCHOOL.

THE prizes were distributed at St. Thomas's Hospital Medical School by Sir John Bland-Sutton, P.R.C.S., on June 22nd. Sir Arthur Stanley, treasurer of the hospital, who presided, said that the governors were greatly indebted to the medical school and clinical staff for their successful efforts to raise the amount (£15,000) which enabled the hospital to take advantage of the equivalent sum offered as a benefaction by the Rockefeller Foundation. Sir Cuthbert Wallace, dean of the school, after presenting the other prize-winners, mentioned that, unhappily, the winner of the Bristowe and Mead medals, Mr. R. B. Alston, incurred a poisoned finger in the course of the examination,

and afterwards succumbed. His work in the two-thirds of the examination which he was able to undertake was so far ahead of his competitors that it was felt that his name should appear as the recipient of the awards.

Sir John Bland-Sutton, in his address, began by observing that the schools of medicine in London had formed a sort of archipelago with very little communication between the several islands. There had been times, indeed, when the schools were in absolute conflict; that was, happily, of the past, or what remained was the honourable antagonism of the sports ground. The insularity of London medical schools was in some measure due to the habit—in its way very meritorious—of filling up the places on a school staff by men trained in that school. This inbreeding had some serious drawbacks, but St. Thomas's had suffered least in this respect. He instanced that great physician of St. Thomas's, Richard Mead, who was educated in Holland and graduated at Padua. In 1703 he came to London, was elected to the Royal Society, and made a great name by writing a paper on a very trivial subject—namely, itch. But such was the reputation that he made for himself that St. Thomas's took possession of him. Another great transplantation to St. Thomas's of a later date was that of Sir William MacCormac, who was trained in Belfast, came to London, and eventually became President of the Royal College of Surgeons. Many would still remember his distinguished presence, subtly emphasized in his later days by the invariable company of a magnificent dog. In striking contrast was the slim figure of Professor Shattock, who was transplanted from University College. It was delightful to find in the museum at St. Thomas's, which he did so much to enhance, a conspicuous tablet to his memory. Addressing the students particularly, he said that a medal was only a piece of metal, of no use in currency, struck to commemorate some person or event, but some medals were very beautiful objects, of great intrinsic value, as well as imaginative and inspiring. The Royal Society, which had eight gold medals to present annually, at one time found that certain of the persons to whom they were awarded, being impecunious, as scientists frequently were, were selling them for their value in gold, which in one instance was as much as £50. Accordingly it had now become the custom to give the medal in silver or bronze, and to hand the balance to the recipient in cash. He had himself profited in his early days from such an arrangement, and on his prize money he had wandered in Europe, visiting Paris and Vienna; there was no better way of preventing any undue conceit in a medallist than that he should go into the wider world and so discover that there were other men as good as himself who had done work at least as excellent. Medals were milestones in the history of an institution; they were given, not for ostentation, but for remembrance and reward. They brought to mind the names of great men who laid the foundations of that which the present generation enjoyed, and which it would be the duty of those who came after to extend.

Sir George Makins proposed, and Dr. A. E. Russell, senior physician, seconded, a vote of thanks to Sir John Bland-Sutton, after which the visitors were escorted round the hospital, and enjoyed tea and music on the terrace.

THE CRIPPLE PROBLEM IN ESSEX.

On June 18th Sir Robert Jones gave an address at River Plate House, Finsbury Circus, on the cripple problem, at the invitation of the Essex County Council. Alderman H. E. Brooks presided. Sir Robert Jones said that there were 100,000 cripples in the country at the moment, and a large proportion of them were even now becoming steadily worse. Big things had to be done for them because little things were not done at an early stage. The majority of cases not caused by war fell, he said, into four or five groups: tubercle; rickets; the paralytic group, due directly to infection; congenital defects, such as club-foot; the industrial group, due to accidents. For tuberculous cripples, he said, there ought to be a national scheme. Tubercle affecting bones, glands, and joints was due to infection, and was not hereditary. Congenital tubercle was a different thing; it dated from the time the child started to live and was so rare that it need not be taken into account. Sir Robert Jones said

that 60 out of 100 cases of bone and joint tubercle were due to the *bovine bacillus*. To prevent infection by the human bacillus some means must be found to safeguard children from coming in contact with people in the active stages of the disease. Cases sent home from sanatoriums to die were dangerous, and in a room occupied by a tuberculous person the carpet was infected, and children playing in the room would become infected. Rickets, said Sir Robert Jones, was absolutely under control and could be prevented by proper diet, sunlight, and fresh air. The hunchback might have escaped his deformity if it had been discovered in infancy and he had been put to lie down in proper surroundings; the club-foot, if moulded into shape when discovered, could have been put right, but left for three or four years was all but incurable. In any scheme Essex adopted there should be beds for adults as well as children, and there should not be too much strictness about the age when a child ceased to be a child, so that he might be perfectly recovered when he went out. A suitable hospital would not be too expensive. Essex with its population of nearly a million would want 300 beds. In regard to after-care clinics, he said the cost of looking after children in them was about £4 a year, as compared with £130 a year in a hospital.

ORTHOPAEDIC HOSPITAL AND HOME, BRISTOL.

The forty-ninth annual meeting of the Orthopaedic Hospital and Home for Crippled Children, Redland, Bristol, was held on May 31st. The hospital is one of the oldest in England for the treatment of crippling disease. A joint subcommittee with the Bristol Crippled Children's Society has been appointed to make arrangements for amalgamation of the two bodies, with a view to building a new country open-air hospital school, and abandoning the present little hospital and home. Mr. G. R. Girdlestone, surgeon to the Wingfield Orthopaedic Hospital, Oxford, in the course of an address, called attention to the difference between orthopaedic work in the present and in the past. The difference was not so much an improvement in surgery as an improvement in the work done by committees and the public. Orthopaedic hospitals in the past did wonderful work, but their cures were rarely perfect; the patients were only patched up. Then the time came when they got hold of children a little earlier; infant welfare centres realized that if cases were sent early to an orthopaedic hospital they came back cured. When perfect co-operation was achieved, children would be sent at once from general hospitals and by private practitioners to orthopaedic hospitals. What was needed was a union and real teamwork between the hospitals. The Bristol Orthopaedic Hospital and Home was going to have an institution in still more country air, so that during treatment the children could keep in touch with nature. The quality of the present work of the home showed how well it would be done when a proper institution was available. A vote of thanks for his address was given to Mr. Girdlestone.

CENTRAL MIDWIVES BOARD.

The Central Midwives Board for England and Wales on June 3rd held a penal session followed by an ordinary meeting. The following were appointed members of the Approvals Subcommittee for the ensuing year: Dr. J. S. Fairbairn, Miss E. G. Greaves, Miss M. D. Haydon, Dr. R. A. Lyster, Miss A. A. I. Pollard, and Mr. Charles Sangster. A letter from the Ministry of Health was considered. It proposed, for reasons stated, to extend the approval of the rules in their present form for a further period—until September 30th, 1926—and expressed the hope that by that date all suggested amendments to the rules would have been settled, so that the rules, when approved, might remain in force as long as possible without further alteration. In reply the Board expressed the view that it would welcome a return to the original practice of approving the rules for a period of five years. A letter was read from the Poplar guardians stating that the chairman of the guardians and the chairman of the committee directly concerned could not understand the Board's view that the medical officer referred to in Rule E.27 must be a resident medical officer, and asking for the Board's observations on the matter. It was decided to

reply that in the view of the Board the supervision referred to in Rule E.27 could not be exercised satisfactorily by a non-resident medical officer, and that the word "resident" was implied in the words "duly appointed" in the intention of the Board. The appointment, therefore, of a non-resident medical officer, in so far as the rule in question was concerned, could not be considered "due." The report and recommendations of the Approvals Subcommittee were received and adopted. The next meeting will be held on July 15th.

Scotland.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

THE twelfth annual conference of the National Association for the Prevention of Tuberculosis will be held in the McLellan Galleries, Sauchiehall Street, Glasgow, on the first three days of July next. The conference will be formally opened by Sir Matthew W. Montgomery, Lord Provost of Glasgow, at 10.30 a.m. on July 1st. The first subject for discussion, "Provision for the care of non-pulmonary tuberculosis," will be opened by Dr. A. S. M. MacGregor, medical officer of health for the city of Glasgow, and by Mr. James Taylor, consulting surgeon to the corporation hospitals and sanatoriums. Other speakers will be Dr. J. H. Paul of Millport and Dr. J. G. Johnstone, medical superintendent, Heatherwood Hospital, Ascot, Berks. In the afternoon Professor Sir Robert Philip and Dr. Lissant Cox, central tuberculosis officer to the Lancashire County Council, will open a discussion on "The actual place and function of the tuberculosis dispensary in the tuberculosis scheme." Other speakers will be Dr. W. B. Knobel of the London County Council, Dr. J. A. Wilson, Glasgow Public Health Department, Dr. William Brand, tuberculosis officer for Camberwell, Dr. James Crockett, medical superintendent of the Bridge of Weir Sanatoriums, and Dr. J. McCallum Lang, assistant medical officer of health, county of Lanark. On the morning of July 2nd there are four subjects for discussion: "Experimental studies in tuberculosis with reference to the origin of pulmonary tuberculosis," introduced by Professor C. H. Browning, professor of bacteriology, Glasgow University; "The age factor in the incidence of tuberculosis," by Dr. J. A. Wilson; "Some experiences in the treatment of tuberculosis by artificial sunlight," by Dr. Alexander Smith of the Robroyston Sanatorium; and "Glasgow's solution of the smoke problem," by ex-Bailie Brownhill Smith, chairman of the Committee on Health, Corporation of Glasgow. The afternoon of July 2nd and the morning of July 3rd will be devoted to visits to various institutions and to demonstrations. Thus visits have been arranged to corporation housing schemes; to hospitals, sanatoriums, and tuberculosis colonies; to the tuberculosis dispensary and light treatment centre; and to the corporation bacteriological laboratories. Demonstrations will be given by Dr. Fergus L. Henderson of radiograms of the chest, and by Drs. James Taylor, John Watson, and A. Smith of the methods of treatment of non-pulmonary tuberculosis. The Hon. Sir Arthur Stanley, chairman of council, will preside at the meetings. There will be a reception by the Lord Provost and magistrates of the city of Glasgow on the evening of July 1st; and a list of tours to places of interest will be published. The conference is open to all persons on the payment of a fee of one guinea, and each subscriber will receive a copy of the report of proceedings. Reduced fares to Glasgow will be available if normal conditions prevail. Miss Freda Strickland is secretary to the association, of which the address is 20, Hanover Square, W.1.

EDINBURGH HOSPITAL FOR SICK CHILDREN.

The annual meeting of the Royal Edinburgh Hospital for Sick Children was held on June 2nd. Sir John R. Findlay, chairman of directors, who presided, said that while in 1915 the total number of cases treated was 2,100, in 1925 it was 2,968, an increase of 868 in ten years. Speaking of the financial position, he observed that it would be satis-

factory were more received in the form of annual subscriptions and less in the form of legacies, for the actual maintenance of such an institution should be the work of the present generation. Sooner or later the public of Edinburgh would have to face the problem involved in a large extension of this hospital, which was doing most important work in the city and neighbourhood. Lord Provost Sir William L. Sleigh expressed the opinion that the care of children and the healing of their diseases ought to be the first charge on the benevolence of the community, for if the troubles with which children were affected could be eliminated or diminished a long step would have been taken in the direction of building up a Class A population. The report for the year 1925, submitted to the meeting, showed that of the 2,968 cases treated in the wards 1,642 were medical and 1,213 surgical. The number of operations performed in the surgical theatre had been 1,112. At the out-patient department the number of attendances was 25,958, and 2,063 minor surgical operations had been performed. In the medical electrical department 1,482 radiographic examinations had been made, and in the ear and throat department there had been 1,079 new cases with 659 operations. The ordinary income for the year had been £12,270, with an ordinary expenditure of £16,379, and the legacies had amounted to £10,907. The report mentions a new department for treatment by artificial sunlight. The directors had set apart a portion of the out-patient department, consisting of two rooms and a nurses' room, in which patients could receive treatment by ultra-violet rays, and although it had only been open for a short time great benefit had already been derived by the patients from this form of treatment.

INFLUENZA EPIDEMIC AT ST. KILDA.

The island of St. Kilda occupies a position in the Atlantic which, combined with the precipitous nature of its coast, renders all access during the winter months difficult or impossible. The s.s. *Hebrides* made its first call for the season on May 30th for the purpose of landing provisions. The last visit had been paid in August, 1925. The steamer reports by wireless that an influenza epidemic has been ravaging the island for some weeks and has been accompanied by five deaths, of which four took place within a week. The epidemic apparently broke out after the arrival of the mail boat in the late spring for the delivery of this year's mails.

Ireland.

BELFAST MEDICAL APPOINTMENTS.

THE Belfast board of guardians has taken another step in its progressive policy, to which has been due in the past so many advances in the care of the large number of patients under its charge. The late Dr. McLiesh had charge of the midwifery department, of a large number of patients with nervous and mild mental trouble, and of many medical cases. At the meeting of the guardians held on June 15th two medical men were appointed—one, Mr. T. S. Holmes, M.Ch., F.R.C.S. Eng., to be in charge of the maternity and gynaecological departments; and the other, Dr. T. H. Crozier, M.D., M.R.C.P. Lond., to be physician in charge of medical cases. The profession in Northern Ireland will hasten to congratulate the board on the wisdom of this further specialization of its visiting medical staff, which relieves the medical men of an intolerable burden, and at the same time enables them to give the patients more skilled specialized treatment.

LOCAL AUTHORITIES BILL (IRISH FREE STATE).

In the committee stage of the Local Authorities (Officers and Employees) Bill, Mr. P. Baxter (Farmers' Party) moved an amendment to provide that, instead of recommending one candidate, the Civil Service Commission should forward to the local authorities a panel of candidates adjudged by them to have reached the standard of qualifications necessary to perform the duties of such office. Dr. Hennessy opposed the amendment as in practice it would mean that a local candidate would be appointed even

though in regard to merit he was at the bottom of the list. From personal experience he knew that it was a distinct disadvantage for a doctor or an official to have to discharge public duties in his native county. Acceptance of the amendment, he was convinced, would vitiate the whole scheme. The Minister for Local Government said that Mr. Baxter had made no serious case for his amendment. Appointments should be made either by competitive examination or by a selection board. If the former were not accepted as the proper system, he could not see what benefit would accrue from submitting the results of an examination to what was, perhaps, the worst qualified body to decide the final result—the members of a local authority. If competitive examination did not give the best results an attempt should be made to get a body as far removed from all local influence as possible. The intention of the bill was to close the door to abuses. The only effect of the amendment would be to open the half-door to those things. Mr. Baxter's amendment was defeated on a division by 52 votes to 12, and a ministerial amendment, embodying the new form in place of the original subsection, was agreed to, as were consequential amendments substituting where necessary the words "local authority" for the word "Minister."

Correspondence.

VOLUNTARY TREATMENT IN MENTAL HOSPITALS.

SIR,—I desire to bring an important medical issue, affecting the community, to the notice of the medical profession in Scotland.

In itself mental illness is always distressing, but it is made much more so if, before treatment can be obtained, a patient must be certified by doctors and registered by the sheriff as a "person of unsound mind." This additional suffering is, however, in most cases quite unnecessary. It is, for example, not inflicted on the majority of patients of the richer classes, for these regularly enter our mental hospitals not as certified but as voluntary patients. Their admission as such enables them also to avoid the slur that unhappily attaches to those who have been treated in mental hospitals, as in the eyes of the law a voluntary patient, whatever his mental condition may be, is not regarded as a "person of unsound mind." To many it may come as a revelation that two-thirds and more of those with means who undergo treatment in our mental hospitals do so as voluntary patients.

The poor are entitled to exactly the same privileges as those with means, but owing to ignorance and misunderstanding their rights have not been brought to their notice, and in consequence over 99 per cent. of rate-supported patients are certified and registered as "persons of unsound mind." Not 1 per cent. receive treatment as voluntary patients. There is something amiss when such a difference exists in the means of obtaining treatment for an illness by members of these two classes.

Among the misunderstandings is the belief that a voluntary patient costs the ratepayers more than a certified patient. In the latter case it is said the Government gives a grant-in-aid amounting to £7 9s. 6d. per annum, whereas no such relief is afforded the ratepayer in the case of a voluntary patient. This is an error. The cost to the ratepayers is exactly the same in both cases, as the Government grant is not calculated on a capitation basis but consists of a fixed sum given annually as a grant-in-aid to the parishes, irrespective of the number of patients or whether they be certified or voluntary.

Another impression commonly held is that no person of unsound mind whom it is possible to certify can be admitted as a voluntary patient. This also is an error. It has been stated by the highest legal authority on matters connected with lunacy—and his views have not been opposed officially—that if such a condition ever existed it was repealed in the Act of 1913. There is one condition and one only to be observed, and it is that the patient should desire to submit to treatment. The procedure is simplicity

itself. The patient gives to the medical superintendent the following letter:

Dear Sir,—I desire to be admitted as a voluntary patient to the (name the mental hospital). I am, etc.

In other words, a patient entering a mental hospital voluntarily has to express his wish in writing. He has also to give three days' notice of his intention to leave. A rate-supported patient desiring this form of treatment must have the approval of the officials of the parish council—namely, the medical officer and the inspector. I would appeal to every doctor in Scotland to make this provision known to the poor and to recommend every patient of his requiring treatment in a mental hospital to enter as a voluntary patient.

Only those who have seen the distress that medical certificates and sheriff's orders occasion to patients and to their relatives, and know how unnecessary they are in the majority of cases, can realize all the good that will result from following the above advice. The sick in mind and the poor will benefit, and mental hospitals will, we hope, be regarded, not as places of detention, but as hospitals for medical treatment like other hospitals. As for doctors, they will be relieved of a distasteful, a thankless, and a perilous public service.—I am, etc.,

GEORGE M. ROBERTSON.

The University of Edinburgh, June 21st.

OBSTETRICS IN GENERAL PRACTICE.

SIR,—As one with eighteen years' hard midwifery and general practice, both country and town, behind him, may I claim a line on the above subject?

Dr. Kerr leaves me with the impression that all the ill pregnant women are heir to lie at the doors of dirty and careless and ignorant general practitioners. I may say, of course, that in this he is simply echoing what has been before said by Drs. Mclroy, Bourne, and Dano Janet Campbell. Therefore, he says, "remove midwifery from the sphere of the general practitioner and hand it over to midwives and (in Glasgow) ten obstetric specialists."

At the same time, so logical is his mind on the matter, he would prolong and intensify the study of obstetrics by the medical student, and would like general practitioners every three years to take a "refresher" in midwifery. They can then go out and see the midwives and obstetric specialists doing all the midwifery!

He says that of 29,493 births (in Glasgow in 1922) only 8,288 were attended at their homes by doctors. The rest were either attended in institutions or by midwives. Now how can the general practitioner be blamed for all the sepsis? Can he give us the percentage of sepsis in these 8,288, the percentage of sepsis in the 3,025 attended in institutions, and in those attended by midwives? Will he give us his own sepsis percentage?

He compares an operation in general surgery with a midwifery delivery. They cannot be compared, because once a surgeon gets his area aseptic he can keep it so, whereas neither Dr. Kerr nor anyone else ever delivered by the natural passages on a constantly or totally aseptic field. Dr. Kerr, I am sure, is wrong in viewing pregnancy as any more a battle ground than normality is. In all nature pregnancy is a revivifier. It is so normally in women. I grant that a cracked vessel under strain may break. I had the good luck to be for two years under a general practitioner with fifty years' experience. He often impressed on me the fact that practically all his cases of albuminuria of pregnancy occurred in patients where at one time or another the kidney had been hit by scarlatina, etc. He distinguished quite sharply between those cases of simple presence of albumin due to the greater call on the excretory organ (this comes late in pregnancy and is not of great moment) and the scanty but constant albumin which came early and meant old kidney trouble relighted. He did not believe pregnancy *per se* caused albuminuria. His views appear more reasonable than Dr. Kerr's. Dr. Kerr is going to fine or bribe the women to go to his centres by docking or giving them the maternity benefit.

In eighteen years I have attended close on 2,000 cases, with almost exactly one case of puerperal sepsis in every

200 cases. All these were in Glasgow and all in good home conditions. All died.

I have delivered bad cases at the call of midwives under every possible adverse condition, and not one ever turned a hair. Dr. Kerr talks about young and inexperienced men muddling along in midwifery. Of course they do. So did Dr. Kerr. That stage soon passes.—I am, etc.,

Dennistoun, June 15th.

JAMES COOK, M.B.

HYOSCINE IN POST-ENCEPHALITIS LETHARGICA.

SIR,—The use of the term "hysterical" in the article on post-encephalitis lethargica by Drs. McCowan, Harris, and Mann (May 1st, p. 779) raises the question as to the signs and symptoms to which it is applied. Do these authors mean by "hystoria" a condition which is influenced by suggestion, or do they use the term as synonymous with functional—that is, a condition which does not appear to be dependent directly on any demonstrable lesion? Experience teaches us that although, as Dr. Ross has pointed out in his letter (May 8th and 15th, p. 845), direct psychotherapy is rarely of value in the post-encephalitic syndromes, much can be done by such indirect methods as can be applied in an institution—namely, by encouraging the patient to join in the occupations and amusements he sees going on around him, as well as by physiotherapy and drugs.

When Dr. Ross says that hysterical symptoms are not modified in an easy fashion he is making a sweeping statement which, I am sure, he would wish to qualify. One is occasionally fortunate enough to meet with functional disorders of movement which have not had time to become habits, and which react to persuasion with dramatic rapidity. The rapid result surely does not exclude hysteria, as Dr. Ross seems to imply. Again, his statement that the post-encephalitic obtains a better result by conscious attention to his movements is not always borne out by experience. It often happens that when the patient forgets his disability the rigidity is relaxed—for example, when he runs or dances. To say that no practical result is to be gained by any psychological method is, to say the least, unduly pessimistic, unless the methods of indirect psychotherapy are to be excluded as psychological treatment.

The outcome of this discussion is a striking demonstration of the dangers of insisting on too rigid a division between "physical" and "mental." The pragmatic conception of psycho-biology adopted by American psychiatry avoids both the Scylla of attempting to reduce "mind" to neurons, and the Charybdis of a psychic monism, by considering the whole individual and attending to abnormality of function at whatever level (chemical, autonomic, mid-brain, etc., or level of highest integration) it may occur without overlooking its relation to the whole personality. It is by a wide view of this kind that the general practitioner with a human, common-sense approach sometimes succeeds when the specialist who focuses his attention on one system fails. It is more than doubtful whether "physiogenists" and "psychogenists" cling closely to their creeds in practice.—I am, etc.,

WILLIAM S. DAWSON.

The Johns Hopkins Hospital,
Baltimore, Md., June 4th.

ANGINA PECTORIS.

SIR,—Dr. Wynne (June 12th, p. 1012) has forgotten not only (as he is aware) who wrote his *angina* line, but also (as he is unaware) what the writer wrote. The author is Q. Serenus Sammonicus, dated conjecturally A.D. 230. The line, very unfortunately, does not begin "Haustum an/gina ti/bi," but "Angina/ vero si/bi"; quotations from memory on disputed points of quantity are tricky things.

A friend happened to send me a few days ago an apposite anecdote: A brother don burst into H. A. J. Munro's room at Cambridge and cried, "Macaulay has died of angina pectoris!" Munro looked up, said "angina," and returned to his Lucretius.—I am, etc.,

H. W. FOWLER.

SIR,—Mr. E. E. Sikes, President and classical lecturer, St. John's College, Cambridge, writes (BRITISH MEDICAL JOURNAL, June 12th, p. 1012) of "a living wit," who remarked that many scientific words "are compounded of two languages and one false quantity." Can this be Dr. H. R. Tottenham of the same college?

In Dr. Tottenham's *The Highest Locals* (republished from *Cambridge Review*, December 4th, 1890, in "Chivicius His Thoughts," Cambridge, E. Johnson, 1895), which he calls "a strictly confidential report," we read:

"Group W. (Botany).—... Candidates should remember that even the meanest plant has a right to be described by two Latin words and a false concord, if possible."

And again:

"Group A. (Biology).—As there was only one Hydra provided, which was eaten by Rana early in the examination, the practical part fell through, especially as some of the more self-respecting students refused to discuss Lumbricus, which for the purposes of the examination was pronounced with a short 'i.'"

—I am, etc.,

Grasse, A.-M., France, June 15th

HENRY L. P. HULBERT.

ANTIMONY IN ANCIENT EGYPTIAN MEDICINE.

SIR,—Sir StClair Thomson's communication¹ to the Royal Society of Medicine on March 17th, 1926, on "Antimonyall cups" was very informing and interesting. He dealt in an admirable way with the history of antimony in medicine, and traced it back to the time of ancient Egypt, when he quoted Herodotus as saying that "the ancient Egyptians were the healthiest of mankind, and three days in every month they used emetics and enemas." He also regarded antimony as possibly included in the preparation with which Jezebel "painted her face and tired her head" (2 Kings, ix, 30).

The use of antimony in ancient Egyptian medicine is very old; it is mentioned in various papyri, like the Hearst medical papyrus and the Ebers papyrus, both of which date about 1550 B.C. Thero antimony is recommended for many different conditions. As an emetic I was not able to trace it in the medical papyri, but as a local remedy it was used enormously.

The ancient Egyptian name of stibium is *més-demt*. Antimony was used by the ancient Egyptians in:

- (1) Headache: antimony combined with other remedies, locally applied.—Ebers, 260.
- (2) Purulent conjunctivitis (?): local application to eyes.—Ebers, prescription No. 354.
- (3) Trachoma (?) (*pedest*): locally applied in combination with copper sulphate (?) (*gesfen*).—Ebers, prescription No. 355.
- (4) Proctitis: antimony enters into a suppository.—Ebers, prescription No. 155.
- (5) To cause an abscess to open by itself (?), as a local remedy.—Hearst Medical Papyrus, prescription No. 141.

—I am, etc.,

H. KAMAL, M.B., B.S., M.R.C.S.,

L.R.C.P.

Government Fever Hospital, Cairo, Egypt.

April 30th.

FOOT-AND-MOUTH DISEASE.

SIR,—I quite agree with the opinion expressed in your last issue (p. 1002) "that the pole-axe method cannot be indefinitely used to stamp out" foot-and-mouth disease; as a practical remedy it has been a failure, and can only be beneficial in isolated or early outbreaks. When the incidence of the disease has been so general as recently it is a waste of public money.

I had considerable experience with "epizoötic apthae" in the early seventies, and came to the conclusion that the positive loss to the farmer was the loss of condition the animals sustained owing to the mouth ulceration preventing the animal eating, and the irritation in the foot caused constant stamping and restlessness, with the consequent loss of flesh. So soon as the mouth and feet became healthy the animals ate voraciously, and quickly recovered their condition; so much so that many farmers were of the opinion the disease in the end was beneficial. Among several thousand cases the mortality was practically nil, and I am certain the progeny of affected animals had a certain amount of immunity; my personal observations

ROCKEFELLER MEDICAL FELLOWSHIPS.

THE Medical Research Council announces that, on behalf of the Rockefeller Foundation, it has made the following awards of Medical Fellowships provided by the Foundation and tenable in the United States of America during the academic year 1926-27:

GEORGE BOURNE, M.D.Lond., M.R.C.P.; First Assistant in the Medical Unit, St. Bartholomew's Hospital, London.
HUGH WILLIAM BELL CAIRNS, M.B. Adelaide, F.R.C.S.; Assistant Surgeon, London Hospital.
MISS ROSALIE EVELYN LUCAS, M.B. Bristol; Clinical Assistant, Maudsley Hospital, London.
RONALD DOUGLAS MACKENZIE, M.B. Ed., M.R.C.P. Ed.; Lecturer in Pathology, University of Edinburgh.
CARL FREDERICK ABEL PANTIN, M.A. Camb.; Assistant Physiologist, Marius Biological Laboratory, Plymouth.
ARTHUR FREDERICK BERNARD SHAW, M.D. Dubl., F.R.C.P.I.; Lecturer in Pathology, University of Durham.
JAMES CALVERT SPENCE, M.D. Durh., M.R.C.P.; Medical Registrar and Chemical Pathologist, Royal Victoria Infirmary, Newcastle-on-Tyne.
HARRY ELLIS CHARTER WILSON, M.B. Glasg.; Assistant in Chemical Physiology, University of Glasgow.

Dr. Lucas and Mr. Pantin have been appointed on modified conditions while holding scholarships or emoluments from other sources.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

THE House of Commons this week completed the Committee stage of the Finance Bill, had a second reading debate on the Government's bill for reorganizing the coal-mining industry, and discussed the Estimates for the Ministry of Agriculture. The Parliamentary Medical Committee met on June 23rd. The Select Committee on the registration of nursing homes has completed the taking of evidence. This has been almost uniformly in favour of inspection and registration, and the Committee is expected to present a unanimous report.

Births and Deaths Registration.

On June 18th the Births and Deaths Registration Bill, as amended in Grand Committee, came before the House of Commons on report. This was the last day available for private members' bills. Mr. Basil Peto moved a new clause enjoining that no death should be registered until the registrar had received a certificate signed by a medical practitioner of the fact, and the cause of death, this certificate only to be given after the practitioner had viewed the body. The new clause further proposed that it should be the duty of the General Medical Council to establish a fund by equal annual contributions from all persons on the Register who were actually practising, from which such fee as they might decide should be paid to every medical practitioner for each inspection and certificate. He said the first consideration in the bill should be that the registrar should have definite proof that the person whose death he was asked to certify was, in fact, dead. Clause 7 of the bill contained a provision that the body of a stillborn infant should be inspected by a medical man. In the larger question the medical profession took the view that it was in the interests of somebody else, and not of the medical profession, that inspection of the dead should be made, and that somebody else should pay. With that view he had a certain sympathy, and he thought that in 99 cases out of 100 the doctor's final item for the inspection of a body would be paid as a matter of course. A minute contribution from each practitioner yearly would form a pool from which poorer practitioners with poor patients could draw a reasonable fee as recompense for their loss of time. Mr. Groves said he had an interview with the Registrar-General, who admitted that the percentage of deaths with medical certification was 40. They could produce proof of cases in which people who were not really dead were about to be buried. The panel doctors and infirmary and hospital doctors should view the body as part of their work. Captain Elliot pointed out that the bill had been prepared with great care, closely examined by a committee of the House, and was supported by all parties. The Government could not accept the proposed new clause, and if its promoters pressed it they would wreck the bill. Despite this warning, Mr. Herbert Williams talked the bill out, and as no more time is available for private members' business its passage this session is regarded as impossible.

General Practitioners and Public Health.

On June 17th Dr. Fremantle asked the Minister of Health if it was the policy of the Ministry to secure the replacement of general medical practitioners by specialist medical officers of health throughout the country as and when possible. Mr. Neville Chamberlain said the general policy of his department was to approve, where possible, the appointment by local authorities of whole-time medical officers. Dr. Fremantle asked what was the proportion of whole-time to part-time medical officers of health when this policy was originally adopted by the Local Government Board in 1872; and what was the proportion now. Mr. Chamberlain said a parliamentary return published in 1873 showed that for England and Wales the proportion of whole-time

appointments was about one-quarter. At present the proportion was slightly over one-third, the number of authorities having considerably increased. Dr. Fremantle asked whether this did not show that the policy of getting whole-time officers was impossible. No answer was given.

Dr. Fremantle further asked the Minister of Health if he proposed to utilize general medical practitioners for the prevention as well as cure of disease in the community in his reorganization of the public health system and his proposals for reform of the Poor Law; and what steps he was taking to improve education in the medical curriculum accordingly. Mr. Chamberlain said that, in common with his predecessors, he had always been anxious that general practitioners should take their full share in preventive medicine, but the proposals for the reform of the Poor Law would not affect the responsibilities of general practitioners in this regard. He saw no necessity at present to invite the Lord President of the Council to advise the General Medical Council to consider any further modification of the medical curriculum for this end. Dr. Fremantle asked whether the Sanitary Commission of 1869-71 suggested that Poor Law medical officers should be made the basis of the sanitary service of this country, a duty for which they were not at present fully educated, their education being almost entirely therapeutical. He asked whether it would not be an advantage that they should be fully educated. Mr. Chamberlain remarked that he was in favour of education for everybody.

Scottish Board of Health.

On the vote of £1,858,345 for the Scottish Board of Health, on June 17th, Dr. Elliot (Under Secretary for Health, Scotland) said the issue of the report of the Board of Health had been delayed by the general strike. The vital statistics of Scotland had justified the hope that the unfavourable movement of the curves during 1924 would not be continued. The general death rate, which in 1924 was 14.4, fell in 1925 to 13.4, and infantile mortality from 97 per 1,000 to 90. The death rate between 1 and 5 years had gone down from 15 to 12—equal to the rate for 1923, the lowest ever recorded in Scotland. Infantile mortality was lower than in any year except 1921 and 1923. Such a continuous fall in the mortality statistics—infant, child, and adult—showed clearly that the general physical condition of the people was maintained in spite of a long-continued industrial depression. The tuberculosis rate had fallen from 80 per 100,000 in 1924 to 76, while the non-pulmonary tuberculosis rate had fallen from 36 to 34. In both instances the death rate for each year was the lowest ever recorded in Scottish statistics, and the death rate for pulmonary tuberculosis was a record for the whole of Great Britain. The English rate was 83. It might be hoped that the campaigns for cleaner milk and better food would reduce the non-pulmonary tuberculosis rate. Though rickets was still prevalent in Scottish cities, a marked decline was recorded by all the public health authorities except at Paisley. Rickets did not show that correlation with housing which had been expected. It occurred among the better class of people as well as among the poorer. Mr. Stewart said Lord Mackenzie's committee estimated that there was a shortage of 3,600 beds—3,000 in general and 600 in maternity hospitals. No provision was made to accommodate patients suffering from certain infectious diseases. Many births took place in one-room or two-room houses, and according to medical evidence when complications ensued these rooms were unsuitable for carrying out any operation. The committee also drew attention to the fact that, while Scotland on the whole was not badly provided with sanatorium accommodation, more was required for the treatment of surgical tuberculosis in children. What was the Government doing in this direction? He also called attention to the fact that in Glasgow the people would not use well equipped Poor Law hospitals. Steps should be taken quickly to divorce these hospitals from Poor Law administration. The Mackenzie committee had condemned the Poor Law hospitals in many parts of Scotland as insufficient and out of date. Nursing was bad and proper medical attention could not be given. He hoped the Government would force parish councils, singly or in combination, to provide a higher standard of treatment. The grant of £42,000 to provide medical treatment in the Highlands and Islands was not sufficient to pay the medical officers, and there was nothing left to provide the hospitals, which were required. Mr. Scurie asked for information about the institution for mentally defective children in Dundee and about the after-histories of persons who had left tuberculosis sanatoriums to follow their occupations. He was disappointed at the progress in dealing with mentally deficient adults. In large institutions the patients were huddled together. Mr. Sullivan said the Government was reducing by £5,000 the vote for the treatment of tuberculosis. The vote for the treatment of venereal disease had been reduced by £6,000. Captain Elliot said this was a nominal reduction due to close estimating. Sir John Gilmour (Secretary for Scotland) said that the Board of Health was closely considering the matters raised by the Mackenzie committee, and hoped in the course of time to arrange for the provision of an increased number of beds. This year it was making a grant to institutions in the Stornoway area. Sanatorium treatment had not realized all the hopes aroused, but progress was being made. Some progress was being made also with the problem of venereal disease.

A motion for reduction of the vote was withdrawn and the vote itself was left outstanding for further debate on a later day.

Income Tax on Scottish Mental Hospitals.

On June 21st, on the Committee stage of the Finance Bill, Sir R. Hutchison moved the second reading of a clause exempting the royal asylums in Scotland from income tax. He said that these asylums had been subscribed to by the public. They were not run for

profit, and the funds were administered by individuals who gave their time for no remuneration whatsoever. These asylums had, in many cases, saved the parish councils large capital expenditure in that they accepted and catered for patients sent to them by those parishes at a very low rate. In later years the administration of the asylums had treated a large number of cases from the parish councils, so that the asylums were not only doing the charitable work which they were originally intended to do, but also a public work. Any surplus their funds showed at the end of a year was devoted entirely to reducing the rates which were charged to the various patients, as well as to the maintenance of the buildings and generally to developing these very good institutions. There were also one or two smaller institutions—not royal hospitals, but district asylums—which to-day were exempt from this tax. At the present moment the district asylums were only exempt under Schedule D, and it seemed very hard that these royal asylums should not be so treated. Under a Royal Charter, in 1913, they were given the duty of looking after the patients coming forward from public authorities, and for that reason were entitled to be exempt from many of the duties on which they were now assessed. They took patients who otherwise would cost a very large sum of money, and further than that they subscribed part of what otherwise would be charged to poor patients and to necessitous mental cases who could not afford to pay. Those cases were taken by the royal asylums at a specially low rate, below the actual cost. This showed that these asylums were within the category of charitable institutions. The general running of these institutions came well within the definite word of "hospital" within the meaning of the Act. He hoped that the Chancellor of the Exchequer would give some relief to these very excellent institutions.

The Chancellor of the Exchequer declined to accept the proposal. At the present time a very wide exemption was given to charity, much wider than the Royal Commission on Income Tax recommended. This exemption cost the revenue over £10,000,000 a year. The question arose in all these matters, Where are you going to draw the line? He found great difficulty in widening the scope of the exemptions now granted to charities. In order to restrict them within bounds so as not to make very serious inroads on the revenue, certain conditions had been insisted on; they were the only bulwark which the revenue had against an altogether indefinite variety of arguments for the extension of these exemptions. The courts had laid down that in the case of a hospital or charity exemption only applied to institutions maintained to a great extent by charitable endowments or subscriptions. It was not sufficient to say that they were not working for a profit. There were several of these royal asylums in Scotland, but only two of them escaped these provisions—Montrose and Aberdeen. For the sake of meeting the difficulties of these two hospitals it would be a very serious thing to throw over the whole of the existing basis of the exemptions from income tax. The district asylums differed from these two royal asylums in that they depended, to a substantial extent, on money from charitable sources. The whole question of charitable relief, notwithstanding the somewhat adverse recommendation of the Royal Commission, might well be a subject of future reflection. There was no doubt that even trying to draw the lines where they had to be drawn—and some lines must be drawn—a number of hard cases must arise. If at any time it were possible to take a more liberal view of those borderland cases, that ought to be done, not for a variety of special institutions, but as a result of a comprehensive and general consideration of the question and of a successful attempt to lay down a more harmonious limiting of principles which would prevent the indefinite exemptions which were now the law.

[The clause was rejected.]

Registration of Nursing Homes.

At a meeting of the Select Committee on the registration of nursing homes, at the House of Commons on June 15th, Dr. Francis Underhill expressed the fear that patients in doctors' houses might resent the interference and loss of privacy involved in registration and inspection. In reply to Sir Cyril Cobb, the chairman, the witness thought that inquiry into the housing and feeding of patients, if conducted by a visitor of the standing of a county medical officer of health, would not be distasteful. He would object to some young man or a nurse as inspector, but saw no objection to a matron of a hospital, if deputed by the Ministry of Health. In reply to Dr. Davies, Dr. Underhill agreed that in some cases it might be desirable that a nursing home should be inspected. But he would dislike an inspector entering his house and talking to his guests. He would not object to having to produce a certificate from two of his medical brethren.

Dr. C. F. T. Scott said that he took occasional patients into his house. He thought registration of a doctor's home entirely unnecessary. He drew a distinction between nursing homes and inspection of patients in a doctor's house in the latter; but relationship between patient and doctor. The inspector would want to look at the patient to see if he was in decent physical condition. Dr. Shiels remarked that this had never been suggested; the inspection would be into structural fitness and management. Dr. Scott maintained that inspection of doctors' houses would be undesirable, futile, and costly, and would tend to grow patients. If there were inspection, it should only be done by persons high up in the profession, and not by trained nurses or health visitors. He had never seen nursing homes of the "Dorsetbury" type.

Mr. Herbert J. Paterson, senior surgeon of the London Temperance Hospital, represented the Royal British Nurses' Association.

He said that many nursing homes were quite unsuitable for their purpose. The staircases were narrow, there was danger of fire, sanitary arrangements in many cases were inadequate or defective, the operating theatre often unsatisfactory, with open gas burners in rooms where ether was administered. The nursing staff was often partly or totally unqualified; and the nurses, being dressed in nurses' uniform, were a fraud on the public. It should be obligatory that the person in charge of the nursing arrangements should be fully qualified.

The Committee concluded the taking of evidence on June 17th, when a woman witness who had been a patient at several nursing homes said she had to pay 16 to 18 guineas a week, but to provide her own nurses. In one home one night nurse had charge of fourteen patients. Patients suffered from intimidation, and nurses seemed afraid of sending for the doctor. The Select Committee heard other evidence in camera, and will now prepare its report.

Sale of Venereal Disinfectants.

On June 16th Mr. Basil Peto presented a Venereal Disease Amendment Bill, 1926, to permit the sale by chemists of disinfectants for protection against venereal disease. The bill was supported by Dr. Fremantle, Dr. Haden Guest, Dr. Drummond Shiels, and Dr. T. Watts, and was read a first time. A memorandum attached set forth that the object of the bill was to give legislative effect to the recommendation contained in Clause 14 of the report of the committee appointed in 1923 by the Ministry of Health under the chairmanship of Lord Trevelchin: "We think that the law should be altered so as to permit properly qualified chemists to sell *ad hoc* disinfectants, provided such disinfectants are sold in a form approved, and with instructions for use, approved by some competent authority." Clause 1 of the bill amends Clause 2 of the Venereal Disease Act of 1917, so far as it relates to prevention of venereal disease. Clause 2 of the bill provides for the setting up of the competent authority, which is to be a committee nominated by the Royal College of Physicians and the Society of Medical Officers of Health.

In commending the bill to the House Mr. Peto quoted what the Minister of Health had said in reply to a deputation which waited upon him in July, 1923, and was introduced by the late President of the Society for the Prevention of Venereal Disease (Lord Willoughby de Broke). The Minister said:

"I have been to the best fountain I could, the Law Officers of the Crown, and I have put to them certain questions as to the exact meaning of the relevant section to the Act of 1917. We have taken this position, that to-day a chemist may sell *ad hoc* disinfectants for the purpose of prevention. To-day a chemist may verbally recommend to a customer such preparations for such purposes. What he may not do is to give any written or printed instructions, although he may give verbally such instructions to the customer. . . . It is clear that it would require an alteration in the law to permit the chemist to give printed or written instructions, and personally I think that if these things are to be sold, printed or written instructions should be supplied with them. It would also be necessary to pass legislation if the sale of these preparations is to be limited to such as are approved by a competent authority."

Mr. Peto said there was agreement as to the desirability of taking all steps possible for the prevention of this terrible disease. Evidence on the efficacy of preventive measures accumulated during the late war. Sir James Barrett, who was in medical charge of the Australian Forces during the war, said: "In my experience primary prophylaxis has been practically certain in its results." Sir James stated that in one camp, out of 4,400 men who reported exposure to infection, as a result of primary prophylaxis only thirteen infections resulted. Surgeon-Captain Hamilton Boyden, who was in medical charge of the Naval Gunnery School at Portsmouth during the two years from 1918 to 1920, said that 923 bottles of 1 in 1,000 solution of potassium permanganate were supplied to men who intended to incur danger of infection, and only one man was infected. During 1917 the men at the Royal Artillery Barracks at Portsmouth were carefully instructed to disinfect without delay, and out of 3,750 only five were infected during a period of nine months. There was also evidence from Colonel Harrison on what would be the effect of similar steps on the civil population. Mr. Peto held that the civilian population should have free access to reliable preventives against venereal disease. They had to consider the effect of this scourge on future generations. The best medical opinion was unanimous that a very large proportion of the cases of paralysis, malformation, mental deficiency, insanity, epilepsy, and blindness, which cost the country almost untold loss in the efficiency of the population, and a direct loss in keeping these unfortunate victims, was due directly to parental syphilis or gonorrhoea. The report of the Departmental Committee on the Causes and Prevention of Blindness, issued by the Ministry of Health in 1922, stated that of 1,855 cases of school blindness occurring in the schools for the blind of the London Education Committee in 1920 alone, 369 were due to parental gonorrhoea and 618 due to parental syphilis. The cost of the present method of dealing with this disease exclusively from the surface, was, according to the Annual Report of the Ministry of Health for 1924-25, very great. The grants paid in one year in aid of venereal disease schemes amounted to £231,000, and the cost to local authorities of carrying out these schemes was over £358,000, making a total of £600,000.

Tracing of Anatomy.—Mr. Noville Chamberlain, replying to Mr. Whiteley, on June 21st, said the number of bodies removed to medical schools in England and Wales for the purpose of anatomical examination and operative surgery was 519 during 1924 and 581

Crown Members of the General Medical Council.—Answering Lord Sandon, on June 10th, Major Hennessy, for the Lord President of the Council, said that the dates of expiry of the terms of office of Crown nominees on the General Medical Council, other than Mr. Hilton Young, who had just been appointed, were: Sir Edward Coey Bigger, January 23rd, 1927; Sir Nestor Tirard, March 2nd, 1927; Sir W. Leslie Mackenzie, October 27th, 1927; Sir George Newman, October 8th, 1927. Lord Sandon asked whether the ensuing vacancies would then be filled by non-professional persons. Major Hennessy replied that it was not possible to say in advance what action the Lord President of the Council of the day might see fit to take.

Midwives and Maternity Homes.—In the House of Lords, on June 17th, the Midwives and Maternity Homes Bill was, on the motion of the Marquess of Salisbury, read the third time and passed.

Poor Law.—On June 21st Mr. Neville Chamberlain told Mr. Whiteley that the expenditure on institutional Poor Law relief in England and Wales was £20,430,569 during 1923-24 and £21,070,000 during 1924-25. These sums included the cost of maintenance of pauper lunatics in asylums, but excluded administrative expenses, such as clerks' salaries and office expenses. The provisional total of deaths in Poor Law institutions in England and Wales for 1924 was 65,974. The corresponding figure for 1925 would not be available for a week or so. The money payments to Poor Law medical officers, dispensers, nurses, and other officers employed in the treatment or care of the sick in England and Wales amounted to £1,500,921 during 1923-24 and £1,552,000 during 1924-25. The figures for 1925-26 were not available.

Cost of Mental Hospitals.—For the financial year 1924-25 the expenditure on the maintenance, supervision, and treatment of the insane in county and borough mental hospitals in England and Wales was £6,510,639. This does not include any expenditure in respect of loan charges, repairs, additions and alterations of buildings, or purchase or rental of land and buildings.

Maternity Benefit.—Mr. Neville Chamberlain told Sir Charles Wilson that as a result of the second valuation of approved societies the average rate of maternity benefit had been increased from 40s. to 46s., and on the average the total amount which the mother would receive would be £4 12s. He did not see his way to introduce amending regulations to extend the period of this benefit from one month to three months where a mother abstained from work to suckle her infant. This would impose a further burden on insurance funds, and the recent Royal Commission did not propose it.

Medical Examination of Seamen.—Answering several members who, on June 16th, put questions on the regulation of the New York port health authorities, requiring the crews of British ships to undergo a medical examination before going ashore, Sir Austen Chamberlain said the examination was under the American Immigration Laws and Regulations of 1925, which enabled United States immigration officers to subject alien seamen to the same medical examination as alien passengers. He did not consider that any useful purpose would be served by making representations. Dr. Watts asked whether, owing to the prevalence of small-pox in the United Kingdom, and the fact that effective vaccination was a preventive, one of the reasons for the examination was to make sure these seamen were efficiently vaccinated. The Foreign Secretary said this might be true, but he did not know.

Plague in the Punjab.—On June 21st Earl Winterton stated that the number of deaths from plague in the Punjab between March 1st and May 15th was about 54,000. No report of the steps taken by the Government in relation to the present outbreak had been received, but the Secretary for India had no doubt that recourse had been had as usual to vigorous measures of inoculation and disinfection.

Sexual Offences.—During the third reading of the Criminal Justice Bill, on June 16th, Dr. Vernon Davies asked whether, before the bill was taken in the Lords, the Government would consider the introduction of an amendment that all persons convicted of sexual offences should, after conviction, but before sentence, be medically examined. A committee had been sitting for some time with regard to such offences, and it recommended that after conviction the person accused should be remanded for medical examination. Captain Hacking (Under Secretary for Home Affairs) said he would certainly consider the suggestion. The bill was read a third time by 88 to 54.

Ministry of Defence.—In the House of Lords, on June 16th, Lord Thomson asked the Government whether it had considered the establishment of a single Ministry of Defence. He said there was already co-ordination between the fighting services in many matters, and the assumption made in the House of Commons that each department did not co-operate with the other two in regard to hospitals was not justified. Lord Thomson argued against the establishment of a single Ministry of Defence. The Earl of Balfour and Viscount Haldane concurred, and the motion was withdrawn.

Notes in Brief.

On the motion of the Minister of Health, the Smoke Abatement Bill, which has already passed through the House of Lords, was read a second time in the House of Commons on June 22nd.

On June 1st, 1925, there were 2,385 maternity and child welfare centres known to the Ministry of Health in England and Wales, and on June 1st, 1926, 2,463.

There is no objection to the use of suitable metal caps for sealing bottles containing certified milk.

In April last, of 3,350 shell-shock cases under treatment, all save 351 were being treated in hospitals or clinics owned by or under the medical control of the Ministry of Pensions.

The Minister of Health does not contemplate any immediate enlargement of the powers of local authorities responsible for administration of the existing law as to the sale of food and drugs.

A Milk and Dairies Order is shortly to be made which the Minister of Health hopes will secure further improvement in the condition of the milk supply.

Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health), on June 14th, informed Mr. Thurtle that his department had not reconsidered the question of permitting the giving of birth control information at maternity and child welfare centres.

Obituary.

THE LATE SIR FREDERICK MOTT.—Sir James Dundas-Grant writes: Among the many tributes which have been paid to the great work of Sir Frederick Mott, nothing is more sincere than that due to him for a work which was begun by him at the Maudsley Hospital for ex-soldiers. He expressed himself as follows:

"I am convinced by experience that all encouragement is due to those who undertake this work of speech re-education, and teaching of choral and part-singing to disabled soldiers, for it will prove a material aid to their recovery and earlier return to useful occupations in civil life." (*Révue*, No. 3, February, 1919.)

Hundreds of ex-soldiers whose mental balance and joy in life has been restored by the training given by the Vocal Therapy Society owe to Sir Frederick Mott a deep debt of gratitude.

THE LATE DR. R. GORDON BELL.—Last week we published a brief obituary of Dr. R. Gordon Bell. We have since received from "C. O. H." the following tribute, which gives some account of his student career.

Bell was a Glasgow graduate, and in his day was the best known student in all the faculties of the University; no position of responsibility or honour but he was called by his fellows to fill it. Whether in the hurly-burly of a rectorial election, or the council chamber of the Union or Dialectic Society, or the social relaxation of a college bazaar, his place was ever at the front, and loyalty as to a chief was given to him in ungrudging measure.

In practice his personal force and professional thoroughness inevitably gained the confidence of patients, and he was ever alert for efficiency and for modern developments and improvements. Here again his fellows found him wise in counsel and skilful and resolute in action. By no means particularly prone to the soft answer that turneth away wrath, he never failed in goodwill, and no one doubted his sincerity and his freedom from any desire for a mere selfish or personal triumph.

Equipped as he was by nature with the qualities which make for leadership, his organizing ability, his debating power, his courage, and his enterprise might well have led to success on a more conspicuous platform, and of this he was not unaware. But he deliberately selected a comparatively modest stage for the practice of his profession and for the application of his personal qualities to the service of such causes as the promotion of the public health and the enlargement of educational opportunities and efficiency.

For facilities which might otherwise have been denied them successive generations in the northern town will owe gratitude in large measure to Gordon Bell's foresight and resolution in the cause of technical education. Here as well as in other directions he has written his name deeply on the life and welfare of his adopted town, and though this came through many keen controversies he was too generous an advocate to sow bitterness in the opposing camp, and he will be gratefully remembered as one who served well and faithfully his day and generation.

In his personal characteristics duty, courage, decision, determination, and loyalty had perhaps the leading place, and at least at one date in his life he supported a heavy and unexpected burden with a resolution that knew no dismay. He made devoted friends, and some of his juniors have grateful memories of a practical help and sympathy that appeared quietly, effectively, and at the appropriate moment. His name and his record of many virtues will not readily fade from the affections of those who shared his comradeship, or from the memory of the community to which he gave sustained and devoted service.

Dr. JOHN HOWLAND, professor of pediatrics at Johns Hopkins Hospital, Baltimore, died in London on June 20th, after a short illness. He had a severe illness at the beginning of this year, and left America for Europe in March for a prolonged holiday. He became ill again in Paris, but

was able to reach friends in London a little over a week before he died. Professor Howland will be missed by many friends in Britain who are interested in children's diseases. He was only 52 years of age.

Medical News.

In the King's Bench Division on June 17th two appeals by the Commissioners of Inland Revenue against decisions of Special Commissioners in favour of two medical charities were heard by Mr. Justice Rowlatt. The respondent in the one case was the *Society for the Relief of Widows and Orphans of Medical Men*, and in the other the *Medical Charitable Society for the West Riding of Yorkshire*. The essential question in each case was the right to exemption of the society's funds from income tax under Section 19 of the Finance Act of 1925. Mr. Justice Rowlatt, in his judgement dismissing both appeals, with costs, said that, taken as a whole, the two societies were in his opinion institutions for charitable purposes only, and therefore exempt from tax. What had to be considered was, not the source of the income, but the purpose for which it was held.

FOUNDER'S day celebrations at Epsom College will take place on Saturday, July 24th. The cricket match began on the previous day will be resumed at 11 a.m., and at noon there will be a service in the chapel. Viscount Gray of Fallodon will distribute the prizes at 2.45 p.m., after which he will declare the new chemical clock open. Tea will be served on the cricket ground at 4.15, and at 8 o'clock there will be a choral performance of *Merric England* by the College Musical Society.

THE annual dinner of the Cambridge Graduates' Medical Club will be held at St. John's College, Cambridge, at 7.30 p.m., on Saturday, July 3rd. The president of the club, Sir Humphry Rolleston, Bt., will be in the chair.

THE St. Bartholomew's old students' dinner will be held on Friday, October 1st, in the great hall of the hospital, at 7.30 p.m., with Mr. W. T. Holmes Spicer, F.R.C.S., in the chair.

THE annual luncheon of the Irish Medical Schools' and Graduates' Association will be held at the Black Boy Hotel, Nottingham, on Wednesday, July 21st, at 1 p.m. The President-Elect of the British Medical Association, Mr. R. G. Hogarth, C.B.E., F.R.C.S., will be the guest of the association. Tickets (5s. each, exclusive of wine) may be obtained from the honorary secretary for the provinces, Dr. Falkland L. Cary, 67, Kings Road, Harrogate.

THE annual meeting of the Medical Mission Auxiliary of the Church Missionary Society will be held at the Central Hospital, Westminster, on Tuesday, June 29th. The chair will be taken by Sir Richard H. Luce, K.C.M.G., C.B., F.R.C.S., at 7.30 p.m. Tickets of admission can be obtained on application to the Loan Department, Church Missionary Society, Salisbury Square, E.C.4; a small number of reserved seats at 1s. each are available.

AT the annual meeting of the Society for the Study of Inebriety, at the Medical Society of London (11, Chandos Street, Cavendish Square, London, W.) on Tuesday, July 13th, at 4 p.m., Dr. Alfred E. A. Carrer, medical director, Caldecote Hall Retreat for Inebriate Men, will open a discussion on the institutional treatment of alcohol and drug addiction.

THE annual meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held at Caxton Hall, Westminster, on Tuesday, July 6th, at 5.30 p.m., when a discussion on tonsils and adenoids will be opened by Mr. George Waugh, who will give an historical survey of the subject. Dr. R. C. Clarke will follow with a paper on the etiology, and the causes of failure of operation, and Dr. Harold Waller will speak on early symptoms. After the meeting there will be a dinner at the Florence Restaurant, Rupert Street, at 7.30. Full particulars can be obtained from the honorary secretary, Dr. Margaret Emslie, 1, Upper Montague Street, W.C.1.

MR. DORNE will give a clinical demonstration in ophthalmology for the Fellowship of Medicine on Thursday, July 1st, at 12 noon, at the Royal London Ophthalmic Hospital (Moorfields), City Road, E.C. This demonstration is open to the medical profession without fee. The Prince of Wales's General Hospital, Tottenham, will hold a vacation course occupying all day from July 19th to 31st. The course will consist of clinical and laboratory methods, demonstration of groups of selected cases, general hospital work, and clinical lectures dealing with various subjects. From July 5th to 17th an intensive course will be held at the National Hospital for Diseases of the Heart, and between the same dates there

will be an afternoon course at the Hospital for Diseases of the Skin, Blackfriars. At the West End Hospital for Nervous Diseases a four weeks' late afternoon course, comprising lectures and clinical demonstrations upon selected cases, will be given between July 19th and August 11th in the Out-patient Department, 73, Welbeck Street, W. From July 12th to 24th at the Royal Eye Hospital, St. George's Circus, S.E., there will be a series of demonstrations on eye diseases from 3 p.m. daily. During August the following courses will take place: in medicine, surgery, and the specialties, at the Queen Mary's Hospital (Stratford); diseases of the chest, at Brompton Hospital; and diseases of children, at the Queen's Hospital, Hackney. All of these courses will be all-day ones. Copies of all syllabuses and of the general course programme may be had on application to the Secretary of the Fellowship of Medicine, who will also supply copies of the *Post-Graduate Medical Journal*.

TO instruct the public in the disease-carrying propensities of certain insects, an extremely good series of wax models is now being exhibited in the Natural History section of the British Museum at South Kensington. The insects in the representative models, on the subject, from 20 times to as much in the case of the plague flea. By this magnification the outward characteristics are made intelligible to the general public. The species represented include malarial, yellow fever, and other mosquito; the sandfly; a small West African horse-fly which conveys Calabar swelling; two kinds of tsetse fly; plague fleas; and the better known disease carriers—the louse, the tick, and the house-fly. In the cases containing the models there are various accessory exhibits, such as diagrams of the organs and of sections of the insects; models and pictures of the germ it carries; and preserved specimens of the insect itself. In the house-fly case there is an unpleasant model of a tray holding the constituents of a lunch, all of which, including the glass of milk, are covered with flies. This exhibit should wake the public conscience! The models are the work of Mrs. E. D. Blackman, Miss Grace Edwards, and Mr. A. J. Engel Terzl.

EXHIBITION lawn tennis matches will take place at Essex Lodge, Sussex Place, Regent's Park, on Monday, July 5th, from 3 to 7 p.m., in aid of the Hackney Branch of the Invalid Children's Aid Association. A large number of well known players have consented to take part in matches, including Miss Suzanne Lenglen and Messrs. Lacoste and Borotra. Tickets, price £1 5s. each, including tea, can be obtained from Lady Fripp, 19, Portland Place, London, W.1.

THE annual oration of the London Dermatological Society was delivered on June 16th at St. John's Hospital, Leicester Square, by Sir Humphry Rolleston, Bt., K.C.B., M.D., F.R.C.P., who selected as his subject, "The relations of dermatology and general medicine." Dr. W. Griffith, president, was in the chair, and at the conclusion of the meeting a vote of thanks to the orator was, on the motion of Dr. Knowsley Sibley, seconded by Dr. MacLeod, carried with acclamation. At the annual dinner after the meeting the official guests of the society included Sir Humphry Rolleston, Dr. J. H. Stowers, Dr. J. H. Sequeira, Dr. Haldin Davis, Dr. H. W. Barber, and Dr. H. G. Adamson.

THE Earl of Balfour presided at the first annual general meeting of the British Institute of Philosophical Studies on June 18th. The institute, he said, must "counteract the natural prejudice by which a man likes his opinions couched in the most violent and uncompromising terms, written in the largest letters, put on the most prominent hoarding, and supplying a creed to which, while readily assenting himself, he desires every citizen to give his adhesion." The institute, he continued, "(1) promotes the advancement of philosophic study by teaching and research, (2) helps those interested in and perplexed by the problems of modern life, to ask the right questions, and to indicate the most promising directions from which some important answers to these questions may be expected to come." Among the lectures given during the past year was one on psychology, by Professor T. H. Pear; and the subject at an evening meeting was "The idea of responsibility, legal and medical," by Sir Travers Humphreys and Dr. William Brown. The council of the institute consists of men and women of very varied interests and activities in life; among the medical members are Lord Dawson of Penn, Dr. Henry Head, and Dr. C. S. Myers, F.R.S.

THE Faculty of Medicine of the University of Paris announces a vacation course in children's diseases to be held at the Hôpital des Enfants Malades from July 26th to August 14th next. The course will be under the direction of Professor Nobécourt and Dr. Lerchoullet. The fee is 250 francs, and tickets will be issued by the Faculty. A certificate will be granted at the end of the course to those who are duly registered at the secretariat of the Faculty.

THE Bishop of Chelmsford, who presided at commemoration day at the Livingstone College, Leyton, on June 9th, pointed out that the college existed to help to give all those who were sent out by missionary societies of the Church some knowledge of the management of their own health and of the health of other people. He recalled the association with the college since its beginning of Dr. C. F. Harford. An address was given by the Rev. B. T. Butcher, of the London Missionary Society, Papua, who gave illustrations of the services he had been able to render to natives as the result of his training at the Livingstone College. The treasurer, Mr. R. L. Barclay, reported the progress of the £3,000 fund which is being raised in memory of Dr. Harford. Last year 103 students entered the college, including the short course and vacation course students.

It appears that statements have lately been made in the press to the effect that the French Government proposes to impose certain restrictions which may interfere with touring in that country. The Director of the Office Français du Tourisme (56, Haymarket, London, S.W.1) informs us that any restrictions contemplated will have no influence whatever on the general comfort of tourists, and that no restrictions will be enforced with regard to the consumption of petrol. English tourists may rest assured that there will be no interference with their use of the roads in France this year.

Dr. JAMES BENNETT (Warrington) and Dr. Frank Radcliffe (Oldham) have been appointed to the Commission of the Peace for the County Palatine of Lancaster.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, **British Medical Association House, Tavistock Square, W.C.1**, on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9361, 9362, 9363, and 9364** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitiology Westcent, London.*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Mediscera Westcent, London.*

The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*); telephone: 4737 (Dublin), and of the Scottish Office, 6, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*); telephone: 4361 (Central).

QUERIES AND ANSWERS.

DR. JANIE MCBIRNIE (West Kirby) writes: A lady aged 71, suffering from chronic bronchitis and asthma, is confined to bed each winter, but in the summer is able to go about apparently well. Can any of your readers recommend a suitable winter resort?

"F. H." asks for advice in the treatment of lymphangitis of the lower lip. Streptococcus vaccine, autogenous vaccine, mixed serum, have been applied locally, and although improved the lip does not really clear up, and periodically swells anew.

INCOME TAX.

Basis of Return.

"F. T." inquires (1) whether there will be any reduction in the taxation of light cars "in view of the new tax on petrol which comes into force on January 1st, 1927," and (2) also as to the basis of his return of profits and an allowance for a motor car renewal.

* * The taxation of petrol, to which "F. T." refers, is apparently a matter for the indefinite future; when and if it becomes operative presumably the present rates of taxation of cars will be revised. The amount of the allowance for the car renewal which has been effected is £215-£255=£150—that is, the actual out-of-pocket cost. If "F. T." carries out the proposed further replacement the same basis will apply, but the net amount expended will presumably be very much smaller. As regards

the basis of the return of profits, "F. T." is liable for 1926-27, according to the previous three years' average profits of his predecessor, but if he can show that his profits for the first year have fallen short since his succession to the practice from some specific cause, he can then claim to substitute for the average the actual profits of his first year.

Three Years' Average.

"J. N." inquires how expenses should be dealt with in calculating liability.

* * Each year's net profit (receipts less expenses of the year) should be separately calculated, and the net results averaged. "J. N." seems to have misunderstood the Inspector's computation, however. The figures quoted are apparently the amounts of net profits, but in one year £9 has been added, presumably on the ground that it represents additional capital outlay.

Car Allowances.

"T. G." asks for advice with regard to the allowances due for his car.

* * It should be borne in mind that the "renewal" allowance has to be dealt with as an expense incurred as for the year in which the transaction takes place. We suggest that he accept (under protest) the 10 per cent. allowance for the year 1925-26—many inspectors would allow 20 per cent., we believe—and when computing the profits for the year to March 17th, 1927, claim as an "obsolescence" allowance the cost of replacement less the depreciation allowance made—that is, £125, less (say) £19=£106. With regard to the private use of the car, so much depends on the particular facts that we cannot answer such a question specifically. We can only say that to the extent to which a car is used for private purposes the allowances have to be restricted—for example, if one mile in every twenty is for private purposes then one-twentieth should be taken off all allowances, depreciation, running costs, etc. It is, of course, unfortunate that the bills for petrol, oil, etc., have not been kept—we do not know whether "T. G." has a detailed record of such expenses; if he has he should, we think, hold to it; if not he is, of course, driven back on an estimate; there is no recognized mileage scale for such costs. We may perhaps point out that there is a right of appeal from the Inspector's decision to the district commissioner or, if preferred, to the special commissioners on circuit from London. If the Inspector is not prepared to deal reasonably with the matter, such an appeal might be well worth while.

LETTERS, NOTES, ETC.

TREATMENT OF GOUT.

WE have received a communication from the Clayton Aniline Company calling attention to a letter by Dr. Vaughan Pendred on the treatment of gout, published in our issue of June 5th (p. 976). The manager of the pharmaceutical department of the company says that "atoguinol," to which he presumes Dr. Pendred refers under the name "aguinol," is not the Swiss equivalent of atophan (phenylcinchoninic acid), but is the allyl ester of phenylcinchoninic acid. The manager also states that atoguinol contains no guinine, and therefore cannot act as a haemolyser through that drug. Further, our correspondent observes that Dr. Pendred, while stating that his patient's gout was uninfluenced by "aguinol," does not say whether he followed an appropriate diet with increased intake of fluid.

JOHN WATKINS, F.R.C.S.

IN the year 1864 Mr. John Watkins, F.R.C.S., F.S.A., F.R.G.S., of London, was entertained to dinner at Radley's Hotel by a large party of his friends, most of whom had been his patients, and presented with his bust in marble. The bust was inscribed, "Johanni Watkins, sanatori grati sanati" ("the healed to the healer"). The question of the present home of the bust having been raised, any reader who happens to have information on the point is requested to communicate with the Medical Secretary.

EMERGENCY COOKING BLOCK.

MR. E. S. SHRAPNELL-SMITH, chairman of the Empire Motor Fuels Committee of the Imperial Motor Transport Council, suggests a simple method of improvising an emergency cooking block during the coal shortage. A piece of hearthstone, 4 in. by 3 in., is soaked for half an hour in methylated spirit and placed on a tin support. The kettle or pan is then placed on the block and a light applied. The lighted block can be extinguished by an empty tin and the block re-soaked. After drying with a duster or blotting paper the soaked block can be kept indefinitely in a closed tin.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 245.

Medicine.

1. Asthma and Foreign Proteins.

A. BESSEMAN (*Le Scalpel*, November 14th, 1925, p. 1157) reports a very chronic case of bronchitis and asthma cured finally by the simultaneous injection of a mixed autogenous vaccine, of tuberculin, and of a sensitizing substance from bed fluff, mainly of a woolly nature. He thinks that the sensitizing substance had penetrated the epithelial cells of the respiratory passages, favoured by the pre-existing acute bronchitis. He found that the patient could distinguish the tuberculin injection from the others by the feeling of relief afforded, but that this remedy by itself was inadequate. It became clear that the case was one of mixed infection on which a special form of allergic sensitization had been imposed. Intradermal inoculation defined the nature of this sensitization and indicated the appropriate treatment. Bessemans adds that the desensitizing treatment must be gradual and prolonged, with very small increases in the injections and careful avoidance of reactions.

2. Peripheral Forms of Epidemic Encephalitis.

L. BÉRIEL and A. DEVIC (*Presse Méd.*, October 31st, 1925, p. 1441) describe a form of disease in which the nerves and nerve roots are exclusively attacked; they believe it to have the same etiology as epidemic encephalitis. The symptoms include polyneuritis and flaccid paraplegia with abolition of reflexes. As a general rule the paralysis spreads to the abdomen, and eventually to the upper limbs, though there are cases in which only the lower limbs are involved. The sphincters are frequently affected, and in two cases the disease spread to the cranial nerves; in one case a facial and in the other a glosso-pharyngeal paralysis developed. Pain was rarely severe, but in some cases necessitated morphine. Sensation is usually affected. There is never a true anaesthesia; but hyperaesthesia and paraesthesia, particularly the latter, are common. There is an excess of albumin in the cerebro-spinal fluid. The patients generally make a complete recovery in one to five or six months. In only one case, still under observation, did the paralysis persist for as long as eight months, the pelvic girdle, the buttocks, and the abdominal parietes being involved. In its early stages the condition has to be distinguished from infantile paralysis, which is more dramatic in its onset and severe in its paralysis. If the polyneuritis takes five or six days to prostrate the patient the diagnosis is clear. But there are cases in which the onset is more rapid. For treatment the authors recommend the prevention of muscular contractures, the administration of strychnine, and the application of the continuous current.

3. Non-syphilitic Aortitis.

L. NEUMAN (*Journ. Amer. Med. Assoc.*, October 31st, 1925, p. 1361) states that both acute and chronic non-syphilitic aortitis are not rare conditions. Although it is generally agreed that aortitis can be of syphilitic origin, some have denied that it can be the result of any other infection. Neuman thinks that the predisposing causes of the non-syphilitic type are the irregular lymphatic supply to the aorta, the numerous lymph nodes lying along it, and their direct connexion with the large drainage spaces of the body. Another factor, according to Westenhöfer, is man's phylogeny and his assumption of the upright position. Neuman points out that the causative agent may be toxic or bacterial, and may be brought to the site of the disease by the blood circulating in the aorta or the vasa vasorum, or very occasionally by direct continuity from an adjacent infection. This may occur in the course of any infectious disease and in any conditions where there are foci of infection. Other associated factors seem to be high pressure work and play and other excesses. He states that the symptoms vary in intensity in different cases; pain is the most constant and is usually retrosternal, but it sometimes radiates to the arm. While the pain sometimes resembles that of angina pectoris it is more often described as a sense of fullness, pressure, or tightness; it frequently interferes with respiration, and the patient complains that the heart feels as though it were turning over. The pain is more noticeable in cold weather and especially when walking; it is often relieved by stopping for a few minutes. It must be distinguished from cardiac pain. Dyspnoea is often present and may be the predominant symptom; tachycardia is common but is seldom accompanied by any irregularity. The blood pressure is never high in

uncomplicated cases. Fever is present in many cases; it is seldom high but is extremely irregular. Oedema of the extremities is rarely observed. In the 29 cases of aortitis which the author examined repeated Wassermann tests were performed to eliminate the possibility of syphilis. The prognosis in mild cases is good; none of his patients died and 90 per cent. improved considerably. Neuman recommends rest in bed for long periods, the removal of all foci of infection, and a careful regulation of the habits and exercise during convalescence. Overeating must be avoided and moderation observed in everything. He usually gave iodides in large doses over long periods, purely on empirical grounds.

4. Radial Nerve Paralysis.

H. DUFOUR and A. BLONDEL (*Bull. Soc. Méd. de Paris*, November 12th, 1925, p. 1380) report a case of typical and complete radial nerve paralysis with diminished reflexes, no trophic changes, and a negative Wassermann reaction. There were no other symptoms. The condition did not respond to treatment, and remained unchanged until six weeks later, when there occurred an acute arthritis of the shoulder on the same side, and in a few days the wrist became affected. Salicylates were given, with the result that the arthritis disappeared and the paralysis diminished gradually until at present only a slight weakness of the thenar muscles is left. It is suggested that the rheumatic diathesis may be concerned even in cases of neuritis of a single nerve, and that treatment by salicylates should therefore be tried.

5. Incipient Hypothyroidism.

W. H. HIGGINS (*Journ. Amer. Med. Assoc.*, October 3rd, 1925, p. 1015) deals with a group of cases of incipient hypothyroidism in which the metabolic rates were sufficiently near the border-line to make the diagnosis of hypothyroidism doubtful, unless other evidences were forthcoming, and records twenty-three cases where the basal metabolic readings were from -11 to -25. He describes a clinical syndrome which differs from that of true myxoedema, and comprises moderate dryness of the hair and skin, neuroses of various types, and vague pains. Obesity is relatively uncommon, and the weight is often below normal. Cases of incipient thyroid deficiency are found to occur, not uncommonly, near the menopause, and Higgins suggests that the condition is connected in some way with ovarian activity.

Surgery.

6. Diagnosis of Acute Pancreatitis.

R. R. CRANMER (*Minnesota Med.*, November, 1925, p. 675) states that during the last few years there has been a great increase in the number of reported cases of acute pancreatitis, but that a pre-operative diagnosis is rarely made, since there is no one definite pathognomonic sign or symptom. Moreover, this condition is most often seen in persons who have previously had severe abdominal disorders, and who at the time need immediate surgical intervention without waiting for a definite diagnosis. The author points out that of the five cases of acute pancreatitis which he reports one was diagnosed pre-operatively as perforating duodenal ulcer, one as stone in the common bile duct, and another as empyema of the gall bladder. He states that the onset of symptoms usually occurs soon after a heavy meal, and takes the form of a sudden acute pain and tenderness in the epigastrium, generally a little to the left of the mid-line. This is accompanied by continuous vomiting of food, bile, and mucus. The upper abdomen is slightly distended, resistance is not sharply defined, the pulse is weak, there is collapse, and sometimes cyanosis. After a few hours the epigastric swelling becomes definite, and jaundice may appear if there is obstruction of the ampulla of Vater due to gall stones, swelling of the duodenal mucosa, or other causes. The patient is usually constipated; later there is peritonitis, abdominal rigidity, marked distension of the abdomen, rapid and thready pulse, and the patient complains of intense thirst. Then follow rapidly delirium, coma, and death. If an abscess ruptures into the stomach or bowel, pancreatic detritus may appear in the vomit or stools. The urine may contain a small amount of sugar, while the blood sugar may remain normal. Acute pancreatitis has to be distinguished from perforated gastric or duodenal ulcer, perforated gall bladder, poisoning by irritants, acute intestinal obstruction, and stone in the common bile duct. There is no pathognomonic sign or

symptom of acute pancreatitis, but this possibility should always be remembered in all acute conditions of the upper abdomen in which the symptomatology does not definitely indicate one of the more common disorders of this part.

7. Partial Ligature of the Common Carotid.

H. H. KERR (*Surg., Gynecol. and Obstet.*, November, 1925, p. 565) describes an original method of incomplete occlusion of the common carotid artery in the treatment of pulsating exophthalmos; notes of three cases are given. An arterio-venous fistula between the internal carotid artery and the cavernous sinus may result from fracture of the base of the skull or direct violence; or it may arise spontaneously from the rupture of an aneurysm of the carotid, or an unruptured aneurysm of the ophthalmic artery within the orbit. The condition leads eventually to blindness of the affected eye with a bruit, which is most distressing to the patient. In order that the collateral circulation may not be restricted unduly a strip of fascia lata is passed, under local anaesthesia, round the artery below the bifurcation; by this means the artery can be gradually constricted until the pulsation in the eyeball ceases, and without producing signs of cerebral anaemia. The patient, being conscious, is able to help in judging the exact degree of constriction required; when this has been ascertained the fascial band is sutured and the wound closed, the lumen of the artery having been reduced normally about one-half. Temporary improvement resulted in all three cases, but as the symptoms showed signs of recurrence about three weeks later the carotid was completely tied just above the fascial band, with permanent benefit and without such signs of cerebral anaemia as were often encountered when the preliminary operation was not performed.

8. Extrapleural Thoracoplasty in Pulmonary Tuberculosis.

W. H. THEARLE (*Med. Journ. and Record*, October 7th, 1925, p. 399) records the result of sixty cases of extrapleural thoracoplasty for pulmonary tuberculosis. The frequent failure of sanatorium treatment to arrest the disease and the impracticability of pneumothorax in many cases owing to pleural adhesions are responsible for the recent recognition of this operation. The aim of the operation is to bring about the collapse of one lung mechanically by a diminution in size of half the thorax by a paravertebral resection of the upper eleven ribs, usually in two stages. The chest after the operation requires support by adhesive straps over gauze pads. The operation may be performed from below upwards or in the opposite direction; it produces immediate permanent collapse and the patient is spared prolonged medical treatment. A two-stage operation appears the best for most cases. Phrenicotomy as a preliminary measure tests the effect of additional work on the better lung. In sixty cases the disease was arrested in 30 per cent., improved in 25 per cent., and there was a mortality of 18 per cent. Thearle thinks that the operation is indicated in chronic fibrous disease with excavation, and also in recurrent haemorrhage. Five cases are reported in detail with radiograms and photographs of the patients after treatment.

9. Hernia of the Ovary in Infants.

H. L. ROCHER (*Journ. de Méd. de Bordeaux*, November 10th, 1925, p. 991) describes eight cases of infantile hernia of the ovary treated by himself and a colleague during the last six years, and mentions the importance of bearing such a possibility in mind in the case of an infant with a small protruding lump at the inguinal canal. It is, as a rule, painless and movable, but irreducible, and is accompanied by no gastrointestinal symptoms. The usual diagnosis is a cyst in the canal of Nuck, the operative treatment for which is usually deferred until the child is older. If, however, the condition is hernia of the ovary an immediate operation is indicated, because the vitality of the organ is at stake, and also because strangulation is liable to occur. In three out of the eight cases cited it was necessary to remove the ovary and tube owing to pathological changes due to acute or gradual strangulation.

10. Ectopia Testis.

F. BERNHARD (*Zentralbl. f. Chir.*, November 14th, 1925, p. 2592) records a case of displacement of the left testis in a man aged 24. The organ was of normal size and lay on the dorsal surface of the penis at the junction of the upper and middle thirds. At the operation a small hernial sac at the left external ring was found and excised. Both layers of the tunica vaginalis were divided and the testis was placed in normal position in the scrotum. Bernhard found that the vaginal process had united with the transversalis fascia, thus diverting the testis from its normal course and preventing its descent into the scrotum.

Therapeutics.

11. Urea in Cardiac Oedema.

J. H. CRAWFORD and J. F. MCINTOSH (*Arch. Intern. Med.*, October 15th, 1925, p. 530) state that while it has been known for a long time that the administration of urea in large doses produces a considerable diuresis, little effort has been made until recently to utilize this drug for therapeutic purposes. They have therefore investigated its value in eight patients with advanced heart failure and considerable oedema. The treatment included rest in bed, salt-free diet, thorough digitalization, and restriction of fluid to a daily intake of 1,200 c.cm. Urea was given in a small quantity of water after meals in order to avoid gastric disturbance; in some cases it was administered in two doses of 15 grams a day, and in others in steadily increasing doses up to 60 grams a day. The authors found that there was an immediate rise in the urine output, which followed closely the curve of urea excretion, but that this increased output was not maintained unless the urea administration was continued. Blood urea estimations showed that the changes in the urine volume and urea excretion were dependent on the concentration of urea in the blood. The authors found no appreciable increase in the amount of chlorides excreted, and no evidence of kidney irritation, but where the latter was present previously it rapidly disappeared after the urea treatment had begun. In some cases there was slight intolerance to urea, as shown by loss of appetite, nausea, vomiting, and a feeling of weakness or lassitude; on discontinuing the administration these symptoms disappeared. Most of the patients complained of thirst and headache during the treatment, but these were never sufficiently severe to compel its suspension. In all their cases the authors found there was considerable improvement in the general condition, the patients felt better, and the oedema disappeared. They therefore conclude that urea is a useful drug in the treatment of cases of heart failure with oedema in which treatment of the cardiac condition has failed to remove the oedema or to maintain an adequate excretion of water.

12. Treatment of Hodgkin's Disease.

LORTAT-JACOB, SCHMITE, and LERASLE (*Bull. Soc. Méd. de Paris*, November 12th, 1925, p. 1394) report two cases of Hodgkin's disease both treated by x-rays. In one the treatment was for a time successful. The patient's condition improved and all palpable glands disappeared. There was a fatal recurrence, however, later. The second patient did not do so well. It occurred to the authors that in x-ray therapy substances inimical to the growth of the lymphadenoma were being set free in the blood. They therefore injected serum from the blood of the first "convalescent" patient into the second, who was failing to react to treatment. This had a remarkable effect on the blood picture, the red cells rising from $3\frac{1}{2}$ to $4\frac{1}{2}$ million and the whites from 12,000 to 25,000. Serum injections were given daily, beginning with $1\frac{1}{4}$ c.cm. and rising to 1 c.cm., this dose being then continued for twelve days. A further course was given later. During the whole period x-ray treatment was given. All the symptoms, including holls which had been most intractable, cleared up, and the patient was discharged. The authors suggest that the serum augments but does not take the place of x-ray therapy.

13. Ichthyol in Gonorrhoea.

A. STRASZYNSKI (*Polska gazeta lekarska*, November 1st, 1925, p. 927) describes the treatment of 41 cases of venereal and skin diseases by intramuscular injections of a 2 per cent. solution of ammonium sulpho-ichthyolate in doses of 3 c.cm. every second or third day. The ichthyol should be diluted just before the injection. The author has obtained the best results in cases of gonorrhoeal epididymitis; in 17 out of 20 cases thus treated the pain ceased and the swelling was diminished after the first injection, while four or five injections were, as a rule, sufficient to enable the patient to be discharged well or to confine himself to local treatment. In a case of pyelitis with urethritis and epididymitis which was not due to the gonococcus the swelling had gone down after the third injection and the urine had cleared. On the other hand, no therapeutic benefit was observed in skin diseases treated by ichthyol, except in one case of furunculosis and two of psoriasis.

14. Therapeutic Uses of Peptone.

H. POLLITZER (*Wien. klin. Woch.*, November 5th, 1925, p. 1201) employs a sterile 5 per cent. solution in 1 c.cm. capsules, of either Merck's or Armour's peptone; Witte's preparation has been avoided because of its high histamine content. The basis of the therapeutic action of peptone is its constriction of the valves controlling the portal and pulmonary venous systems, thus tending to produce congestion, the reverse of what occurs

with the drug novasurol. The therapeutic value of peptone in bronchial asthma is explained as being due to shock effect on the sympathetic nervous system, and the pulmonary vessels and bronchial muscle fibres under its control. The action of peptone may be very pronounced; in an unselected case of lymphatic leukaemia an injection of peptone raised the weight 5½ lb. in three days. It is often rapidly effective in checking some forms of severe diarrhoea, haemoptysis, and asthma, the latter being probably its chief field of use at present. It is given by intramuscular injection. Pyrexia should never follow; if it does it indicates the existence of idiosyncrasy, failure of therapeutic action, or sepsis.

15. Sugar Treatment of Epilepsy.

S. WLADYCZKO (*Presse Méd.*, November 7th, 1925, p. 1475) noticed that in a district in Russia sugar shortage increased the incidence of epilepsy and aggravated already existing cases. Investigations of the blood sugar content of epileptics produced discordant results. One of the author's epileptic patients showed just before the attack only half the normal amount of blood sugar, and so Wladyczko determined to try the administration of sugar in such cases. He now recommends glucose in doses of 50 to 100 grams by the mouth, given in water, or else ordinary sugar, 200 grains, in either case once daily. This may be varied by giving sugary foods, such as jam or preserved fruit. The sugar cure should be combined with other medication, such as luminal or bromides, although in some cases sugar alone relieved all symptoms. The treatment is controlled by periodical examination of the blood and urine. The results were that in 18 cases the fits became less frequent and severe; in 5 cases the fits returned only once at intervals of four, five, or six months, whereas previously they had occurred every day in one patient, and in the others nearly once a week.

Ophthalmology.

16. Estimation of the Ocular Muscle Balance.

C. S. O'BRIEN (*Journ. Amer. Med. Assoc.*, October 24th, 1925, p. 1295) recommends prolonged monocular occlusion for the correct estimation of deficiency in the ocular muscle balance. He states that orthophoria is almost as rare as emmetropia, and that although the majority of heterophorias are of small degree, and are easily corrected by the average person without giving rise to symptoms, nevertheless where there is also present some other type of pathological change which affects the ocular muscles, or their innervation, or where the errors are large enough to require a constant spasm of the muscles in order to maintain binocular single vision, this test is necessary. The indications for the test are: (1) where the patient already has glasses which properly correct any refractive error, and yet continues to suffer from asthenopia; (2) where vision is distinct with one eye but becomes blurred when two are used; (3) where there is as much or more discomfort in distant vision as in accommodation; (4) when the patient shows pronounced symptoms of asthenopia after visiting a cinema or theatre; (5) where the symptoms are out of all proportion to the refractive error; (6) where headaches, vertigo, or vomiting are caused by riding in a swiftly moving vehicle. O'Brien has found that by this test he has been able to reveal high degrees of imperfect balance which were undetected by the ordinary methods. He considers this method to be analogous to that of estimating errors of refraction by using a mydriatic, since by prolonged monocular occlusion rest is given to the ocular muscles. When the test was originally devised by Marlow the period of occlusion recommended was about a week, but O'Brien had found that two or three hours suffice in the majority of cases.

17. Conical Cornea.

V. WESCOTT (*Amer. Journ. of Ophthalmol.*, October, 1925, p. 803), discussing the condition known as conical cornea, is inclined to attribute it to a developmental defect whereby the growth of the fibrous elements of the cornea is retarded; this retardation is most marked at the centre of the cornea, which is farthest removed from the blood supply. The fact that the disease usually appears just after puberty suggests, on the other hand, that it may be due to some metabolic change occurring at that time of life. While diagnosis of a well marked case is easy, Wescott thinks that many slight cases are probably overlooked. He has seen no good result produced by general medical treatment. The various operative measures, such as needling the lens, the formation of a slit-like pupil, paracentesis of the anterior chamber, trephining or cauterizing the cornea, and excising portions of the cornea with subsequent suturing, are mentioned. The author thinks that on the whole conservative measures are best, and that the prolonged use of miotics with a pressure

bandage gives the best result in most cases. In very extreme cases operative treatment may possibly be justifiable, he adds, but the state of the other eye must be considered in this connexion. In most cases vision can be improved by lenses.

18. Ocular Signs of Temporal Tumours.

W. I. LILLIE (*Journ. Amer. Med. Assoc.*, November 7th, 1925, p. 1465) has investigated the ocular changes in 53 patients suffering from temporal lobe tumours. He distinguishes four types of changes: (1) changes in visual acuity; (2) changes in the optic discs; (3) changes in the visual field; and (4) oculo-motor changes. He found that out of 168 verified cerebral tumours 53 were of the temporal lobes, thus suggesting that these are more common than was previously believed. He states that except for the absence of visual hallucinations in these cases his findings closely agree with those published by Cushing in 1921. Oculo-motor changes were not common and occurred in only 13 of his cases, but all these changes, with the exception of convergence weakness, were present on the left side, whereas the tumours were about equally divided between the two sides. Bilateral choking of the discs was present in 45 cases and was higher on the contralateral side as often as on the homolateral. He considers that an ocular syndrome could be established for early temporal lobe tumours—namely, normal visual acuity, bilateral choked discs, and homonymous quadrant defects either for colour or form. These last he found present in 43 out of his 51 patients in whom he was able to chart the fields, and he believes them to be of great importance in the diagnosis of temporal lobe tumours, especially when associated with bilateral choked discs.

Obstetrics and Gynaecology.

19. Control of Uterine Haemorrhage.

W. S. NEWCOMET (*Journ. Amer. Med. Assoc.*, November 7th, 1925, p. 1459) recalls that the cells of the generative organs are more susceptible to x rays than any other cells in the body, and that radium and irradiation have been used for the control of uterine haemorrhage for the last ten to twenty years. While with radium there has been considerable success the scarring and skin changes resulting from the use of large doses of x rays have deterred most practitioners from recommending their general employment. Radium, however, requires careful preparation of the patient before its use; the exposure is somewhat long, and disturbing results have been observed. Newcomet therefore investigated the control of uterine haemorrhage without checking menstruation by means of smaller doses of x rays than had previously been used. His method was to cover the body of the patient completely with a leaded rubber sheet or thin lead plates, and to expose four areas over the anterior portion of the pelvis, each 2 inches square, for four minutes, at a 10-inch focal distance, to rays produced by a current of 4 milliamperes, with an 8-inch spark-gap, and a 3 mm. aluminium filter. Subsequent applications depended largely on the results obtained by the first. If necessary a second application to five areas on the back were given at the end of three weeks, using the same technique. If still further sittings were required cross-firing from the two sides was adopted after six to eight weeks. In very few cases was there any tanning of the skin, and the pubic hair was retained in every case. By this treatment he has had 45 successful results in 60 cases of uterine haemorrhage. In some it was possible to control the bleeding without stopping menstruation, but the author states that in women nearing the menopause this method is likely to lead to permanent cessation of menstruation. In some of the younger women the periods ceased temporarily but returned later.

20. Necrobiosis in Fibromyomata.

FORGET-URION (*La Gynéc.*, October, 1925, p. 579) discusses the complications introduced into pregnancy, labour, and the puerperium by the uterine fibroids, and states that, while the size of the tumour is the most common cause of difficulty, yet such other conditions as degeneration, sepsis, and gangrene should not be overlooked. He recalls the opinion of Pinard that fibromyomata arise as perversions of genital activity owing to there having been no pregnancy before the age of 25, and that pregnancy is the best prophylactic and curative treatment. Considering the problem of whether marriage should be recommended in such cases, the present author points out that small fibromyomata occurring in older primiparae do little more than lengthen labour and render it irregular, while large fibromyomata are relatively infrequent in these patients. He mentions briefly the well known

mechanical complications, such as torsion, and points out that necrobiosis due to interference with the blood supply of the tumour is a definite danger which deserves more consideration than is usual. The degenerative change usually starts near the centre of the fibroid owing to its vascular arrangement, and an aseptic fluid mass results; this may, however, become infected secondarily, and particularly after delivery. The most distinctive sign of this degenerative process is pain in the fibroid and tenderness on pressure, which persist in spite of rest and cold applications. General signs of toxic absorption become apparent later, but without pyrexia or with transient spells of fever only. For treatment myomectomy is indicated when possible, or hysterectomy if there are multiple necrosed fibroids. Other forms of degeneration are said to be rare; only one case of true gangrene seems to have been reported during pregnancy, but this condition is relatively more common after delivery.

21. Brow Presentation.

F. JESS (*Zentralbl. f. Gynäk.*, November 14th, 1925, p. 2609) cites various observers who have recently drawn attention to a mechanism of labour in brow presentations which differs from that usually described in that the antero-posterior diameter of the foetal head passes through the pelvis in the transverse or oblique rather than the conjugate diameter. He records two cases of brow presentation in which the long axis of the foetal head engaged in the transverse diameter of the pelvis. In the first case oblique forceps application led with great difficulty to delivery of the head with the sagittal suture in an oblique diameter. In the second case the child was born alive; the forceps application was made transversely, one blade grasping the malar region and face and the other the vertex and occiput. The passage was aided by traction, first to one side and then to the other. Jess remarks that, owing to the rarity of brow presentations and their late recognition in labour, trustworthy observations in a series of cases are obtainable only with great difficulty; the publication of observations by general practitioners is desirable. There is some theoretical and actual evidence that rotation of the sagittal suture into the antero-posterior pelvic diameter is normally absent or incomplete in brow presentation, and that the commonly accepted indications for the use of forceps or other operative treatment need reconsideration.

22. Prolapse of the Ovary.

U. TROPEA-MANDALARI (*Riv. d'Ostet. e Ginecol. Prat.*, November, 1925, p. 482) regards prolapse of the ovary within the pouch of Douglas as a malady having fairly characteristic signs and symptoms. More often acquired than congenital, its predisposing cause is to be found in abnormal length and extensibility of the utero-ovarian and suspensory ligaments. The immediate causative agencies are trauma, the puerperal state, uterine and vaginal prolapse, and retroposition of the uterus. The symptoms consist in (1) pain, which is more often acute than subacute, (2) menstrual disturbances, (3) dyspareunia, (4) pain in defaecation. A symptom which, if present, is characteristic, is participation of the mammary gland in the attacks of pain. Diagnosis from ectopic pregnancy is usually easy, but from appendicitis and inflammatory adnexal conditions it may be very difficult. Palpated in the pouch of Douglas, the prolapsed ovary is very tender and is rounded and hard; the tumour associated with salpingitis, on the contrary, appears very closely connected with the posterior wall of the uterus and is soft and elongated. A valuable diagnostic sign in ovarian prolapse is the ascent of the tumour from the pouch of Douglas when the patient is examined with the pelvis elevated. In treatment pessaries are of little avail. Removal of the ovary is rarely justifiable. The operative method recommended is that of Merletti, who sutures the infundibulo-pelvic ligament to the round ligament about 3 cm. from the nterine insertion of the latter.

Pathology.

23. Callus Formation and Restoration of Function.

J. L. YATES and G. W. STEVENS (*Annals of Surgery*, October, 1925, p. 617) point out that the formation of callus in the repair of a fractured bone is comparable with the healing processes in other tissues, and that the amount and strength of the callus will depend upon the movements of the bony fragments. In those animals and birds which survive fracture of a bone the function of the limb is in most cases completely restored, and this is due to the persistence of active movements limited only by pain. The authors further compare callus with atrophic bone, in that in both there is less than the normal amount of bone tissue within the outer shell, and

therefore if the callus is subject to normal stresses there tend to be produced areas of more compact bone along the lines of these applied forces. If these stresses are present but not excessive the use of the limb is more rapidly regained than if immobilization is employed. Should the movements be excessive, then an increased and pathological form of callus results, which tends to imperfect union and to deformities. The amount of callus present is therefore no indication of its competence; the efficiency of the callus should be judged rather from radiograms which demonstrate the development of these lines of increased density. Complete immobilization of a limb produces atrophy of the bones and rigidity of the joints, and while these can be corrected by the resumption of active movements it is better that these evils should be prevented, as far as possible, by not allowing immobilization to be complete. The authors conclude that the treatment of fractures should proceed along the lines which assist the ordinary reparative processes of nature, as little support as possible being given. If immobilization is necessary it should be interrupted at frequent intervals by active movements. Plaster casts are undesirable unless they allow earlier active movement than other apparatus, since they render impossible the valuable use of sunlight. Above all, strict attention to the general physical and mental condition of the patient will greatly assist in hastening repair and obtaining efficient function.

24. The Cerebro-spinal Fluid in Diphtherial Paralysis.

P. FORNARA (*La Clinica Pediatrica*, September, 1925, p. 547) records his observations on the changes in the cerebro-spinal fluid in seven cases of generalized diphtherial paralysis in children aged from 2 to 10 years. Although this subject has received much attention in France, Germany, and the United States, this is stated to be the first paper in Italian on the cerebro-spinal fluid in diphtherial paralysis. Fornara found that the intensity of the changes in the cerebro-spinal fluid bore no relation to the severity of the paralysis. The fluid was perfectly clear in all cases. In five it escaped under considerable pressure. In only one case was there a great increase in the number of cells, while in the rest the number of cells was normal or only slightly increased. On chemical examination there was an increase in the albumin and especially of the globulin. Pandey's reaction was positive in all, the Nonne-Apert-Ross Jones test was weaker and less constant, the Welebrodt reaction was definite and sometimes well marked, Boveri's reaction and the Voisinet-Ajello reaction were positive in all cases. The spinal sugar was increased in all cases, with values intermediate between 0.70 and 0.85 per 1,000. The Wassermann reaction was always negative. The colloidal benzoin test was perfectly normal in three cases, doubtfully positive in one, and in three slightly deviated to the right. The cerebro-spinal fluid thus presented slight but definite changes in all cases of diphtherial paralysis, as had been shown by Laverigne and Regan.

25. Posterior Pituitary Extract.

W. SCHLAPP (*Quart. Journ. Exper. Physiol.*, October 30th, 1925, p. 327) investigated the active principles of the posterior lobe of the pituitary body with a view to finding out whether the many physiological responses evoked by its extracts were attributable to one or more active principles. The methods used in the preparation and preservation of extracts and in the estimation of their oxytocic, pressor, and other activities are described; so far as the pressor and oxytocic principles are concerned there appears to be evidence of the existence of different substances, though it may be that the pressor and melanophore responses are due to the same substances. It was found that when depressor-free extracts were boiled with dilute hydrochloric acid the oxytocic, pressor, and melanophore responses were slowly and simultaneously destroyed. It was possible also to separate a fraction containing the greater part of the oxytocic activity by treating depressor-free extracts with N-butyl alcohol. Experiments indicated that the oxytocic activity on the one hand, and the pressor and melanophore on the other, must be due to distinct substances, but there was no positive evidence that the two latter were not attributable to one and the same principle.

26. Basal Metabolism in Cancer of the Stomach.

C. B. UDAONDO, J. E. CARULLA, and H. ZUNINO (*Arch. Arg. de enferm. del apar. dig. y de la nutrición*, October, 1925, p. 13) record their observations on eighteen cases of carcinoma of the stomach in various stages in which they studied the basal metabolism. In every case there was a more or less considerable fall in the metabolic ratio. This fall did not bear any relation to the size of the growth, but was attributed by the authors to the reduction in the amount of food taken owing to the anorexia which is the rule in this disease.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

27. The Blood Pressure in Tuberculosis.

W. B. JAMESON (*Therapeutic Gazette*, November 15th, 1925, p. 770) has studied the blood pressure in 1,200 patients suffering from pulmonary tuberculosis, and has found that the average for men is—systolic 113 mm., diastolic 68 mm.; while for women it is—systolic 106 mm., diastolic 63 mm. He also found that age had very little effect on the blood pressure of the tuberculous patient, but that the rate of lowering of the blood pressure was proportional to the rapidity and extent of involvement of lung tissues. He states that the lower the blood pressure the worse is the prognosis. Wilkes believed that a low systolic pressure without any other manifest disease to cause it pointed conclusively to tuberculosis, but Jameson considers a low pressure to be only suggestive of this disease; he advises that patients with low systolic pressure should be carefully watched.

28. M. VILLARET and M. MARTINY (*Presse Méd.*, November 28th, 1925, p. 1563) have investigated venous pressure in a series of 200 cases of tuberculosis, and find that the pressure is raised in most cases. The exceptions occur in cases of a very toxic type, as in miliary tuberculosis. They recognize two other factors which might cause this rise—one is venous engorgement, due to cardiac weakness, and the other is direct pressure on the veins in the thorax; but they hold that a rise may also occur when neither of these factors is applicable. They add that clinically the importance of these findings is, first, that a venous rise precedes a haemoptysis in every case, and secondly, that in artificial pneumothorax a rise indicates that the limits of tolerance have been reached.

29. The Development of Endocarditis.

M. RENAUD (*Bull. et Mém. des Hôp. de Paris*, November 5th, 1925, p. 1352) remarks that nowadays the distinction between simple and malignant endocarditis is not retained in classification. Examination of the anatomical lesions of endocarditis shows that the essential feature is alteration of the superficial layers of the endocardium by thrombosis. Clinically there are three categories: acute endocarditis developing in the course of some acute illness; chronic endocarditis secondary to some unknown focus and manifesting itself in pyrexia and pyaemia; and, lastly, there is the much underrated endocarditis of cancer patients, Renaud having found endocarditis fourteen times in 136 cancer necropsies. The cancers most often complicated thus are large ulcerating lesions of the rectum, face, or uterus. He adds that clinically, at any rate, these complications of cancer by endocarditis are most insidious; diagnosis during life is perhaps possible only by blood cultures, though the necropsy discloses as copious valvular lesions as in typical malignant endocarditis. Every intermediate degree may be found between a quickly fatal endocarditis and the type which continues almost indefinitely.

30. Collapse in Typhoid Fever.

R. DE BRUN (*Thèse de Paris*, 1925, No. 197), who reports fourteen cases of collapse in enteric fever, holds that the term "typhoid collapse" should be reserved for a definite syndrome which is the same in all carefully studied cases. The essential features are as follows: (1) A sudden fall of temperature which is more or less steep and may reach an extreme degree of hypothermia. (2) An equally sudden fall of blood pressure, which is more or less marked and often steep. It may be latent. When it is well developed it is manifested by the following symptoms: a remarkable change in the expression, the face being pinched as in peritonitis, and cyanosis which sometimes affects the skin generally. The various clinical forms depend on the rapidity, depth, and duration of the fall of temperature. Sometimes a sudden fall of blood pressure is manifested by transient syncope, convulsions, and sudden death. These two symptoms—the fall of blood pressure and the fall of temperature—are almost constant features of typhoid collapse, but there may also be transient tachycardia and, less frequently, transient polypnoea. The curves of the fall of temperature and blood pressure are not simultaneous or identical, but run their course independently. The principal feature of typhoid collapse is its essentially transient evolution. It is an attack which may last from three or four hours to three or even four days. The prognosis of the attack is often good, but relapses are frequent. In most cases the temperature is a guide to the duration of the collapse, just as the fall of

temperature is to the gravity of the condition. The occurrence of collapse is independent of the gravity of the original disease, and in like manner it has no effect on the progress of the disease, which pursues its ordinary course when the collapse has passed off. The collapse is not due to cardiac failure, as examination of the heart before, during, and after an attack remains negative. It can only be due to a bulbar deficiency, which is sudden though transient. The different centres (thermal, vasomotor, cardiac, and pulmonary) may be inhibited more or less completely.

31. Purpura Haemorrhagica of the Bladder.

F. DE GIRONCOLI (*Arch. Ital. di Urol.*, July, 1925, p. 632) states that the first example of this condition was described by F. Kidd in 1913, since when nine cases have been recorded, including the following case which came under his own observation. The patient was a robust and previously healthy girl, aged 17, who suddenly developed frequent micturition, strangury, and haematuria. Cultures of the urine were sterile. The Wassermann reaction was negative. The red cells numbered 4,500,000 and the leucocytes 6,300; haemoglobin 80 per cent.; differential count: polymorphonuclear leucocytes 46.5 per cent., lymphocytes 45 per cent., monocytes 4 per cent., transitionals 4 per cent., Türk's cells 0.5 per cent. On cystoscopic examination punctiform haemorrhages were seen in the mucous membrane of the bladder. Large ecchymoses developed at the sites where the blood had been taken for diagnostic purposes. Under treatment by vesical lavage with silver nitrate solution the vesical haemorrhages soon disappeared and complete recovery followed. The author concludes: (1) Purpura haemorrhagica of the bladder is not a nosological entity but the expression of a haemorrhagic diathesis of the whole organism, usually due to a toxoinfection. (2) Purpura haemorrhagica of the bladder and simple ulcer of the bladder are two distinct affections with the same etiology. (3) The diagnosis of purpura haemorrhagica of the bladder is made by cystoscopy, which shows the presence of characteristic haemorrhages in the fundus of the bladder. (4) Treatment consists in vesical lavage with a solution of silver nitrate in a strength of 1/4 to 1 in 1,000. (5) The prognosis is favourable. Under suitable treatment the haemorrhages and subjective disturbances disappear in a few weeks' time.

Surgery.

32. Plexiform Neuromata.

G. BELL and K. INGLIS (*Med. Journ. of Australia*, October 3rd, 1925, p. 423) report a case of plexiform neuroma with associated local hypertrophy and multiple chondromata in a girl, aged 20, who had had the middle finger of the left hand removed in infancy for hypertrophy. The swelling in the left index finger of which she now complained had been noticed first when she was 14 years of age. This swelling had increased in size and had extended upwards so as to occupy a great part of the radial side of the hand and the flexor aspect of the lower third of the forearm; there was some pain. The authors also report (*ibid.*, p. 427) a similar case in a farmer, aged 54. He gave a history of having been born with a large left upper limb, the thumb, index, and middle fingers of which were removed when he was 18 months of age. Nine months before he was admitted to hospital he fractured his right femur, and after this he noticed weakness in the left arm and increase in its size. In both cases the tumours were soft with an irregular cord-like structure, and on pathological examination were proved to be plexiform neuromata. As a result of their experience in these cases and study of the literature the authors suggest that the plexiform neuroma is the primary and essential lesion, the localized hypertrophy and multiple chondromata being secondary effects.

33. Apophysitis of the Os Calcis.

P. LEWIN (*Surg., Gynecol. and Obstet.*, November, 1925, p. 579) describes apophysitis, or inflammation of the epiphysis at the posterior portion of the os calcis, a condition but little noticed in the textbooks or literature. He considers that it is analogous to Legg's disease in the hip or Osgood-Schlatter's disease of the tibia, and attributes it to internal or external trauma combined with local circulatory disturbances affecting the apophysis at its critical period of growth. The onset is insidious, with or without history of injury, and occurs

usually in boys between the ages of 9 and 13. A limp is generally the earliest symptom, and there may be pain, tenderness, and thickening over the affected part, a slight equinus condition developing owing to disinclination to stretch the tendo Achillis. Radiographical examination shows irregularity and thickening. The prognosis is excellent if the limb is put in plaster from the toes to above the knee, with the foot in slight equinus and the knee in slight flexion to relax the pull of the triceps. After a fortnight this is replaced by another plaster application from the toes to just below the knee, the foot being now placed at a right angle. A month later a high laced shoe is used with three-quarters of an inch cork lift for the heel, crutches being used for a further two weeks. In very mild cases elevation of the heel and the insertion of a felt or rubber pad may be all that is necessary.

34. Bursal Exostosis.

A. ABRAMOWA (*Zentralbl. f. Chir.*, November 21st, 1925, p. 2649) describes a case of bursal exostosis. The etiology of this disease is obscure and the diagnosis may be difficult when the bony tumour is situated deeply under muscles. A peasant woman, aged 48, whose eldest daughter had died from tuberculous osteitis, complained of a swelling in the lower part of the right popliteal space, which, although not increasing in size, rendered prolonged standing or walking impossible on account of pain radiating down the leg. There was some oedema of the right leg below the swelling, which was of bony hardness and quite immobile. The circumference of the right knee was less than that of the left joint, and flexion was limited to 60 degrees. All movements of the ankle and foot were free. On separating the two heads of the gastrocnemius, the tumour was found to consist of three thin-walled sacs, communicating with each other by narrow necks; these were filled by three masses of bone united by slender pedicles, and a thicker pedicle formed the attachment to the upper third of the posterior surface of the tibia, apparently at the level of the junction of the epiphysis and shaft. The three sacs represented the bursa beneath the semimembranosus. The large proximal mass consisted of bone and hyaline cartilage, and was attached to the tibia by a thick pedicle which had to be divided by a chisel. The operation two years ago was completely successful, and there has been no recurrence.

35. Pancreatic Cysts.

H. ROTH (*Amer. Journ. of Surg.*, November, 1925, p. 257) points out that cysts of the pancreas are not at all common, and that their diagnosis is usually difficult. Pain is often present and loss of weight is generally marked; sugar in the urine is sometimes present. It is believed by many that these cases of so-called pancreatic cyst when of traumatic origin are really effusions into the lesser sac of the peritoneum. Traumatism may cause a true cyst or a pseudo-cyst; if true, the cyst may appear soon or late after the injury. Haemorrhagic cysts are usually of traumatic origin, but may also result from acute pancreatitis. Cysts of the pancreas are usually single; they have a smooth surface and are tense. The early symptoms are vague, including epigastric pain, flatulence, and indigestion; jaundice may be present, and there is usually loss of weight. The tumour is usually fixed, but may be movable. The diagnosis is often only made at exploratory operation, and treatment is always surgical. If the cyst has a small pedicle it may be entirely removed. The safest operation, however, is evacuation of the fluid and drainage of the cyst. Frequent changes of dressing are necessary and the skin must be protected from irritation. The cavity fills up with granulations, though occasionally a fistula persists. X-ray treatment and antidiabetic diet have been advised to hasten closure of the fistula. The results of surgical treatment are usually satisfactory.

36. Treatment of Liver Abscess.

O. CIGNOZZI (*Lyon Chir.*, September-October, 1925, p. 597), dealing with the surgical treatment of hepatic abscesses, distinguishes between those arising in the right lobe and those in the left lobe of the liver. The abscess may be found uncomplicated or it may be adherent to the abdominal parietes. The author bases his experience on thirty-three cases, and finds that abscesses of the right lobe are always larger and more extensive than those arising on the left side. He holds that the best approach for an abscess of the left side is by a longitudinal mid-line incision above the umbilicus. If the liver is not adherent to the abdominal wall it may be sutured to the parietal peritoneum or packed round with gauze before the abscess is opened. After evacuating the pus the abscess cavity is packed for several days. Abscesses of the right lobe when large may be drained through an incision dividing the fibres of the right rectus muscle. Where the abscess lies under the costal region an oblique incision below the lower ribs is made; this is considered preferable to

resection of the ninth or tenth rib, which often results in a fistula. In the rare cases where the abscess lies on the posterior aspect of the right lobe it should be drained by a transverse incision in the lumbar region which gives satisfactory drainage. In the thirty-three cases recorded there were seven deaths. Death is usually due to hepatic insufficiency or toxæmia, and sometimes to pyæmia or the secondary formation of a subphrenic abscess.

Therapeutics.

37. Sanocrysin in Pulmonary Tuberculosis.

V. BIE (*Ugeskrift for Læger*, November 19th, 1925, p. 1023) records several cases of acute febrile pulmonary tuberculosis treated with sanocrysin. He started with a dose of 0.25 gram and gradually increased to 1 gram, a total of 5.25 to 5.50 grams being given in one series of injections, and the interval between each injection being at least five days. An interval of three to four weeks was allowed between the first and second series of injections. In those cases which responded satisfactorily the temperature gradually fell to normal during the first series of injections, but it was only later that improvement was detected in the appetite, the general condition, and the stethoscopic signs. P. KÜHNEL (*ibid.*, p. 1036) has compared the results in twenty cases one month after the completion of treatment with the results in fifteen of these cases from two to seven months later. The first results were fair with three exceptions, two patients in the third stage of the disease and one in the second stage developing violent and fatal exacerbations. Between two and seven months later two more patients had died, and only three of the remaining fifteen had maintained their improvement. Kühnel fears, therefore, that even when the immediate effects of sanocrysin are good, the gain is seldom maintained. G. E. PERMIN (*ibid.*, p. 1037) recommends for adults a first dose of from 5 to 10 cc., and every fourth day, when the febrile reaction has passed off, this dose is increased by 5 to 10 cc. provided there is no albuminuria or rash. When the dose has been increased to 25 or 30 cc. the interval between each injection is lengthened to one week, and each dose is increased by 5, 10, 15, or 20 cc., the rate of increase being determined by clinical indications. When the dose has reached 1 gram the injections are continued at this level till no reaction occurs. He recommends also a second series of injections during which the dose may be increased more rapidly. He claims that the discomforts and dangers of early sanocrysin treatment have been much reduced, and that the results are as good as those with the original dosage.

38. C. BENEDETTI (*Il Policlinico*, November 9th, 1925, p. 1557), after a careful study of the results obtained in the treatment of pulmonary tuberculosis by sanocrysin, gives a qualified approval. He agrees that it has a bactericidal action on the tubercle bacillus, but is not devoid of danger, the chief troubles being albuminuria, shock, and the minor inconveniences of serum injection. He finds that the most suitable cases are those of the recent exudative type where the disease is neither extensive nor very active; little benefit was obtained in fibrous types or in surgical tuberculosis. Improvement was indicated by decrease of the cough, gain in weight, and disappearance of night sweats, while there was also radiographic evidence of benefit. Benedetti agrees also that sanocrysin must not be used when there is much fever, cardiac weakness, diarrhoea, or profuse night sweats, and that in any case sanatorium treatment should be given simultaneously.

39. Serum Treatment of Typhoid Fever.

A. RODET (*Journ. de méd. de Lyon*, November 5th, 1925, p. 619), who has collected more or less detailed information about 1,500 cases of typhoid fever in France and foreign countries treated by his serum, records statistics of 679 cases. Of these patients, 66 died—a mortality of 9.7 per cent. The best results were obtained when the serum was given early, the mortality being only 2.3 per cent. among 86 cases treated within the first five days. Like the mortality, the average duration of the disease and the frequency of complications and relapses were reduced by early administration of the serum. Rodet claims that serum treatment is superior to balneo-therapy, not only in being simpler to apply, but also in shortening the duration of the disease and even causing it to abort, if the treatment is begun sufficiently early. The serum may be given at any stage of the disease, but it is best to use it as early as possible. It should be given in larger doses than has hitherto been done, at least in some cases. It should be the only form of treatment applied and should not be associated with antipyretic drugs, baths, or other methods of reducing the temperature.

30. Vaccine Treatment of Whooping-cough.

A. PONDMAN (*Nederl. Tijdschr. v. Geneesk.*, October 24th, 1925, p. 1893) records the results of a questionnaire sent to medical practitioners who had employed the pertussis vaccine prepared by the Dutch Serological Institute at Utrecht; 89 answers were received, with the following results. The local reaction appears to have been insignificant. Only six practitioners stated that a small infiltration had occurred after large doses had been given, and in one case a transient urticaria was observed. As regards a general reaction 18 showed a slight rise of temperature not exceeding one degree, and in 5 the temperature was somewhat higher, the highest recorded being 102.6°. No reply was received about a focal reaction—that is to say, the effect of the vaccine on the respiratory tract. As regards the prophylactic value of the vaccine 12 answers were received, of which 8 were favourable, 3 were partly favourable, and 1 unfavourable. Of the 89 answers concerning the curative effect of the vaccine, 21 had to be excluded as the numbers treated were too small to justify a conclusion. Of the remaining 68, 61 were favourable and 7 unfavourable. Pondman's conclusions as the result of the answers to the questionnaire are as follows: (1) As a general rule it is advisable to increase the dose. (2) There is no objection to this, as no bad results were reported. (3) The vaccine should be used as early as possible. (4) It is essential that it should be prepared from different strains of pertussis bacilli.

Laryngology and Otology.**31. Tracheotomy in Tuberculous Laryngitis.**

T. RITCHIE RODGER (*Journ. of Laryngol. and Otol.*, October, 1925, p. 639) describes four cases of tuberculous laryngitis in which urgent tracheotomy had to be performed on account of dyspnoea. Three patients progressed extremely well after this procedure and the laryngeal tuberculosis cleared up satisfactorily. The fourth patient had very extensive lung infection and died about two months after the operation; he had, however, derived great benefit from the tracheotomy. In all four cases a fatal issue was certain without a tracheotomy. In these cases there is no question about the propriety of performing tracheotomy, but a much more difficult problem is set by the severe tuberculous laryngitis which does not improve and which has no signs of dyspnoea. Even after tracheotomy the cords move during deglutition, during quiet respiration, and during forced movements of the arms, as was pointed out by Negus. Tracheotomy, therefore, does not put the larynx at rest completely, but it eliminates speech, and is of value chiefly in those cases in which the disease is progressing, and the patient is incapable of observing the rule of strict silence. In favour of tracheotomy it may be said that the inspired air no longer passes over an ulcerated tuberculous area nor does the infected sputum reach the already damaged laryngeal mucosa. Against tracheotomy is the fact that cold dry unfiltered air is passed straight into the lungs, which are already weakened by tuberculosis, and there is the much greater difficulty of protecting the nursing staff and other attendants from the infected sputum. The author concludes that tracheotomy should be reserved for cases of marked dyspnoea and for patients in whom the complete silence regime is not possible.

32. Leptomeningitis in Acute Otitis.

C. FERRETTI (*Arch. Ital. di Otol., Rinol. e Laringol.*, October, 1925, p. 628) recalls the conferences at Perugia and Paris in 1922 on meningitis following otitis media and the various methods of treatment adopted. Gradenigo relied on a very extensive excision of the diseased area in the tympanum and mastoid process, laying bare a wide area of the dura mater, and on repeated lumbar puncture. He also injected autogenous vaccines and colloidal metals. Jenkins, however, considers that the infection travels through the labyrinth and internal auditory meatus, and treats such cases by opening up the internal ear and draining through the meatus. Turner performs the mastoid operation and employs lumbar puncture, but if this does not bring relief he at once drains through the labyrinth. Ferretti now records the case of a man with acute otitis media who after seven days showed signs of labyrinthine affection—vertigo, headache, and tremors. By the tenth day he had definite signs of meningitis—retraction of the head and Kernig's sign. A very wide mastoid operation was performed, and the operation area was irrigated by the Carrel-Dakin method. Lumbar puncture was performed four times daily with evacuation of large quantities (30 to 40 c.cm.) of turbid fluid. An autogenous vaccine was prepared and injected intramuscularly. Improvement began at once, and in a month the patient was discharged quite well. Three weeks later there was a recrudescence, but by thoroughly irrigating

the mastoid cavity with Dakin's solution and practising lumbar puncture recovery was speedy and complete. The author considers that the above is the ideal method of treatment and is strongly opposed to opening up the dura mater or of interfering unnecessarily with the labyrinth. When, however, the meningitic symptoms are preceded by signs of labyrinthine inflammation drainage through the internal ear is not irrational, though in many of these cases his own line of treatment proved sufficient. The repeated lumbar puncture he considers most important, as it serves to wash out the cerebro-spinal space and to keep down the pressure of the fluid, which tends to inhibit the cerebral blood supply.

33. Oto-sclerosis.

R. LAKE (*Journ. of Laryngol. and Otol.*, August, 1925, p. 512) does not accept heredity and congenital syphilis as etiological factors in oto-sclerosis. According to him any hereditary taint is confined to a tendency to nasal deformation and to tonsillar disease. Middle-ear disease is common in connexion with nasal irregularities and the consequent catarrh, but is more often found in cases of slight degree, and especially when the deformity is skeletal and not merely of the soft tissue. Tonsillar disease is very prolific of middle-ear disease, and acts as a septic focus which appears to be the exciting cause in a great many cases. Lake states that a considerable number of the so-called cases of oto-sclerosis in children are really of a different nature and tend to get better, a phenomenon which apparently rules out oto-sclerosis. The typical symptoms of oto-sclerosis are Bezold's triad (loss of low tones, prolonged bone conduction, and negative Rinne reaction), tinnitus, and the ability to hear better in a noise. The loss of low tone is a symptom which is present in all cases of Eustachian obstruction, and varies enormously with the type and pitch of tuning-fork used. Prolonged bone conduction is, again, a symptom of Eustachian obstruction, but also occurs as a result of rigidity of the ossicular chain. Rinne's reaction naturally varies in concert with the above test. Tinnitus commencing early in deafness is Eustachian in origin; when occurring in more established deafness it is probably due to stapedial immobility. Paraensis Willisii always occurs in stapedial immobility, but also appears in boiler-maker's deafness and the like. The author considers that the red reflex in the drum is a sign of a patch of rarefying osteitis beneath. Treatment consists in the radical elimination of septic tonsils, teeth, and other foci of infection, and the correction of nasal deformities. In conclusion, the author is doubtful if there is really a definite entity to be called oto-sclerosis, and suggests that further work will put this group of symptoms into the main category of non-suppurative deafness.

Obstetrics and Gynaecology.**34. Version in Central Placenta Praevia.**

P. BALARD (*Gaz. hebdom. des Sci. Méd.*, November 29th, 1925, p. 756) reports a case of total placenta praevia occurring in a country district in which removal to hospital would have meant recurrence of the bleeding and a dangerous delay. He emphasizes the point that obstetrical, as compared with surgical, treatment has a wider application in multiparae than in primiparae. Nevertheless, although his patient was a primipara, he at once perforated the placenta, performed version (there had been a head presentation), and delivered a living child; the mother was able to leave her bed on the fifteenth day. In this case the os was soft, and nearly the size of a penny; a primipara with a small rigid os would have required different treatment. Balard adds that another factor to be kept in view when determining treatment is that sepsis supervening upon obstetrical measures is a slower and more amenable complication than sepsis following Caesarean section, which may happen in spite of every care being taken with the abdominal wound.

35. The Cause of Eclampsia.

H. ELWYN (*Amer. Journ. Obstet. and Gynecol.*, November, 1925, p. 698) remarks that there have been several attempts to explain the phenomena of eclampsia in pregnancy, and that the modern tendency is to ascribe them to the toxic effects of metabolic substances derived from the placenta. Volhard thought that the clinical manifestations of eclampsia resulted from a general arterial spastic contraction. Elwyn states that stimuli controlling both uterine contraction and vaso-constriction travel along the thoracic-lumbar branches of the sympathetic nervous system; that uterine contractions can be influenced by stimuli applied to the anterior part of the optic thalamus and to the floor of the third ventricle; that in the medulla there is a vasomotor control centre; and that general vaso-constriction can be obtained by stimulating the region of the hypothalamus. He concludes that the

centres for control of vaso-constriction and uterine contraction are closely related to one another and the impulses travel along almost the same neural paths. He suggests that with the beginning of pregnancy there is an increase in the excitability of the nerve supply to the uterus and of the corresponding centre in the brain, and that the close proximity of the centre for vaso-constriction permits this increased excitability to spread to it. This condition of the nervous mechanism becomes more marked as pregnancy progresses and lasts as long as the uterus is required to contract—that is, into the puerperium. Eliwyn states further that the increased excitability is probably present to some extent in every case of pregnancy, but that only in some cases does it become sufficiently pronounced to cause a general spastic contraction of the pre-capillary arterioles. He suggests that those stimuli which cause eclampsia are variable, and include emotional stress, excessive physical effort, and the passage of the child's blood into the mother's circulation should incompatibility exist. It is this general arteriole contraction which, in his opinion, gives rise to the clinical manifestations of eclampsia and to the histological changes found in this disease.

46. The Physiology of Menstruation.

S. D. LUDLUM and E. McDONALD (*Surg., Gynecol. and Obstet.*, November, 1925, p. 569) recall that the longitudinal muscle of the uterus is stimulated by the vagus and inhibited by the sympathetic system, that the circular muscle is stimulated by the sympathetic and inhibited by the vagus, and that the muscle of the intestine reacts in the same way to the same impulses. Acting on this they have made a number of radiographic examinations of the intestinal muscular tone before and during menstruation. These examinations indicated that normally during the intermenstrual period the innervation inclined towards sympatheticotonia; during menstruation there was a preponderance of vagus stimulation, and during the subsequent five days the smooth muscle reaction gradually returned to normal. They suggest that the pains and cramps associated with menstruation may be due to vagus stimulation of intestinal muscle, and that the constipation which so often occurs at this time may be the result of stimulation of the pelvic branch of the vagus. They believe that Blair Bell's conclusions in regard to the influence of calcium on menstruation are probably correct, and suggest that the vagotonia during this period is, in part at least, due to the accumulation of calcium in the blood and tissues and that calcium is excreted during menstruation. They have found that drugs and salts which inhibit the vagus or stimulate the sympathetic lessen the pain of dysmenorrhoea, and those which stimulate the vagus increase the menstrual pain and flow.

47. Endometrial Hypertrophy and Ovarian Tumours.

H. O. NEUMANN (*Zentralbl. f. Gynäk.*, November 28th, 1925, p. 2695) has been able independently to confirm a recent report of R. Meyer that a pathological hypertrophy of the endometrium is not infrequently associated with the presence of ovarian tumours. Meyer's cases, like those of French observers, were chiefly those of women who had passed the climacteric; but Neumann's patients included three aged respectively 34, 35, and 36. In one of these a considerable degree of hyperplasia and hypertrophy of the endometrium was demonstrated microscopically, and in the other two the uterus was found by clinical examination and at operation to be enlarged and soft. In one of Neumann's cases, and in a patient aged 25 reported by Aschner, irregular and copious haemorrhages were succeeded, after removal of the ovarian tumour, by regular and less abundant menstruation. In another case the patient, aged 50, had post-climacteric bleeding in association with recently developed ovarian carcinoma. Neumann feels justified in concluding that an endometrial hypertrophy is brought about by internal secretion of the granulosa cells in ovarian tumours.

Pathology.

48. The Action of Iodine in Exophthalmic Goitre.

W. F. RIENHOFF, jun. (*Bull. Johns Hopkins Hosp.*, November, 1925, p. 285), discusses the histological changes brought about in cases of exophthalmic goitre by the administration of iodine. Three successive typical cases were studied, in each of which the basal metabolic reaction was well above 50 before the administration of iodine, but afterwards there was a striking clinical improvement with a precipitous drop in the basal metabolic rate. The changes produced by iodine were found to be an increase in the size of the gland with a decrease in vascularity and probably in lymph flow through the gland; there was a large increase in the amount of

fibrous connective tissue and of colloid. The acini from being laco-like papillomatous ingrowths became even-walled, smooth, and regular in size and form, with a transition of epithelium from high columnar to flat cuboidal and occasionally low columnar. The large clear nuclei of the epithelial cells became altered to the small irregular pyknotic type, and many mitotic figures present before the use of iodine disappeared after it had been given. The clinical improvement and lowered rate of basal metabolism were directly associated with the change from a typical histological exophthalmic goitre picture to a resting colloid state. Similar changes were noted in fifteen cases of exophthalmic goitre treated with iodine, as compared with fifteen who had had no medication. Rienhoff points out that an artificial remission is produced by iodine, and in the case of exophthalmic goitre this is associated with a change from a hyperplastic to a colloid state, even though definite hyperplasia remains, it being a question of relative hyperplasia. In operating he had noticed for some time that the glands of patients who had not been given iodine were more vascular than the glands of those who had been so treated; in the iodized cases also the glands were more fibrous, appeared to contain more colloid, and frequently showed small cystic areas.

49. The Pathology of Terminal Gastritis in Pulmonary Tuberculosis.

J. PARISOT, L. CÔRNIL, and P. HANSAL (*Rev. méd. de l'Est*, October 1st, 1925, p. 690) remark that until Marfan made a careful study in 1887 of the terminal gastritis in pulmonary tuberculosis little of value had been published by previous observers, as they had frequently mistaken the normal post-mortem changes in the gastric mucous membrane for pathological lesions. Marfan came to the conclusion that the most frequent lesions were a mammillated appearance of the gastric mucosa with thickening; more rarely the mucous membrane showed polypoid vegetations or punctiform erosions. On microscopical examination the inflammation was found to be interstitial at first, the covering epithelium undergoing only secondary changes. The erosion corresponded to accumulations of lymphocytes. Marfan regarded the lesions as indicating an infective gastritis like that found in general diseases with a tendency to suppuration, or as an irritative gastritis due to swallowing tuberculous sputum. Subsequent investigations have lent support to Marfan's views. As the result of naked eye and microscopical examination of the stomach in three cases of pulmonary tuberculosis in which the specimen was removed from three-quarters of an hour to two hours after death so as to avoid autolysis, the present authors found the following lesions: (1) Subacute gastritis characterized by granular and vacuolar degeneration of the gland cells in the fundus and especially the pyloric region. (2) A very abundant inflammatory infiltration of an interstitial lymphoplasmatic type with hyperplasia of the lymphoid follicles without specific tuberculous lesions. (3) Considerable congestion of the vessels of the mucosa and submucosa and even a few lesions of periarteritis and periplebitis.

50. The Virulence of *B. typhosus* for the Oyster.

S. COSTA, R. HOVASSE, and L. BOYER (*C. R. Soc. de Biologie*, December 11th, 1925, pp. 1439 and 1441) inoculated ten oysters with about 200 million typhoid bacilli; all the oysters became diseased within four days, and nine died within three weeks. A loopful of the almost lysed body was used for culture after death, and in five out of the nine oysters *B. typhosus* was recovered. The water in which they had been kept was found free from typhoid bacilli. In another experiment twenty oysters were placed in water that had been contaminated with *B. typhosus* by the addition of one slope culture per litre of water. The majority soon showed signs of illness, and eighteen died within three weeks. Cultures were taken from seven of the oysters after death, and the typhoid bacillus was recovered four times. In one instance an oyster dying twenty-one days after the commencement of the experiment was not examined till a fortnight later; a culture of the putrid material proved positive, showing that the body of the dead oyster seems to be not unfavourable for the growth of this bacillus. The authors state that it is not justifiable to conclude from these experiments that the typhoid bacillus is pathogenic for oysters, because the mortality amongst the control uninoculated oysters was very high—60 per cent. But it does appear that the bacillus is able to live and probably to multiply in the body and visceral glands of the oyster—in other words, to prove virulent to it. Further experiments undertaken to determine how long an oyster may remain infected showed that when placed in contaminated water the oyster rapidly became infected, and remained infected for at least twelve days, when the experiment ended. The method of purifying oysters by placing them in clean water for a week or so would therefore seem to be ineffective.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

51. Isolated Post-scarlatinal Adenitis.

P. NOBÉCOURT and L. LEBÉE (*Paris méd.*, November 7th, 1925, p. 385), who record an illustrative case in a boy aged 11, have drawn up the following classification of the types of adenitis occurring in scarlet fever: (1) Adenitis as the first manifestation of the disease, preceding the other symptoms and even the sore throat, and usually situated below the angle of the jaw. (2) Adenitis of the onset occurring simultaneously with the sore throat, rarely of large size and seldom ending in suppuration. (3) Adenitis of the second week of scarlet fever, usually situated below the angle of the jaw, accompanied by a rise of temperature, as a rule, of a few days' duration and with a good prognosis. (4) The typical scarlet fever bulbo, which also occurs about the second week, and is associated with the tonsillar and pharyngeal complications of this stage of the disease. (5) The adenitis described by Leichtenstern in 1882 and by Stembo in 1900. This occurs a little later than the last form, is usually situated below the angle of the jaw, and is not accompanied by sore throat. It is a mild complication in itself, but is of grave prognosis, as it precedes the appearance of severe nephritis by one or two days. (6) True post-scarlatinal adenitis, which occurs towards the end of the third week, or in the fourth or fifth. It may be an isolated phenomenon. It is important that the practitioner should be familiar with it, so that he should not attribute it to another cause, especially tuberculosis. It also serves as an indication of a previous attack of unrecognized scarlet fever, like desquamation of the fingers and toes. It cannot be determined at present whether the late adenitis is due to a recrudescence of the agent of scarlet fever or to a secondary infection. Isolated post-scarlatinal adenitis is accompanied at its onset by a transient rise of temperature, and sometimes by slight headache and vomiting. It may assume three different types: (1) As a rule, it is most pronounced below the angle of the jaw; it is sometimes unilateral and may be confined to a single gland. (2) Sometimes the swelling of the face is so marked as to suggest nephritis, and it is difficult to distinguish the separate glands. (3) Sometimes, as in the case reported by the present authors, the first gland to be enlarged is in the supraclavicular region, the cervical chain being affected later.

52. Acquired Immunity to Tuberculosis.

A. DE BESCHE and J. O. JØRGENSEN (*Norsk Mag. for Lægevidenskaben*, November, 1925, p. 1229) have compared the death rate from pulmonary tuberculosis in Oslo during 1921 and 1922 among the natives of this city with that among the persons who had moved from other parts of Norway into it and had died there. It has been calculated that by the time a native of Oslo has reached the age of 7 there are overwhelming odds in favour of tuberculosis having already been acquired. On the other hand, a certain proportion of the persons moving into Oslo from country districts may be supposed to have escaped infection with tuberculosis in early childhood. Comparison of the natives and the immigrants gives a clue to the influence of early tuberculosis in adult life. If a slight infection in early childhood confers immunity in adult life, then the mortality from tuberculosis among the adult natives of Oslo should be less than that of the immigrants into this city. Of the 5,849 persons who died in Oslo in 1921 and 1922, only 2,301, or 39.3 per cent., had been born there. There were 762 deaths from pulmonary tuberculosis—that is, about 13 per cent. of all the deaths—and between the ages of 15 and 40 the deaths from pulmonary tuberculosis numbered 337 among the natives and 155 among the immigrants. Thus, in this age group as great a proportion as 53.5 per cent. of all the deaths among the natives was due to pulmonary tuberculosis, whereas this was the case with only 34.2 per cent. of all the deaths among the immigrants. Above the age of 40, 5.7 per cent. of all the deaths among the immigrants were due to pulmonary tuberculosis, the corresponding figure for the natives being 6.7 per cent. The authors conclude that the total mortality among the immigrants was somewhat less than among the natives, and that in the age group 15 to 40 the mortality from pulmonary tuberculosis was less among the immigrants than among the natives of Oslo. They are sceptical, therefore, about the soundness of the frequently held opinion that tuberculosis infection in early childhood confers immunity later in life.

53. Pulsating Veins in Cardiac Failure.

W. J. KERR and S. L. WARREN (*Arch. Intern. Med.*, November 15th, 1925, p. 593) discuss the occurrence of pulsations in the peripheral veins in failure of the heart with congestion associated with pulsation of the liver and tricuspid regurgitation. From observations of 56 cases of pulsations in the basilic veins the authors found that the condition was associated with some degree of myocardial damage and showed many of the signs of tricuspid incompetency—namely, cyanosis and dyspnoea, oedema and ascites, dilated right heart, a systolic murmur over the lower sternum, a large pulsating or tender liver, marked pulsations in the jugular veins, increased venous pressure, visible and palpable pulsations in the peripheral veins, especially the basilic, myocardial damage, and occasionally right-sided hypertrophy. In the presence of extensive valvular lesions and marked decompensation these venous pulsations are held to indicate a bad prognosis because of pronounced heart failure, and in less marked cases they should be regarded as a warning of early heart failure. Though other clinical signs may be present, the pulsating veins may be the earliest outstanding sign and be indicative of the degree of myocardial and tricuspid incompetency. The pulsations in the basilic veins may vary from a flicker to large excursions of from 2 to 3 cm.; they are centrifugally propagated by the contractions of the right ventricle and are associated with venous stasis.

54. Tetany and Convulsions in Whooping-cough.

G. F. POWERS (*Amer. Journ. Dis. Child.*, November, 1925, p. 632), who records five cases in infants aged from 4 to 17 months, maintains that infantile tetany and not anatomical injuries or an unknown toxin is often the cause of convulsions in whooping-cough. The electrical reactions of two infants, the only patients in his series on whom these determinations were made, were strongly suggestive of tetany in that they showed anodal hyperirritability. In one case the spinal fluid was examined and found to be negative, so that meningitis and cerebral haemorrhage were eliminated as causes of convulsions in that patient. In all the patients the calcium concentration in the blood was less than the normal 10 mg. per 100 c.c.m., the lowest being 4.9 mg. and the highest 8.9 mg. Powers recommends that the calcium concentration of the blood and electrical reactions of all infants with whooping-cough should be determined if possible, and treatment guided by the evidence for or against the existence of latent tetany. If these determinations cannot be made, calcium chloride should be given to young children who have pertussis complicated by convulsions, even if there is no clinical evidence of tetany and rickets.

55. The Spread of Diphtheria.

D. M. LEWIS (*Boston Med. and Surg. Journ.*, November 12th, 1925, p. 913) discusses the point that while the mortality of diphtheria has now been very greatly reduced, its occurrence has been little if at all influenced. He believes that periodical epidemics of measles are followed by an increased number of outbreaks of diphtheria, and he finds that epidemiologically, statistically, and biologically it is possible to correlate variations in the morbidity of diphtheria with epidemic measles. There appears to be little doubt that the nasal catarrh at the onset of measles, when affecting diphtheria carriers, is an important factor in the spread of diphtheria. Lewis believes that the spread of diphtheria would be much diminished by detecting and isolating diphtheria carriers, whether the bacteria were virulent or avirulent, during and following all respiratory infections, but particularly measles. He doubts, however, whether this would be equally effective in diminishing the mortality. He recommends that laboratory reports should not only state "diphtheria negative," but should define the predominant organism, as in this way the hidden factor in the varying mortality from diphtheria may be discovered. He supports his contentions by much statistical evidence.

56. The Etiology of Osteitis Deformans.

G. GUILLAIN and N. PÉRON (*Ann. de Méd.*, September, 1925, p. 167) report a case of associated tabes dorsalis and osteitis deformans (Paget's disease). While the authors do not think that the latter is always of syphilitic origin, they believe their case to be rather suggestive. A man, aged 54, had suffered from tabes dorsalis since 1919. In March, 1922, his blood serum gave a negative Wassermann reaction, but the cerebro-spinal fluid was positive. In August, 1922, the

patient had a spontaneous fracture of the left femur in the upper third of the shaft. The bones of the pelvis and lower extremities are generally thickened and noduly curved. The circumference of the skull has increased from 21 inches in 1913 to 22½ inches in 1925. The skiagraphs of the cranial and long bones confirm the clinical diagnosis. Large areas of the ilia and sacrum are decalcified, and the lumbar vertebrae show similar changes. The symptoms of tabes dorsalis are typical and progressive. The authors suggest that the syphilitic origin of some cases of Paget's disease is probable, and also that this may not be a definite pathological entity. It is characterized by periods of alternating activity and quiescence, and if antisyphilitic treatment fails to cure either tabes or the bony lesions, it is at any rate probable that the progress of the lesions may be retarded or arrested temporarily.

57. Progressive Muscular Dystrophy in Congenital Syphilis.

G. C. BOLTEN (*Nederl. Tijdschr. v. Geneesk.*, October 17th, 1925, p. 1792) states that the part played by syphilis in the causation of muscular dystrophy is certainly unimportant, as cases with a positive Wassermann reaction have not, to his knowledge, been recorded. The reason for this is that in the great majority of cases progressive muscular dystrophy develops at a period of life when syphilis can usually be excluded, being most commonly found in children under 15 years of age. Bolten now records two cases of the juvenile type of progressive muscular dystrophy of Leyden and Moebius in two brothers, aged 19 and 12 years, in whom the early symptoms were first observed at 9 and 8 years of age respectively. The mother had had several miscarriages and gave a positive Wassermann reaction. The younger boy showed Hutchinson's teeth, although his Wassermann reaction was negative. Antisyphilitic treatment as well as endocrine therapy in the form of pituitary, thyroid, and suprarenal preparations had no effect. Bolten had previously pointed out (*ibid.*, 1925, i, No. 6) that muscular dystrophy was in all probability due to polyglandular insufficiency in which the pituitary, thyroid, and chromaffin system were involved. In the present cases he considers that the muscular dystrophy was caused by the action of syphilis on the endocrine system, just as cases of infantilis in which there is a disturbance of the pituitary and thyroid, and possibly of the chromaffin system, are due to congenital syphilis.

Surgery.

58. Dermatoses as Premonitory Symptoms of Cancer.

A. HART (*Zentralbl. f. Chir.*, November 28th, 1925, p. 2699) recalls the fact that Kuttner has recorded three cases of chronic pruritus in patients who were found subsequently to be suffering from cancer of the stomach. Hart had observed definite skin lesions—prurigo, erythema multiforme, and dermatitis herpetiformis—in cases of sarcoma of the thyroid gland and of the cervical lymph nodes, and in gastric carcinoma. He now reports two recent and typical cases in married women, aged respectively 55 and 57. The first patient had suffered for two years from anæmia and gastric pain, and for one year had had a chronic dermatitis, diagnosed as scabies. During the last two months the gastralgia was associated with nausea. An annular eruption appeared in the umbilical region, accompanied by intense itching and severe abdominal pain. Repeated skiagraphs and chemical examinations of the contents of the alimentary canal failed to reveal any tumour or ulceration. The patient was well nourished, but her face was pale and greyish. The skin of the trunk was dirty and pigmented, and covered with old and recent scratches. No visceral tumour could be discovered. The abdominal wall was pendulous, and at the umbilicus there was a firm irreducible swelling as large as an apple, which was diagnosed as an omphalocele. A large ovarian carcinoma with metastases in the peritoneum (one of which was the supposed umbilical hernia) was discovered at the operation. The second patient, whose health had been good until June, 1924, complained of intolerable itching, with a recurring vesicular eruption over the entire trunk, limbs, and neck. Several dermatologists had made a diagnosis of dermatitis herpetiformis. For six months she had suffered from nausea, with eructations but no vomiting. Her complexion was greyish and she was rather emaciated. The left side of the neck was covered with a recent fine vesicular eruption. The trunk and limbs were extensively pigmented, the colour varying from light to dark brown. On the inside of both thighs the skin was much thickened, rugose, and dark grey. There was increased resistance and tenderness on pressure in the right hypochondrium. A skiagram showed delay in passage of food through the pylorus. An exploratory laparotomy revealed extensive carcinomatous infiltration of

the pyloric region with fixation of the posterior wall of the stomach. Hart suggests that these dermatoses are due to absorption of toxins. No local treatment alleviated the skin lesions.

59. Periarterial Sympathectomy.

G. PIERI (*Arch. Ital. di Chir.*, October, 1925, p. 433) states that down to July, 1925, he had performed 23 periarterial sympathectomies on 19 subjects. In one case the sympathectomy was performed on the brachial artery under ether anaesthesia, and in 22 on the femoral artery under spinal anaesthesia, except in one case where, owing to the early age of the patient, ether was employed. The indications for the operation were as follows: (1) perforating ulcer, 2 cases; (2) simple or varicose ulcers of the legs, 3 cases; (3) osteo-articular tuberculosis, 4 cases; (4) neuropathic gangrene, 1 case; (5) circulatory disturbances in the lower limbs of arterial origin, consisting in more or less severe pain and occasionally gangrene of a circumscribed or progressive character, 9 cases. The results were as follows: In every case the operation had a good effect upon the symptom pain, but did not appear to exercise a definitely favourable influence on the nutrition of the tissues and local circulation. In some cases symptoms of ischaemic necrosis developed and usually increased, while in others the autopsy showed that in cases of bilateral circulatory disturbance unilateral sympathectomy was not only not followed by permanent vaso-dilatation, but the calibre of the small arteries such as the dorsalis pedis was smaller than on the side where no operation had been performed. G. BONANI (*La Chirurgia degli organi di movimento*, October, 1925, p. 569) performed perifaral sympathectomy for varicose ulcers in 7 cases. The immediate results were fairly good, cicatrization being complete in 4, partial in 2, and absent in only one. The remote results, however, were disappointing. In only one of the four cases in which cicatrization was complete did the cure persist for eighteen months, while the other three had recurrence of their ulcers in fifteen days, three months, and five months respectively. Bonani therefore concludes that Lerlehe's operation has only very limited indications in the treatment of chronic varicose ulcer.

60. Surgical Treatment of Scoliosis.

H. PLAGEMANN (*Zentralbl. f. Chir.*, November 7th, 1925, p. 2528) states that the frequent failure of spinal supports to relieve the severe intercostal neuralgia in scoliosis and the excessive displacement of the back muscles in rachitic scoliosis are sometimes remedied by prolonged gymnastic treatment. By an elastic bandage the displaced scapulae may be approximated to each other and to the thoracic wall; the intercostal nerves are thus relieved from pressure, and the overstretched muscles may recover their tone. If this treatment fails Plagemann recommends the following operation. Two small horizontal skin incisions are made over the outer part of each scapular spine, the bone is exposed and through it a number of holes are drilled. Silk threads are then passed subcutaneously between the scapulae by means of a pedicle needle, and on "lacing" the threads through the perforations the scapulae are approximated. The ends of the silk are tied under the skin and cut off. A plaster bandage is applied for seven to ten days, and after its removal a light bandage is worn for a short time. Plagemann has performed this operation on a number of patients at ages varying between 3 and 30 years. G. PERTHES (*ibid.*, p. 2529) criticizes Plagemann's operation, and doubts whether the good results are likely to persist.

61. Perforation of Peptic Ulcer into Peritoneal Cavity.

M. CHARBONNEL and F. LEURET (*Gaz. hebdomadaire des Sci. méd.*, November 15th, 1925, p. 727) describe a case in which gastro-enterostomy had been performed three years previously, and double ulcers, jejunal and gastro-jejunal, had subsequently perforated into the peritoneal cavity in consequence of the patient transgressing the dietary rules ordered. The patient died though a second operation was attempted. The authors consider such an occurrence very rare. In a recent series of twenty-three peptic ulcers there had been no case of perforation, which was prevented probably by early operation. Formerly, when the surgery of gastric and peptic ulcers was mainly confined to emergency treatment, perforation into the open peritoneum was much more common, whereas now it is almost limited to patients in whom the ulcer is latent or who have been poorly supervised. As in any other case of perforation, violent exertion or the overloading of the stomach conduces to its occurrence. Of peptic ulcers the gastro-duodenal is the commonest form. The treatment recommended is suture after excision of the edges, as in the case of an ordinary ulcer, together with verification of the size of the gastro-jejunal orifice; if this orifice is too small a rapid new anastomosis is made, using the button.

62. Acute Arterio-mesenteric Ileus.

E. M. McLAUGHLIN (*Minnesota Med.*, November, 1925, p. 670) reports two cases of acute arterio-mesenteric ileus occurring as a post-operative complication. This condition, he states, is characterized by symptoms of high obstruction, and usually occurs in persons who have lost considerable weight and who have general viscerosptosis. In these circumstances, when the patient is in the dorsal position there is a considerable pull on the superior mesenteric artery, and thus the angle which the artery makes with the vertebral column and the aorta is obliterated. This compresses the transverse portion of the duodenum between the artery and the aorta, thereby producing obstruction. The patient persistently vomits a dark-colored bilious material, which continues in spite of stomach lavage. There is no great abdominal distension and flatus is easily removed by enema. The respiration is shallow, the pulse rapid and weak, and the general condition becomes serious. The treatment which McLaughlin has found successful is to raise the foot of the bed on to 18-inch blocks, and to turn the patient into the right lateral prone position; this allows the caecum and intestines to float upwards and release the tension on the mesentery.

63. Appendicitis in Old Age.

A. G. J. HERMANS (*Nederl. Tijdschr. v. Geneesk.*, November 14th, 1925, p. 2188) remarks that appendicitis is pre-eminently a disease of early life, most of the cases occurring between the ages of 10 and 30. According to Strasburger, only 10 per cent. of the cases occur under 10 years of age, and then usually between 5 and 10. According to R. de Bovis, only 5 or 6 per cent. of all cases of appendicitis occur after the age of 50. The present author's paper is based on observations on 850 patients admitted to the Hospital of St. Francis at Rotterdam for appendicitis during the last four years. Of these, 33 patients, or 3.88 per cent., were aged 50 and over. The oldest was a woman aged 75, the oldest man was aged 63; 19 were men and 14 women; 18 were between 50 and 60, 13 between 61 and 70, and 2 were 71 and over. The diseases assumed the following different forms: (1) Acute appendicitis in 9 cases, 5 of which were in men and 4 in women. (2) Chronic appendicitis in 5 cases, 4 of which were in men and 1 in a woman. (3) A pseudo-neoplastic form in 6 cases, the disease simulating a malignant growth of the caecum or bladder. (4) Encapsulated abscess in 4 cases, 1 of which was in a man and 3 in women. (5) Appendicitis in a beryl sac in 3 cases, 2 of which were in an inguinal hernia in men and 1 in a femoral hernia in a woman. (6) Ileus in 3 cases; in only one of these was there a true ileus through the formation of bands originating from the appendix; in the other two there was a pseudo-ileus with no connection of appendix to other processes—namely, (7) Cancers of the caecum and duodenal ulcer in 1 case. Two cases of the first group and all those of the sixth group ended fatally. Dubs reports a mortality of 12 per cent. among 500 cases of appendicitis over the age of 50, and Mertens a mortality of 25 per cent. In 47 cases over 60, the causes of death being diffuse peritonitis, pulmonary embolism, collapse, or hypostatic pneumonia.

64. Acute Hypotension of Cerebro-spinal Fluid.

E. STULZ and P. STRICKER (*Annals of Surgery*, November, 1925, p. 678) consider the rational treatment of acute hypotension of the cerebro-spinal fluid to be intravenous injections of 30 to 50 c.cm. of distilled water. Hypotension occurs rather frequently in fracture of the skull, and the authors report three cases in which it followed cranial trauma and was efficiently treated by their method. Two patients required two injections in order to restore the pressure, and in one of these the pressure was actually seen to rise during the course of the second injection. Three injections were necessary in the other case. The authors have found the treatment both easy and safe, but they can offer no suggestion as to its mode of action except that possibly the injections alter the osmotic changes between the blood in the choroid plexus and the cerebro-spinal fluid in the sub-arachnoid spaces.

65. Lymphosarcoma.

F. BATTAGLIA (*Arch. Ital. di Chir.*, September, 1925, p. 113), who records two personal cases in men aged 60 and 29 respectively, states that lymphoid tissue is subject to morbid processes in which the clinical and pathological features are so ill defined that it is difficult to determine whether they are examples of lymphosarcoma or pseudo-leukemia. A distinction between lymphosarcoma and small round-celled sarcoma is probably to be found in the karyokinesis which is present in the cells of the latter and absent in the former. X-ray treatment produces a diminution in size in sarcoma, and sometimes a sufficiently pronounced improvement in the patient's general condition to suggest a cure, but sooner or later the growth resumes its course and death occurs.

Therapeutics.**66. Ether Injections in Pertussis.**

A. GOLDBLOOM (*Journ. Amer. Med. Assoc.*, December 5th, 1925, p. 1791) discusses the treatment of pertussis by intramuscular and rectal injections of ether and points out the advantages of the latter method, except in very severe cases. Within one or two minutes after the injection of 1 to 2 c.cm. of ether intramuscularly it could be detected in the breath and remained noticeable for six to eight hours, with immediate and lasting improvement to the paroxysms; but the pain attending its administration and the possible danger of necrosis are serious drawbacks. The beneficial effect appears to depend upon the temporary sedative action during excretion through the alveoli, any specific bactericidal action being as yet unproved. Goldbloom has treated twenty-one children by rectal injections twice daily of half a drachm of ether in half an ounce of olive oil, and finds that the results compared favourably with those in patients treated intramuscularly. The rectal method can be easily employed by the mother or a nurse; the child is not in fear of a painful operation; there is no danger of necrosis; and the treatment can be safely continued for a much longer period than in the case of intramuscular injections. In an infant, aged 2 months, the paroxysms were completely controlled for six or eight hours, during which time the child scarcely coughed, though it ate and slept well.

67. Sugar Treatment of Acute Infections.

R. LATZEL (*Med. Klin.*, November 27th, 1925, p. 1797) describes a number of cases in adults in which threatening oedema of the lung and collapse were averted by the intravenous injection of 20 c.cm. of a 50 per cent. solution of grape sugar. In one case where there was cardiac degeneration a second injection was given. The patients recovered in all cases. The author then proceeded to treat a series of cases in the following manner. Protein shock was induced by the administration of an injection of 8 to 10 c.cm. of milk. This was followed twenty hours later by an injection of sugar solution with or without the addition of strychnine. This produced a rapid rise in temperature after the first injection, followed by an equally rapid fall after the second, and an amelioration of the symptoms leading to recovery. The treatment was most successful in adults between the ages of 25 and 45. Children did not react so well, and in some cases a rise of temperature occurred again a few hours later.

68. Phosphorus in Various Diseases.

A. CASTELLANI (*Journ. Trop. Med. and Hygiene*, November 2nd, 1925, p. 377) investigated the action of phosphorus in the treatment of various diseases, having discovered that the phosphorated oil of the *British Pharmacopoeia* could be administered hypodermically. Ampoules containing 5 minims of pure phosphorus oil and others containing half a minim diluted in 10 minims of almond oil may be obtained. In Oriental sores its action is specific, especially in old intractable cases with extensive ulceration, the oil being applied to the fundus and margin of the sore every other day. In nodular lesions 3 to 5 minims of oil may be injected into and around the nodule twice a week. Of two cases of granuloma inguinale one responded to the treatment and the other did not. No beneficial results followed its use in tropical sore, psoriasis, and lichen planus; and while it has no specific effect upon the malaria parasite, the administration of half a minim to 3 minims of the oil twice a week appears to act as an adjunct of quinine. Encouraging results followed its use in rickets, osteomalacia, and beri-beri. The author adds that the action of phosphorus on the liver must be borne in mind and every precaution taken in its use, though he has not encountered any untoward result from its administration.

69. Treatment of Asthma with Tuberculin.

C. R. ØSTERGAARD (*Ugeskrift for Læger*, November 12th, 1925, p. 1001) has checked and confirmed, at the Bispebjerg Hospital in Copenhagen, the claims made by Storm van Leeuwen and other Dutch writers as to the efficacy of tuberculin in asthma. Altogether 11 cases were treated. In 4 it was ineffective, but in all these cases the treatment could not be carried through satisfactorily. In the remaining 7 cases the results were excellent, although all the patients were much debilitated, had suffered from asthma for many years, and were subject to several attacks a day. Many had been given other forms of protein-shock treatment, but in no case with permanent improvement. Tuberculin would therefore seem to be a much more effective remedy than the other proteins commonly in use in the treatment of asthma. The first subcutaneous injection consisted of 0.0001 gram of Koch's old tuberculin. The temperature was then taken three times a day, and when there was a considerable rise the next injection

tion was deferred till the temperature had become normal. As long as the temperature was normal the dose was doubled at each injection until a dose of 0.001 gram was reached. After this each dose was increased by 50 to 30 per cent. until a dose of 0.01 gram was reached. This treatment usually extended over about two months, and the patients had to be kept in bed only when an injection provoked a reaction. This was seldom violent, but most patients complained of slight headache, giddiness, and lassitude. The first injections usually gave rise only to a cutaneous reaction, but at a later stage they provoked a malaise suggestive of influenza. After this reaction had passed off the asthmatic attacks became less frequent and prolonged, and expectoration became easier and more profuse. The last injections seldom caused much disturbance, and in no case were alarming symptoms observed.

70. Sodium Sulphocyanate in Hyperpiesia.

J. B. NICHOLS (*Amer. Journ. Med. Sci.*, November, 1925, p. 735) recalls that the therapeutic use of sulphocyanates was first suggested in 1903 by Pauli, who found them to have a valuable sedative action in various circulatory and nerve disorders as well as in arterial hypertension. Nichols has used sodium sulphocyanate in the treatment of hyperpiesia for the last fourteen years with most satisfactory results. Those cases in which the hypertension was not due to organic changes in the arteries were the most amenable to treatment. He has found sodium sulphocyanate superior to any other drug in the reduction of blood pressure in appropriate cases, and has obtained marked lowering of 20 to 40 mm. or more after a few doses, although in some other cases the decline was more gradual. Nichols gives doses of 5 grains (1 teaspoonful of an 8 per cent. solution in water) thrice daily, well diluted, after meals; to this solution he adds a little phenol to prevent growth of fungi, and peppermint or similar aromatic to lessen the nausea which many of his patients experienced. This dose may be reduced to a half or a quarter of a teaspoonful if necessitated by the development of disagreeable symptoms, or as the blood pressure falls, and may be continued for several weeks in order to retain the lowered tension. He has found no indication of the sedative effects suggested by Pauli and other previous investigators. Nichols adds that there need be no apprehension of the formation of cyanide from the use of sodium sulphocyanate in therapeutic doses, although the drug is probably excreted slowly and a quantity greater than $\frac{3}{4}$ drachms may cause death in man.

71. Bismuth Hydroxide in Syphilis.

F. W. PORTMANN (*Dermatol. Woch.*, December 5th, 1925, p. 1781) recommends twice weekly injections of a milky colloidal preparation of bismuth hydroxide in syphilis. Commencing with a dose of 50 mg. of a proprietary preparation, all subsequent doses were of 100 mg.; the total number of injections given to each patient ranged from ten to fourteen. After such a course of intravenous injections it was found that the Wassermann reaction became negative, even in cases in which a previous course of salvarsan injections had failed to produce this result. After the first injection condylomata began to shrink, their surfaces became dry, and usually, after three or four injections, they disappeared entirely. In almost all cases spirochaetes had disappeared within twenty-four hours of the administration of the first injection. The value of bismuth in salvarsan-resistant cases was shown by a case of secondary syphilis in which there were numerous hypertrophic papillomata on the genitals. The Wassermann reaction was strongly positive after a course of twelve injections of salvarsan, which had had no effect upon the papillomata. After one injection of 50 mg. of bismuth diarsenol the warts began to shrink, and after three more injections (each of 100 mg.) they disappeared, and the Wassermann reaction became negative. Though most bismuth preparations tend to produce stomatitis, gingivitis, and renal lesions, in no case in Portmann's series was there any evidence of toxic effect.

Radiology.

72. Uretero-pyelography.

S. A. SARMIENTO (*Arch. de med., cir. y esp.*, November 14th, 1925, p. 292), in a thesis on the technique, accidents, and clinical applications of uretero-pyelography, comes to the following conclusions: (1) Uretero-pyelography is a valuable exploratory method in urology. (2) The injection of opaque fluid should be made with a burette and not with a syringe, so as not to use force on the renal pelvis; small ureteral sounds should be employed so as to allow a return flow to the bladder. (3) Collargol may be used in cases of vesico-renal reflux, but in all other cases solutions of crystals should be employed, and preferably sodium bromide, which is the least toxic. (4) The technique should be as

follows: complete radiography of the whole urinary system on a single plate, one picture being made before the fluid is injected and another afterwards; careful lavage of the renal pelvis should then be carried out. (5) The accidents observed in pyelography are due to defects in technique, such as excess of pressure, overdistension, and use of the method in cases where it is contraindicated. (6) Uretero-pyelography is of great help in the diagnosis of ureteral and renal anomalies, vesico-uretero-renal reflux, hydronephrosis, and movable kidney; in the topographical diagnosis of reno-ureteral calculi, hydatid cysts of the kidney opening into the urinary tract, and in the early diagnosis of renal tumours. It is not of much use in the diagnosis of renal tuberculosis, pyonephrosis, chronic pyelonephritis, and least of all in renal cysts. Occasionally it may be of service in other conditions, such as renal or ureteral fistulae, spasm of the muscles of the calices, and so on. (7) Uretero-pyelography should not be employed simultaneously on both sides, and it is contraindicated in cases of great weakness, extreme intoxication, high fever, impaired function of the opposite kidney, acute pyelitis and pyelonephritis, and renal tumours. (8) Uretero-pyelography should be employed more extensively and systematically in clinical medicine, and like ureteral catheterization should form part of the routine examination of the kidneys. It represents one of the most important advances made in modern urology, and has a brilliant future in store.

73. Radium in Epitheliomata of the Tongue.

CL. REGAUD (*Brit. Journ. Radiol.*, October, 1925, p. 361) summarizes the results of four years' experience of the treatment of epithelial cancers of the tongue and floor of the mouth at the Radium Institute of Paris. Of 174 patients 24.1 per cent. remained cured at the end of 1924, while 22.4 per cent. had the tongue lesion healed but not their adenopathy. Nearly one-fourth of all the cases were completely cured and in almost another quarter the lingual lesion alone disappeared. Poor results were obtained from α rays, but since these have given good results in cancers of the pharynx Regaud believes that in cancers of the pars dorsalis posterior, in which radium gives but poor results, α -ray treatment should be more successful. Some patients suffering from very advanced cancers beyond even local or partial healing may nevertheless be benefited by radium therapy. The aim of treatment should be to distribute numerous weak radio-active foci in the whole cancerized part, using the gamma rays only and giving continuous irradiation for a long time by a single treatment. In the treatment of adenopathies of the neck irradiation by external radio-active foci should be provided by means of protected radio-active tubes placed upon two layers of wax which maintain a uniform 4 cm. skin distance.

74. X-ray Treatment of Local Infections.

F. M. HODGES (*Journ. Amer. Med. Assoc.*, October 24th, 1925, p. 1292) has treated carbuncles, erysipelas, ischio-rectal abscess, chronic parotitis, and other forms of local infection by means of α rays. The technique he employed in most cases included a current of 4 milliamperes, a 9-inch spark-gap, an exposure of eight minutes, filtration through 9 mm. of aluminium, and a distance of 9 inches. Half this dose was repeated about the fourth day, and again several days later if necessary. For the first treatment the area included at least one inch of healthy tissue; the later applications were directed towards the central part of the lesions, although this was more likely to produce necrosis. A small incision was made directly any part of the lesion showed signs of softening. In erysipelas and in some carbuncles unfiltered rays were used with a current of 4 milliamperes, a 7-inch spark-gap, and three and a half minutes' exposure at a distance of 10 inches. The most noticeable feature of this treatment was the almost immediate disappearance of pain. The majority of carbuncles, even in very extensive lesions when the inflammation was limited mainly to the skin and subcutaneous tissues, responded very well: in the deep-seated types, when treated after the carbuncle was well developed, the results were almost as good; but in two cases which were treated early no benefit could be traced, and there was probably a delayed breaking down and healing. Hodges states that cases of erysipelas must be treated early, when only a small area of skin is involved and there is no severe constitutional disturbance: he says that he would not attempt to treat a severe advanced case of erysipelas by this method. Chronic parotitis responded equally well to his treatment, but cases require care in selection, since there is some risk of a salivary fistula forming. Hodges believes that moderate doses of α rays cause increase in the activity of the cells and in the phagocytic powers of the blood. He suggests that the rapid destruction of the lymphocytes and the action of the rays on other tissues may cause the liberation of a substance that has a marked effect on the inflamed areas and possibly on the infecting organisms.

Obstetrics and Gynaecology.

75. Hydatidiform Mole.

R. DÉGHIN (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, 1925, No. 9, p. 718) describes two cases admitted to hospital with the diagnosis of placenta praevia; vaginal examination showed commencing cervical dilatation, and it was possible to remove from the uterus characteristic hydatidiform vesicles. After further dilating the cervix under general anaesthesia the mole was removed digitally; curetting with the soft ennette followed. The author remarks that although curetting in these cases is fraught with danger of perforating the soft and loaded uterus, there is reason to doubt whether complete digital removal of every part of a hydatidiform mole is practicable. In a third case described a 3-para consulted her doctor because she felt no foetal movements in spite of four months' amenorrhoea. The uterus at this time corresponded to a three months' gestation, and subsequently was noted to have remained stationary in size at several successive monthly examinations. Slight and painless vaginal bleeding occurred during the ninth and tenth months; finally, ten and a half months after the last regular menstruation, a hydatidiform mole was expelled spontaneously after a labour unaccompanied by haemorrhage. This mole had the usual characters of being surrounded by a translucent non-adherent capsule, containing an intact amniotic sac, without trace of a foetus, and of having undergone mummification with desiccation of the vesicles, which, however, were perfectly preserved.

76. J. VANVERTS (*ibid.*, p. 716) describes the case of a woman, aged 49, whose third child had been born seven years previously, and whose menses were normal and regular until her admission to hospital for three weeks' copious bleeding, thought to be due to myoma. The uterus, of which the fundus reached the umbilicus, was uniformly soft and not tender. The menstrual history, the age of the patient, and the size of the uterus were taken to exclude pregnancy, and softened myoma was suspected. Hysterectomy revealed a large hydatidiform mole. In a second case recourse was had to laparotomy to distinguish between a myoma complicating pregnancy and a vesicular mole. It is noteworthy that a blood-stained peritoneal effusion had disappeared when the abdomen was opened a second time, the mole having been expelled per vaginam in the interval.

77. E. KLEIN (*ibid.*, p. 696) states that the persistence of a hydatidiform mole to the eighth month is extremely rare, and records the case of a primipara, aged 29, who had three months' amenorrhoea followed by irregular bleedings. At the eighth month the onset of labour was accompanied by profuse haemorrhage, and placenta praevia was palpable. It was not until version was attempted under general anaesthesia that it was recognized that a foetus was absent. After removal of the low-lying portion of placenta extensive hydatidiform transformation of the remaining part of the foetal envelope was recognized.

78. Spontaneous Rupture of Ovarian Sarcoma.

H. KOSTER (*Amer. Journ. of Obstet. and Gynecol.*, November, 1925, p. 716) reports a case of spontaneous rupture of sarcoma of both ovaries in a girl aged 14. She had been quite well until about four months before admission to hospital, when a gradually increasing swelling in the left side of the neck was noticed and was treated as a tuberculous gland. Menstruation had been established for nine months and there was no abnormality. For three weeks before admission she had suffered from paroxysmal pain in the lower part of the abdomen, which became acute fourteen hours before admission. The general examination suggested acute appendicitis, which diagnosis was provisionally made. At the operation there was found to be a considerable quantity of blood in the peritoneal cavity; both ovaries were fragmented, and pieces of ovarian tissue were lying free in the cavity. Bilateral ovariectomy and appendectomy were performed, but while the immediate result was good, yet the patient rapidly became worse, in spite of radiation, and died two months after leaving the hospital. Microscopic examination of the ovarian tissue showed a small round-celled sarcoma. At no time had there been any palpable abdominal tumour.

79. Treatment of Hyperemesis Gravidarum.

J.-L. HENROTAY (*Bruxelles-Médical*, November 29th, 1925, p. 135) holds that the pernicious vomiting of pregnancy is primarily a hysterical manifestation; the secondary symptoms of acidosis are of greater importance, he points out, in pregnant than in other patients. An essential part of the treatment which he has found effective consists in the

abandonment of feeding by the month until narcotization by rectal administration of chloral hydrate has been secured. For five or six days the patient is completely isolated from her friends and relatives. During the first two days starvation is absolute; the mouth is washed out with an alkaline solution or Vichy water, and evacuation of the bowels is obtained by enemata containing sodium sulphate and senna. During the same period the dehydration and low vascular tension are treated by daily subcutaneous injections of 1 litre of saline solution containing 1 mg. of adrenaline. From the third day onwards the patient is given in the morning a scap and water enema, followed by rectal injection of 6 grams of chloral hydrate suspended in gummy solution. Somnolence being obtained, the patient is given by the mouth, at hourly intervals, first a mixture of milk and Vichy water, then pure milk. In the afternoon a drop-by-drop rectal injection of sodium bicarbonate is given. During convalescence vomiting of small amounts of watery or bilious fluid usually occurs in the afternoon as the effect of the chloral injection passes off. Conversation with the patient must be avoided as far as possible both by the doctor and the nurse. Allusion is made to cases successfully treated on these lines by Convelaire and by Lorier, and in the present paper Henrotay publishes details of two more cases in which cure was obtained, and one which terminated fatally, no autopsy being permitted. Lorier, it is stated, has increased the dose of chloral hydrate to 8 or 9 grams.

80. Treatment of Dysmenorrhoea.

E. KLAUS (*Therapeutic Gazette*, November 15th, 1925, p. 779) states that while the symptoms of dysmenorrhoea sometimes require very radical measures, yet palliative treatment by narcotics is often all that is required. The difficulty of this lies in the facility with which these patients acquire the drug habit. He reports seven cases of spasmodic dysmenorrhoea in which the symptoms were controlled by the administration of chloroform. His usual practice was to give 5 grains two or three times daily for a week before the period. In six cases this was only necessary for a few months, after which the patient appeared cured; in the other case the treatment had to be discontinued owing to the hypnotic and depressing effect of the drug. He found chloroform comparatively non-toxic in this dosage, and that if necessary the dose could safely be increased. In his opinion there is very little risk of habit formation, and chloroform can be given to patients who would not be safe with other hypnotics.

81. Full-term Ectopic Gestation.

P. S. MILLS (*Indian Med. Gazette*, November, 1925, p. 510) reports a case of extrauterine gestation going to full term in which the mother and child both survived. A primipara, aged 20, was admitted to hospital having been in labour for three days. It was found that the foetus occupied a transverse position with the head to the right, and it was not more easily felt than normally. The other parts of the foetus could not be distinguished; foetal heart sounds could not be heard, but weak movements were felt. Abdominal examination revealed nothing to suggest ectopic gestation. There was a thick reddish-brown vaginal discharge unlike that of labour, and on digital examination the cervix was found to admit two fingers; the uterus was about twice the size of the non-pregnant uterus and was lying somewhat to the right of the normal. A diagnosis of ectopic gestation was made. Laparotomy was performed and the foetus was found to be lying in a thin sac in the left broad ligament. There were no adhesions and a living female child was extracted, the pedicle tied, and the sac with the placenta was removed. The left ovary was healthy and there was no enlargement suggestive of a corpus luteum in the right ovary; thus there was no evidence of external migration of the ovum. The mother developed an abscess in the cellular tissue of the left side, but this was drained through the vagina, and she later made an uninterrupted recovery.

82. Absorption from the Vagina.

A. LOESER (*Zentralbl. f. Gynäk.*, December 12th, 1925, p. 2824) mentions salicin, antipyrin, salol, and re-orein as substances which can be absorbed from the human vagina, and cocaine and paraldehyde as substances which are not absorbed if the epithelium be intact. Toxic symptoms are shown after prolonged vaginal applications of ether or alcohol, and a transitory glycosuria follows insertion of phloridzin. The most quickly absorbed substances are mercuric chloride and iodine. Loeser has tested the rate of absorption of the latter in twenty patients by occluding the cervix with a waxed tampon and inserting in the posterior fornix a pessary containing 1 to 2 grams of potassium iodide and twice that weight of cocoa-butter; the urine was then tested for iodine at intervals of five minutes. He finds that healthy women,

aged 20 to 30, show signs of the absorption of iodine in from twenty to thirty minutes; this time becomes longer towards the climacteric. Absorption was also slower in three patients with colpitis, and became normal after cure of the morbid vaginal condition. In a group of nine patients with leucorrhoea of a non-purulent ("cervical") character, ascribed to functional disorders, absorption was notably slow.

Pathology.

83. The Production of Ozaena.

G. BLANC and G. PANGALOS (*C. R. Soc. de Biologie*, November 27th, 1925, pp. 1267 and 1268) have failed to substantiate Perez's claim that the bacillus of ozaena is characterized by a definite selective ability, which enables it even after intravenous inoculation to settle in the nose and to give rise to disease. On the contrary, they find that neither with the *B. ozaenae* nor with the *B. ozogones* (a coliform bacillus recently described by the present authors) is any disease set up in the nose by intravenous, intraperitoneal, or subcutaneous injection in rabbits. Neither the direct inoculation of the organisms on to the nasal mucosa nor washings from the nose of patients suffering from ozaena gave rise to disease, unless preceded by artificial irritation of the membrane with croton oil. The same failure was observed similarly in the case of children. Inoculation of a young man suffering from leprosy, and showing a marked atrophy of the inferior turbinate, proved successful. One month after the inoculation with *B. ozogones* there was a whitish membrane covering the inferior turbinate and the surface of the septum. A fetid odour was present, and cultures of the nasal secretion yielded *B. ozogones*. The authors therefore agree with Leroux-Robert that infection with *B. ozaenae* is a secondary phenomenon occurring only in those who are subjects of atrophic rhinitis and who are specially predisposed to attack by this organism.

84. High Protein Diet and Renal Function.

OWING to the conflicting nature of the evidence concerning the effect of high protein intake on the kidneys of laboratory animals and man, A. J. MILLER (*Journ. Exper. Med.*, December, 1925, p. 897) has undertaken a series of experiments on rats. Seven groups of rats were fed on diets containing protein that varied in amount from 1.36 to 40.13 per cent. of the total dietary, which included grain, casein, meat, and milk; carbohydrates, fat, and vitamins were also provided. From a number of animals one kidney was removed so as to double the work of the remaining one. After a period varying from nine weeks to six months estimations were made of the blood, uric acid, and the blood urea. The animals were then killed and their kidneys examined microscopically. In Group 1, which received only 1.36 per cent. of protein, the animals were markedly emaciated. In the groups receiving from 28.76 to 40.13 per cent. of protein there was definite hypertrophy of the kidneys. The nephrectomized animals that were fed on a high protein dietary showed great hypertrophy of the remaining kidney, amounting in weight to an increase of 85 per cent. over the controls. Chemical estimations revealed no evidence of renal disturbance. From these experiments the author concludes that there is no evidence of kidney damage resulting from a high protein diet. This is in accordance with observations made on human beings, notably on the Eskimos, and on explorers in the Arctic regions who have lived for several months at a time on an exclusively meat dietary. Miller adds that this conclusion must not be held to justify the administration of large amounts of protein to patients with nephritis; it is rational to relieve diseased kidneys of as much work as possible.

85. The Mechanism of Infection in Anthrax.

L. MÜLLER (*C. R. Soc. de Biologie*, November 20th, 1925, p. 1243) relates how, some years ago, he inoculated the interior of a pigeon's egg with virulent anthrax bacilli, sealed up the opening with Canada balsam, and introduced the egg into the peritoneal cavity of a rabbit. The animal died in five weeks of generalized anthrax. Recently this experiment led him to doubt the truth of Besredka's hypothesis that the skin is the only susceptible part of the body to anthrax, and that it is only when the skin is contaminated that infection can occur. In his original experiment the bacilli must have passed through the egg and given rise to a primary peritoneal infection without any involvement of the skin. He now describes a new series of experiments. He found that if the bacilli were introduced into a filter and the filter immersed in broth they eventually grew through the pores of the candle; with an L1 candle the time required for this was six to eight days, and with an L2 candle about three weeks. He therefore inoculated several candles with anthrax bacilli, sealed the ends very carefully, and introduced them intra-

peritoneally into rabbits. Of 9 rabbits treated thus 7 died in a period varying from six to fifty-one days. After death the skin was found to have healed perfectly, and the candles were surrounded by a sac of omentum. Large numbers of bacilli were found in the spleen, and pure cultures were obtained in each case. He considers it certain that in these experiments the infection must have occurred altogether independently of the skin, and that Besredka's hypothesis cannot be considered correct.

86. The Differential Blood Count in Hodgkin's Disease.

M. KRMPOTIC (*Liječnicki Vjesnik*, November, 1925, p. 699) states that neutrophile leucocytosis with eosinophilia is considered to be typical of lymphogranulomatosis, or Hodgkin's disease, but his own experience of ten cases in the last three years indicates that there is no characteristic blood picture in Hodgkin's disease, as the differential count often resembles that of lymphosarcomatosis and of tuberculous or syphilitic granulomata. In lymphosarcoma the leucocyte count may vary from normal to 120,000 white corpuscles, which was recorded by Reinbach in a case of cervical lymphosarcoma, in which the eosinophiles amounted to 48.28 per cent. Lincoln found in one case an eosinophilia varying between 63 and 68.2 per cent. In the majority of cases of Hodgkin's disease there is a moderate polymorphonuclear neutrophilic leucocytosis, but in 20 per cent. of these cases there is leucopenia. In 20 per cent. the differential count is normal, but in others lymphocytosis occurs, which may be transient or variable. In 25 per cent. of these cases there is eosinophilia, usually of moderate degree; myelocytes are common in the higher degrees of leucocytosis. The author adds that a single differential count is of little use in diagnosis, but repeated examinations will usually show a more or less characteristic blood picture.

87. Pulmonary Malignancy following Tar Applications to the Skin.

T. B. MURPHY and E. STURM (*Journ. Exper. Med.*, November, 1925, p. 693) report that mice in which skin cancer did not develop after tar applications were found to have growth in the lungs. It was at first thought that these were pulmonary metastases from skin growths which had healed or sloughed away, but in spite of the most careful examinations, both during life and after death, no cancerous lesions could be found in the skin. Further, the cells of the lung growth were quite different in type from those found in metastases from skin lesions. Although spontaneous tumours have often been observed in the lungs of mice, yet they do not occur generally in young mice, nor with such frequency as in the experiments with tar cancer. To throw light on this problem a number of separate skin areas in mice were treated with tar, but not for so long as to cause skin lesions. The incidence of lung neoplasms was 60 per cent. in one series of experiments and 78.3 in another. Spontaneous pulmonary tumours, even in a stock of mice specially prone to this disease, never exceeded 5.5 per cent., while the average was 1 to 2 per cent. over a period of several years. The experimentally produced neoplasms, however, closely resembled the spontaneous kind. The authors dismiss the suggestion that the pulmonary neoplasms are due to the carriage of tar particles to the lungs by the lymphatics, and state that they have definite evidence that painting with tar reduces resistance to transplanted cancer. They believe that the localization in the lungs was determined by pulmonary irritation due to sawdust particles in the respired air.

88. Antibodies in Tuberculous Pleural Fluids.

M. SALOMON and J. VALTIS (*C. R. Soc. de Biologie*, November 13th, 1925, p. 1145) have examined the blood serum and the pleural fluid of 14 patients suffering from unilateral pulmonary tuberculosis on whom artificial pneumothorax had been performed. Search was made in both fluids for the specific antibody and antigen, the complement fixation test being employed. In 11 of the patients the titre of antibody was the same in the blood serum as in the pleural fluid; in 2 others it was slightly higher in the serum; and in the last antibody was absent in both fluids. In 13 of the patients antigen was found present in considerable quantity. The authors then examined the pleural fluid and serum of 5 patients suffering from spontaneous tuberculous pleurisy. In 3 of them antibody was found, but in none of them was any trace of antigen present. These limited observations indicate that in the pleural fluid associated with artificial pneumothorax both the tuberculous antibody and antigen are present, whereas in the fluid of spontaneous cases of tuberculous pleurisy antibody is generally present, but antigen is absent. The authors seem to think that these differences can be explained by the fact that in the fluid of artificial pneumothorax tubercle bacilli are present in far greater numbers than in the fluid of spontaneous pleurisy.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

88.

High Blood Pressure.

R. D. RUDOLF (*Canadian Med. Assoc. Journ.*, November, 1925, p. 1093) classifies the varieties of hyperpneisis for practical purposes under the headings of nervous, toxic, and organic; into one of these categories all cases may be placed when considering treatment. In nervous hyperpneisis the blood pressure is principally influenced by the emotions, most forms of nervous tension tending to its increase either by intensifying the cardiac action or by causing vaso-constriction, or by both, with possibly an increased adrenergic internal secretion. Starling believes that the vasomotor centre automatically raises the blood pressure to meet its own needs. In toxic hyperpneisis various toxins arising from metabolism, such as guanidin, accumulate and raise the blood pressure, while in intestinal disturbances toxins of the pressor type may be produced and absorbed. In organic hyperpneisis very slight interference with the circulation in some vital centre may cause a compensatory rise in pressure, though true arterio-sclerosis must be widespread before a rise occurs, a considerable amount of obstruction to the general circulation being necessary to raise the pressure. Treatment involves considerations of environment, diet, and specific and symptomatic therapy. Rest, both bodily and mental, and freedom from worry are important, and general restriction of the total diet is often necessary. A milk and vegetable diet, with avoidance of purine-containing foods, and with alcohol and tobacco in moderation, suits these cases best, and the bowels should be regulated with salines and an occasional mercurial pill. An attempt should be made to remove the underlying cause, but Rudolf considers that those patients without symptoms in whom the pressure does not lessen under dieting and rest are best left alone. When, however, symptoms are present, free purgation and diuretics may be beneficial, and the benefit derived from timely venesection in urgent cases is emphasized.

90.

Scarlet Fever.

H. ALDERSHOFF (*Nederl. Tijdschr. v. Geneesk.*, December 12th, 1925, p. 2694), director of the Dutch Serological Institute at Utrecht, summarizes the recent investigations in scarlet fever as follows: The Dick reaction is of considerable assistance in the diagnosis of scarlet fever. If employed judiciously it is a means of distinguishing persons who are susceptible to scarlet fever from those who are not. Antitoxic scarlet fever serum, if used early in the disease, serves to prevent complications. It is not very effective when the rash has faded, and has no influence on late complications. In mild and moderately severe cases the injection of antitoxin can be given intramuscularly, but in severe cases large doses should be given intravenously. The risk of serum sickness can be considerably reduced by the use of refined dealbuminized serum. During a severe epidemic active immunization by injection of scarlet fever toxin is advisable.

91.

Polyneuritis following Wound Diphtheria.

REINHOLD (*Deut. med. Woch.*, December 11th, 1925, p. 2064), who records two illustrative cases, states that Leppmann and Röper showed that a considerable number of cases of so-called polyneuritis following infected wounds were really examples of clinical picture being that of post-diphtheritic paralysis. He finds that, as a general rule, paralysis and cardiac disturbance are less frequent after wound diphtheria than after diphtheria of the fauces, a fact which must be attributed to the slight degree of absorption from granulation tissue. Reinhold has not seen any convincing evidence of the benefit of injections of antitoxic serum in the few cases of diphtheritic paralysis in which he has employed this method. According to pharmacological experiments it is probable that diphtheria antitoxin has as little effect as tetanus antitoxin or toxin which has been taken up by the nervous system, and a protective action only can be expected against absorption of fresh toxin. On the other hand, Reinhold has long been an advocate of injections of strychnine for diphtheritic paralysis. His first case was that of a soldier, aged 21, who, after wounds of both legs, complicated by furunculosis, developed all the signs of diphtheritic paralysis, including difficulty in swallowing, dimness of vision, weakness of the arms and legs, and loss of knee-jerks. The second case was that of a woman, aged 68, who, after an operation for cholecystitis, developed diphtheria of the wound, which was treated by antitoxin. Six weeks later palatal and ciliary

paralysis occurred, followed by loss of knee-jerks. There was no paralysis of the abdominal muscles. Improvement followed the injection of strychnine and digitalin, contrary to the experience of Walshe, who maintains that paralysis of the palate occurs only after faucial diphtheria; in neither case was there any faucial involvement.

92.

Diagnosis of Early Apical Tuberculosis.

D. MAESTRINI (*Il Policlinico*, November 16th, 1925, p. 1593) reports that in early apical tuberculosis he has found present an area of tenderness on moderate pressure over the fossa supraclavicularis minor between the heads of the sterno-mastoid. He considers this indicative of disease of the corresponding apex of the lung; it was not present in disease of the middle or lower lobe. The author reports five cases where this sign was present and the existence of disease was confirmed by radiological and other examination. It was present in the very earliest stages, and was, he thinks, of reflex origin, associated with the sympathetic system and the cervical plexus. He refers to Head's work in this connection, but states that this particular localization is not described by Head. Photographs showing the exact spot are included in the paper.

93.

Progressive Atrophy of the Salivary Glands.

H. GOUGEROT (*Bull. de Derm. et de Syph.*, November 8th, 1925, p. 376) records three cases of progressive atrophy of the salivary, parotid, and submaxillary glands, causing complete dryness of the month with secondary trophic troubles. All the patients were women and treatment was ineffective. The etiology is obscure, but in one case congenital syphilis was present. The author suggests that it may be a specific disease, starting in the month, but capable of spreading to the conjunctiva, larynx, nasal fossae, and the vulva. Various kinds of treatment were tried without success, and the prognosis is bad.

Surgery.

94.

Treatment of Obstructive Jaundice.

J. P. BOWLER (*Boston Med. and Surg. Journ.*, December 3rd, 1925, p. 1045) discusses the treatment of obstructive jaundice as a factor affecting surgical risk. Hepatic insufficiency, uraemia from a toxic nephritis, and haemorrhage from a lack of available calcium are the chief fatal complications in operations for obstructive jaundice, and require pre-operative treatment. By animal experiments and from a study of the part played by the liver in carbohydrate metabolism it has been shown that jaundiced patients should be given large quantities of carbohydrates. A 15 per cent. glucose solution may be administered rectally by the Murphy drip and the patient be encouraged to eat reasonable amounts of sugar. The presence of a toxic nephritis which has developed during the course of obstructive jaundice is disclosed after the operation by a sudden cessation of the drainage of bile accompanied by a steadily increasing albuminuria and the presence of casts. The jaundice gradually deepens and the coagulation time increases; treatment is necessary for uraemia and the maintenance of free biliary drainage. The most frequent post-operative complication is secondary haemorrhage due to a lack of available calcium, as shown by examination of the coagulation time of the blood. Treatment consists in the administration of calcium, either orally as calcium lactate 100 grains a day for three days, or as calcium chloride by slow intravenous injection in 5 c.cm. doses of a 10 per cent. solution for three successive days. Since there is frequently an accompanying infection a large fluid intake should be encouraged. Bowler advises that these patients should receive 4,000 c.cm. of fluid every twenty-four hours for three or four days before the operation, by which time the coagulation period should have been reduced to normal and a more satisfactory surgical risk established.

95.

Gastroptosis.

V. MATTEI (*Il Morgagni*, November 25th, 1925, p. 1377) points out that gastroptosis occurs in the hypotonic and atonic stomach. In ptosis the volume of the stomach is very slightly altered; in dilatation there is an increase. Mattei believes that duodenal ptosis is more common than is generally believed, and enteroptosis may be the cause of some of the various colics, constipation, and uneasy sensations. He refers

to De Giovanni's views on the relation between the morphological type of body of the patient and his gastric signs and symptoms, and points out how much more common these pososes are in the asthenic type; these patients are usually poorly nourished, and have weak muscles, sharp costal angles, sloping ribs, small cold feet and hands, delicate skin with poor growth of hair, increased tendon reflexes, a tendency to mental depression, and occasionally a "floating" tenth rib. As regards treatment, some form of abdominal support is often useful; it should be applied before rising from bed. Food should be light and easily digested, and solids and liquids should be taken together. The emptying of the stomach may be aided by posture and its walls strengthened by strychnine; the general nervous system is improved by suitable tonics, fattening when necessary, regulation of the bowels, raising the foot of the bed, and in some cases prolonged rest in bed. Operation is only advisable in severe cases, since cure is not often obtained and secondary ailments sometimes follow.

96. Foreign Bodies in the Bronchi.

J. BIJTEL (*Nederl. Tijdschr. v. Geneesk.*, October 24th, 1925, p. 1888) states that before laryngoscopy was introduced into current practice in 1866 the mortality from foreign bodies in the respiratory tract was 41.2 per cent. for all cases and 28.2 per cent. for those which received treatment (Procbraschensky). Between 1866 and 1893, when laryngoscopy was generally employed but not bronchoscopy, the mortality for all cases was 30 per cent. and 19.4 per cent. for treated cases (Pohl). Among cases treated by bronchoscopy von Eichen in 1908 reported a mortality of 13.1 per cent. among 305 cases, and Kabler in 1911 a mortality of 9.6 per cent. among 291 cases. Bijtel has collected statistics of 504 cases from the oto-rhino-laryngological clinic at Amsterdam for the period 1908 to 1925, the surgical and laryngological clinics at Groningen from 1907 to 1924, and the bronchoscopic clinic of Chevallier Jackson at Philadelphia as described in Huizinga's Groningen thesis. Of the 504 cases 27 were fatal—a mortality of 5.3 per cent. The cases in Bijtel's series were divided into the following four groups. (1) In organic foreign bodies: 234 cases, with a mortality of 4.3 per cent. (2) Animal foreign bodies: 45 cases, with a mortality of 13 per cent. (3) Vegetable foreign bodies excluding Brazil nuts: 120 cases, with a mortality of 5.8 per cent. (4) Brazil nuts: 106 cases, with a mortality of 3.8 per cent. The causes of death were in most cases pneumonia, purulent bronchitis, and pulmonary abscess, in two cases cardiac failure, and in one case each pyopneumothorax, mediastinal emphysema, pulmonary haemorrhage, and haemorrhagic bronchitis.

97. Blood Transfusion in Post-operative Collapse.

AUMONT (*Bull. et Mém. Soc. Nat. de Chir.*, December 5th, 1925, p. 1008) records the case of a young girl operated on for acute appendicitis. The operation, though somewhat difficult, was successful, and the patient made satisfactory progress with no complications till the tenth day. The temperature then rose and there was marked headache, with later collapse and some gastro-enteritis. The temperature and pulse rate were both increased and the diagnosis remained in doubt as there were no abdominal or other signs present to account for the condition. Blood transfusion was performed, 400 c.cm. of citrated blood being given to the patient. A few hours later she began to improve and after a good night her condition was rapidly restored to the normal; the subsequent history was uneventful. Aumont considers that the abdominal symptoms, marked asthenia, and low blood pressure were probably due to some disturbance of the endocrine system, possibly originating in the suprarenal bodies. There was no doubt that the recovery was due to the blood transfusion, and this line of treatment may be useful in similar conditions of acute toxæmia.

98. Periarterial Sympathectomy.

N. J. GUREWITSCH (*Zentralbl. f. Chir.*, November 14th, 1925, p. 2581) states that the general adoption of the Jabonlay-Leriche-Brüning method of periarterial sympathectomy has revealed two serious dangers: (1) laceration of the arterial wall, and (2) stenosis of the artery by contraction of the scar tissue. These complications have been recorded by several observers, and Gurewitsch has endeavoured to find a method of minimizing these dangers. After removing 6 to 8 cm. of the adventitia of the femoral artery in dogs he excised strips of the fascia lata from the same animals, and fixed these strips with fine catgut over the denuded femoral arteries. The operation wounds were firmly sutured. At periods of from two to five weeks the arteries with their surrounding tissues were excised and examined histologically. No signs of narrowing of the arterial lumen or of thrombosis were found at any period, and at the end of five weeks the

fascia was firmly united to the arterial walls. The author has treated two cases of progressive dry gangrene of the toes, in old men, by Leriche's operation, modified as described above. Primary ulcers occurred in both cases, followed by rapid separation of the necrotic tissues.

Therapeutics.

99.

Treatment of Asthma.

L. HOFBAUER (*Wien. klin. Woch.*, December 3rd, 1925, p. 1311) agrees that in the curative treatment of asthmatic attacks adrenalin injections are very valuable. There may, however, sometimes be such unpleasant symptoms as faintness, pallor, and nausea, while with long-continued use there is the risk of arterio-sclerosis. Adrenaline is less harmful in combination with pituitary extract, but this also must not be kept up for long. The author thinks that theobromin preparations are much safer and probably as good. Diuretin-calcium, taken once or twice in the evening, is recommended as an almost certain preventive of an attack. The better known iodine derivatives of theobromin are depressant and have been said to induce Graves's disease. Tuberculin treatment acts by virtue of its foreign protein content. Hofbauer thinks that the desensitizing theory does not hold good in the great majority of asthma cases, and that the elaborate quest for specific irritants is inadvisable. He adds that the dangers attending resection of the vagus or the sympathetic much outweigh the possible benefits of such operations.

100.

Intravenous Iodine in Influenza.

C. P. Y. SHUNKER (*Indian Med. Gazette*, November, 1925, p. 513) has investigated the use of iodine intravenously during an epidemic of acute catarrhal influenza in a prison. He applied this treatment in patients who had high fever with delirium and prostration, or had developed severe pulmonary complications. His initial dose was 20 minims of a solution containing iodine 1 drachm, potassium iodide 1 drachm, distilled water 42 drachms; this was added to 10 c.cm. of saline solution for intravenous injection. Shunker found that within twenty-four hours after injection most of his patients passed from a condition of anxiety and distress into comparative comfort. If within forty-eight hours of the first injection the temperature and general condition did not improve a second dose of 40 minims of the solution in 10 c.cm. of saline were administered: one patient required as much as five injections. The majority of the patients required only one injection; no bad results followed, and the benefit was usually very rapid.

101. Hexyl Resorcinol as a Urinary Antiseptic.

V. LEONARD and A. WOOD (*Journ. Amer. Med. Assoc.*, December 12th, 1925, p. 1855) have continued their investigation of hexyl resorcinol (see *Epitome*, 1925, vol. 1, paras. 146 and 240) with special reference to its acting equally well in acid and alkaline urines, which is explained in terms of surface tension. They remark that the rate of diffusion of a germicide through the cell membranes of the renal tissue is dependent on the surface tension of the fluid, and by experimental work *in vitro* they have proved that hexyl resorcinol is more effective in a solution of low surface tension. Moreover, this drug itself greatly lowers the surface tension of a solution. They have found that the surface tension of normal urine is about 60 "dynes" (ordinary water 77 dynes), that the administration of hexyl resorcinol in therapeutic doses lowers the surface tension to about 50 dynes, and that the administration of sodium bicarbonate in therapeutic doses raises the surface tension to 66 dynes and over, which explains why it has long been contraindicated in hexyl resorcinol treatment. Free intake of water may raise the surface tension of urine by as much as 15 to 20 dynes. Leonard and Wood have now given hexyl resorcinol in 500 cases of urinary infection with considerable success. They used gelatin capsules containing a 25 per cent. solution in olive oil, equivalent to 0.15 gram hexyl resorcinol; for children the strength was 2.5 per cent., one drachm containing 0.1 gram of the drug. The dosage was, for adults, 0.45 to 0.6 gram thrice daily immediately after meals; for children a relatively larger dose was given. Fluids were not increased and sodium bicarbonate was not given. The authors found that this treatment must be prolonged for considerable periods amounting to sixty to ninety days in the case of *B. coli* infection, which is the most resistant to surface tension changes in the urine. They state that if combined with the usual local measures the length of treatment is shortened and the percentage of successes increased. No toxic effects were observed.

102. Intravenous Administration of Digitalin.

J. SURMONT and A. SCHEROWITZKY (*Presse Méd.*, December 2nd, 1925, p. 1590), while strongly recommending the intravenous administration of digitalin, add that the indications for it are rather exceptional, and that the drug must be very pure. It has been maintained that digitalin by the mouth acts as well, but this is unlikely in view of the fact that cardiac failure entails hepatic insufficiency, which in turn hinders absorption from the alimentary canal. Onabain has also been recommended for intravenous administration, but the authors have observed a number of cases in which after onabain treatment had been tried without benefit the patients made undeniable progress when treated with digitalis. They think that if some form of reactivation is concerned it is a reactivation due to a better method of administration, not to co-operation of the two drugs. Details are given of a man with mitral and aortic disease, asystole, and many grave symptoms, who after eight years' illness—marked by temporary remissions under ordinary treatment, including digitalin and theobromine by the mouth, when at home—came into hospital. There, after digitalin by the mouth and intravenous injections of onabain had failed, digitalin was given intravenously with such dramatic results that in three months the patient returned to work.

103. Treatment of Syphilis.

W. H. GOECKERMAN (*Minnesota Med.*, December 2nd, 1925, p. 740), in a review of recent advances in the therapeutics of syphilis, states that although the supremacy of the arsenobenzols remains unshaken, yet when they fail certain other remedies may be successful. The toxicity of bismuth has been reduced by combinations with other elements, but many of these preparations have little therapeutic value. The author uses sodium potassium bismuth tartrate almost exclusively, giving 0.2 gram intramuscularly about every fifth day. If well borne, twenty doses are given in each course. Although slower in action than the arsenobenzols, bismuth is valuable when these or mercury are not tolerated. Apparently the immediate action of bismuth is superior to that of mercury, but it fails to reduce the induration of chancres or of lymphadenitis. Its influence on syphilides is slower than that of the arsenobenzols, and it does not produce a focal reaction. Its effect on the Wassermann reaction is slower but probably more lasting than that of other remedies. Bismuth has been found repeatedly in the cerebro-spinal fluid, which supports the claim that it is particularly useful in neuro-syphilis. It produces very few complications. Gingivitis and stomatitis appear to be due to neglect of oral hygiene; transient albuminuria is frequent, and the author has never seen dermatitis nor evidence of cumulative action. Sulpharsphenamine is probably less toxic than novarsenobenzol and may be given subcutaneously, intramuscularly, or intravenously in doses of 0.4 gram every five days, a 30 to 40 per cent. solution being best. Spirochaetes disappear from a chancre in seven to ten hours after the first injection; little or no local pain occurs, and chancres heal in from seven to ten days. The author gives three doses of 0.4 gram every third day, then every fifth day. After the third dose mercurial fumigation is commenced and continued for six weeks, when a second course of sulpharsphenamine is commenced; four such courses complete the treatment. Intravenous injection is only required when intramuscular administration is painful. It may produce dermatitis, purpura-haemorrhagica, or aplastic anaemia, even without intensive dosage. Tryparsamide has a marked action on the Wassermann reactions in blood and cerebro-spinal fluid, but it appears that relapses are more frequent than with the arsenobenzols, to which it is inferior in latent and tertiary syphilis. It has been found valuable in some cases of neuro-syphilis after a previous systematic arsenobenzol treatment, but may be followed by retrobulbar neuritis. By malaria treatment the author has obtained satisfactory remissions in more than 50 per cent. of his cases. It has been effective in cases of neuro-syphilis without paresis; the Wassermann reaction of the cerebro-spinal fluid has become negative, while tabetic lightning-pains and optic atrophy have been relieved.

Anaesthetics.

104. Blood Pressure in Anaesthesia.

M. A. MORTENSEN (*Anaesthesia and Analgesia*, December, 1925, p. 333) advocates a careful study of the blood pressure before and during any operation and until convalescence is established as the best means of estimating the cardiac efficiency and anaesthetic risk. By means of a tilting table blood pressure and pulse changes were observed during passive postural changes of the body, the change from the

reclining to the erect position being obtained without any effort on the part of the patient. Comparisons with patients with symptoms of myocardial inefficiency showed a more pronounced drop in the systolic pressure and an abnormally increased pulse rate than in healthy persons, thus affording positive evidence of cardiac weakness. In ninety healthy girls the average systolic pressure was 118, the diastolic 72, and the pulse rate 72 when reclining, while in the erect posture the readings were 114, 80, and 86 respectively. Only rarely was a drop in diastolic pressure noted on putting the patient in the erect posture, and this occurred in those who were prone to fainting attacks. During operations lowering of the blood pressure is the earliest sign of collapse and shock, and it occurs before any other sign of danger. Mortenson therefore advises routine estimation of the blood pressure at five to ten minute intervals. In unfavorable cases the degree of anaesthesia may be altered, or the chest be rubbed with cold compresses to stimulate respiration; in more precarious conditions the slow continuous intravenous injection of Ringer's solution is suggested. After an operation regular estimations reveal the condition of the myocardium, maintenance of blood pressure at the pre-operation level being indicative of sustained cardiac efficiency, while a drop of many millimetres calls for cardiac treatment. Occasionally an increase in pressure is accompanied by alarming symptoms, and a case is mentioned in which the systolic pressure rose from 140 to 200 mm. in consequence of a progressive thrombosis in the ascending vena cava ten days after gastro-enterostomy. Mortenson concludes that careful readings and their correct interpretation are of more value to the anaesthetist and surgeon than any other procedure in affording early detection of a failing myocardium.

105. Anaesthesia in Rectal Operations.

G. M. LINTHICUM (*Amer. Journ. Surg.*, December, 1925, p. 300), in a comparative study of anaesthesia in various rectal operations, concludes that local anaesthetics are preferable to general ones, although he agrees that spinal analgesia is more dangerous than chloroform. He believes, however, that many of the failures and complications of local anaesthesia are due to the administrator rather than to the agent. Sacral or intraspinal anaesthesia is inadvisable when there is any adjacent local infection, and in operations for fistula it is of doubtful value, since the extent of the disease is uncertain and extensive exploration may be necessary. In haemorrhoids and rectal carcinoma the value of sacral anaesthesia is being increasingly recognized, and Lepoutre, after dealing with 500 cases, believes that spinal anaesthesia is indicated in all subumbilical operations. Trans-sacral anaesthesia has been used satisfactorily in low carcinoma, haemorrhoidectomy, and amputations of the rectum, but Linthicum recognizes the difficulty of the method and does not recommend it. Parasacral anaesthesia was used by Staffel in 413 perineal and pelvic operations; he considers it safer and more certain than the lumbar method. For patients with cardiac, respiratory, or renal changes, contra-indicating general ether anaesthesia, but requiring some degree of unconsciousness, Linthicum recommends a gas-oxygen mixture or ethylene.

106. Synergy in Anaesthesia.

J. T. GWATHMEY (*Journ. Amer. Med. Assoc.*, November 7th, 1925, p. 1482) discusses the discovery and development of synergistic analgesia produced by magnesium sulphate and morphine and magnesium sulphate and ether. He describes experiments conducted in collaboration with C. W. Hooper in which they found that the intravenous administration of less than one-half the anaesthetic dose of magnesium sulphate combined with approximately one-ninth the anaesthetic dose of ether produced surgical anaesthesia, and concludes that ether and magnesium sulphate act synergistically without producing any increase in toxicity. Gwathmey states that in the albino rat the addition of 2.5 per cent. procain to 50 per cent. magnesium sulphate, alone or combined with 1/8 grain of morphine for subcutaneous injection, definitely prolongs the effect, and allays irritation without increasing toxicity. He suggests that the combination of 50 per cent. magnesium sulphate with 2.5 per cent. procain may be a good substitute for morphine in general practice. Gwathmey further describes experiments on rats in which it was found that those previously injected intravenously with 0.8 c.c.m. per kilogram of a 50 per cent. magnesium sulphate solution containing 2.5 per cent. procain and 1/8 grain morphine per 2 c.c.m. survived ether anaesthesia for twenty to twenty-five minutes, while animals which had not received this preliminary treatment died within from eight to ten minutes. From this Gwathmey and Hooper conclude that the use of synergistic drugs with ether anaesthesia may result in a considerable saving of life.

Obstetrics and Gynaecology.

107. Cystic Corpus Luteum.

ACCORDING to R. KELLER (*Gynecol. et Obstét.*, December, 1925, p. 288), cysts of the corpus luteum are found in many gynaecological affections; they are not more frequent in ectopic pregnancy than in other conditions. Inflammation and adhesions of the pelvic peritoneum seem to have no share in their formation, and adhesions over them are often not the remains of peritonitis, but of chronic congestion of the pelvic organs. In most cysts the luteal elements are found in a state of retrogression. Some patients complain of pain over the lower abdomen, but this is due to some concomitant affection and not to the cyst. Large cysts, which are rare, may cause symptoms by giving rise to torsion or incarceration. In most cases the menstrual flow was more abundant than normal and sometimes associated with pain, though without change in periodicity.

108. Muscular Attachment of the Cervix.

F. G. DUBOSE (*Surg., Gynecol. and Obstet.*, December, 1925, p. 834) calls attention to the presence of certain muscle fibres inserted into the anterior portion of the cervix uteri which, he states, are analogous to the prostatic fibres of the levator ani muscle in the male. These uterine fibres arise from the pubis and pass backwards along the sides of the vagina over the anterior vaginal fornix and anterior surface of the cervix to be inserted into the anterior surface of the cervix at the isthmus. The fibres of the two sides fuse to form a strong medium aponeurotic band. On either side of this band the tissue is loose, but the band itself is dense and firmly adherent, attaching the base of the bladder to the cervix. The author adds that the function of this muscle is to form a sling for the cervix uteri on its anterior surface when the uterus is normally anteverted. It is separated with difficulty by blunt dissection and in the operation of hysterectomy is usually cut by scissors in the process of separating the cervix from the bladder.

109. Pregnancy in Apparent Absence of Adnexa.

RUDAUX and DURANTE (*Bull. Soc. d'Obstét. et de Gynecol. de Paris*, 1925, No. 9, p. 639) record the case of a woman, aged 32, who died of eclampsia shortly after delivery at term. At the necropsy the adnexa of both sides appeared to be absent. Four years earlier the right Fallopian tube and ovary had been removed for ectopic pregnancy. Microscopical examination of the uterus removed *post mortem* showed on the left side an atrophic Fallopian tube and a corpus luteum surrounded by rudimentary ovarian tissue. They were embedded in loose connective tissue in a small groove in the myometrium, nearer the upper than the lower limit of the uterus, and were covered by peritoneum of normal appearance. No broad ligament was present on the left side. The authors add that this case is of interest in that it casts doubt on cases of unilateral or bilateral absence of the adnexa recorded in the absence of microscopical examination; the occurrence of a similar anomaly may explain the occasional persistence of menstruation after bilateral castration.

110. Treatment of Gonorrhoeal Endocervicitis.

L. BRADY (*Bull. Johns Hopkins Hosp.*, December, 1925, p. 400) records results obtained in 36 cases of gonorrhoeal endocervicitis treated by mercurochrome. The criterion of cure was three successive negative smears at two-week intervals and a further negative smear at the end of a month after the completion of all treatment, by which time, in the great majority of cases, all discharge had ceased. The patients were douched daily except during menstruation and on the days when the smears were taken. Twice a week the vaginal portion of the cervix was painted with a 20 per cent. mercurochrome solution, and, using a thin wire applicator, the entire cervical canal was swabbed up to the internal os. In 4 cases a profuse leucorrhoea with negative smears entirely cleared up in six weeks, and of the remaining 32 cases with positive smears 25 were certainly, and 4 probably, cured, while 3 failed. The 4 probable cures had three successive negative smears and had no vaginal discharge at the end of treatment, but the fourth smear at the end of the month could not be obtained. The three patients in whom the treatment failed had histories suggestive of salpingitis, and in two of them there was infection of Bartholin's glands. Five other patients with evidence of salpingitis on admission were entirely cured with hot douches and mercurochrome treatment, and in no instance did salpingitis develop during treatment. Of the 25 cases absolutely cured the average time occupied by the treatment, including the month during which all treatment

was suspended prior to the fourth examination, was three and two-third months. Brady holds that infection of Bartholin's glands should be treated by their complete removal, and he claims that two distinct advantages of the mercurochrome method are its simplicity and minimal danger of salpingitis resulting.

Pathology.

111. Hepatic Activity in Toxaemia.

E. L. OPIE (*Journ. Amer. Med. Assoc.*, November 14th, 1925, p. 1533) discusses the relation of the liver to toxæmic conditions. It has been shown by many observers that the liver can remove from the blood certain substances owing to the ability of some of the endothelial cells lining the sinusoids of the liver to arrest and engulf minute insoluble inorganic particles circulating in the blood, and also bacteria, substances in colloidal suspension, and probably certain substances dissolved in the plasma. The liver takes up bacteria which have penetrated the intestinal wall and entered the portal circulation, thus preventing their entrance into the systemic circulation; this activity was found to increase with immunization. Micro-organisms that have temporarily lodged within vessels of the lungs or other organs are finally dealt with by the liver. This power of fixation of injurious substances may cause destructive changes and permanent lesions of the liver. Opie adds that experiments suggest that the action of the liver on foreign protein is analogous to its action on bacteria, since in both instances the injurious effect is diminished and the protective action increased as the result of immunization. It seems probable that it has a similar effect on many injurious bacterial products which act as antigens and induce immunity.

112. Effects of Quinine on the Blood Sugar.

T. A. HUGHES (*Indian Journ. Med. Research*, October, 1925, p. 321), as the result of experiments and from a study of the literature, concludes that quinine influences the level of the circulating glucose by stimulating the sympathetic system. This probably results in the secretion of adrenaline leading to hyperglycaemia; insulin is then liberated and causes hypoglycaemia. The method by which quinine may affect the output of insulin is not known, and while it is possible that it acts by stimulating the para-sympathetic nerves, causing a lowering of blood sugar, the hypoglycaemia may be due to induced hyperaemia of the pancreas, which has been shown to cause an increased production of insulin. The effect of insulin on the hyperglycaemia which large doses of quinine produce in rabbits is similar to its effect on adrenaline hyperglycaemia. The glycogenolytic effect of quinine is inhibited by ergotoxin and in a less degree by pituitrin. In antimalarial doses quinine causes a lowering of the blood sugar in man, an effect which is antagonized by pituitrin, and the fall in blood sugar so produced may sometimes set up mild symptoms of hypoglycaemia, which can be prevented by carbohydrate ingestion or by a meal rich in carbohydrate half an hour to an hour after the drug has been taken.

113. The Blanching Phenomenon in Scarlet Fever.

K. E. BIRKHAUG (*Journ. Clin. Investigation*, No. 3, 1925, p. 273) summarizes his observations as follows: (1) Serum from normal persons without a history of scarlet fever or general septic infections produced the Schultz-Charlton rash extinction phenomenon in 4 out of 6 cases tested on the second day of the rash, and in 1 of 7 cases tested on the third day of the rash. (2) Serum from convalescent scarlet fever patients produced the Schultz-Charlton phenomenon in 24 out of 27 cases tested, or in 89 per cent., during the first sixty hours of the rash, but did not cause blanching seventy hours after appearance of the rash. (3) Dochez's serum produced the phenomenon in 40 cases, or 100 per cent., during the first sixty hours of the rash. It continued to produce blanching seventy hours after the appearance of the rash, but did not produce blanching eighty hours after the rash had appeared. This indicates that Dochez's serum possesses the same specific property that is found in normal and convalescent serum, but contains this specific property in considerably greater concentration. (4) Blood serum from scarlet fever patients first showed the property of producing the Schultz-Charlton phenomenon about the eighth day of disease. (5) Epinephrin, normal horse serum, and diphtheria antitoxin consistently failed to produce the phenomenon. (6) Normal horse serum, convalescent scarlet fever serum, and Dochez's serum failed consistently to produce blanching in other eruptive diseases. (7) Rash extinction areas were directly proportional in size to the amount of serum injected.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

114. Local Immunity in Mumps.

A. CRAMER (*Rev. méd. de la Suisse rom.*, December 25th, 1925, p. 893) records a case of mumps which occurred during an epidemic of the disease at Geneva, in a boy aged 16, in whom the disease was confined to the sublingual glands. Three years previously he had had a first attack of mumps, when he had a bilateral swelling of the parotid and submaxillary glands followed by left orchitis. The case was thus an example of local immunity which Askanazy attributes to the endothelial cells, and especially to the cells of connective tissue. In enteric fever, for example, the typhoid or paratyphoid bacilli are attracted by the intestine, and in mumps the salivary and genital glands are specially affected. The cells of these organs show an "avidity" for the mumps virus, and when their "avidity" has been satisfied a fresh dose of the virus has no longer any effect. It seems probable that local immunity is established rapidly long before the appearance of antibodies, so that the participation of the latter in the process of vaccination and immunization does not seem to be proved. It is suggested that in the present case the first attack of mumps vaccinated the cells of the parotid, submaxillary gland, and testis, and that these glands, having become saturated with the virus, became refractory at the time of the second infection, whereas the sublingual glands which had not been in contact with the virus on the first occasion attracted and absorbed it.

115. The Prognosis in Subacute Bacterial Endocarditis.

E. LIBMAN (*Amer. Heart Journ.*, October, 1925, p. 25) records his observations on 800 cases of subacute bacterial endocarditis extending over a period of twenty-five years. He divides the cases into the following five groups: (1) Cases of the usual type, running a course of four to eighteen months or more and characterized by fairly marked elevation of temperature, positive blood cultures, and usually embolic phenomena. Libman has records of at least ten complete recoveries in this group. If cases which recovered and finally developed a fatal recurrence be added, this number is raised to twelve. The cause of death in this group is usually exhaustion. Embolism of a coronary artery is rare, of a cerebral vessel frequent. Other important causes are polynuclear meningitis, subarachnoid and intraventricular haemorrhage due to rupture of embolic aneurysms, and rupture of such aneurysms elsewhere in the body, hyperpyrexia, and anaemia. (2) Cases in the bacteria-free stage. Patients in this group may remain well indefinitely, but are liable to a recurrence, the issue of which may or may not be favourable. (3) Transitional cases in which the symptoms are present but the blood cultures are negative. Such cases are usually fatal in a short time. (4) Mild cases of long or short duration. All the patients which Libman has seen recovered. (5) Recurrent cases in which the recurrence ends in recovery or death. The repetitions of the infection may be due to invasion from a focal infection or to invasion of the blood by bacteria, deposited in the various organs during the previous attack.

116. Spontaneous Meningeal Haemorrhage.

JOSEPHINE B. NEAL (*Journ. Amer. Med. Assoc.*, January 2nd, 1926, p. 6) records 35 cases of spontaneous meningeal haemorrhage and discusses this rare condition. In most of the cases no cause could be determined, but in 4 cases the haemorrhage was associated with an attack of epidemic meningitis and in another 4 cases with a cardiac lesion. Four other cases were associated respectively with pneumonia, syphilis, nephritis, and high blood pressure. Recovery followed treatment in 21 out of the 35 patients, though one died of nephritis a month later. The early symptoms were those of an acute and often of a fulminating meningitis. The onset was sudden, with intense headache, usually vomiting, and not infrequently unconsciousness within a few hours. In some cases there were twitches or convulsions, and stiffness of the neck, and a positive Kernig sign; changes in the reflexes were observed within a few hours or in a day or two. In most instances there was a rise of temperature of 1 to 3 degrees; the pulse was usually but not invariably slow. Early unconsciousness was not found to have any prognostic value. The diagnosis was made chiefly by examination of the spinal fluid, which contained blood evenly distributed through it without signs of coagulation. The author con-

siders that lumbar puncture is a most important measure in treatment. She states that it should be repeated daily, or less often, according to the clinical symptoms; in most of the cases it was followed by improvement. Antimeningitic serum was injected in several cases and may have had a restraining influence on the haemorrhage.

117. Hyperglycaemia without Acetonuria.

W. P. ARGY (*Boston Med. and Surg. Journ.*, December 31st, 1925, p. 1236) gives an account of a case of diabetes mellitus which lasted for six months and was characterized by the absence of acetonuria, high blood sugar concentration, and a considerable amount of acetone in the spinal fluid. The patient, a negro, aged 33, was admitted to hospital in a comatose state, after having been treated by dietetic restriction. The urine contained much albumin and many hyaline casts, together with sugar; the blood sugar was 1.71 per cent. Insulin was given as emergency treatment, but, though the blood sugar concentration was reduced at once, the patient died the next day without recovering consciousness. In the kidneys advanced fatty degeneration and necrosis was found; there was a focal necrosis of the liver with fatty degeneration, cerebral oedema, early bronchopneumonia, and a dense interstitial fibrosis of the pancreas. The author thinks that the large amount of sugar in the urine, together with the absence of acetonuria, may be associated with the kidney complication, as has been previously suggested by Joslin.

118. Congenital Syphilis of the Joints.

P. BLUM and FATOU (*Presse Méd.*, October 14th, 1925, p. 1366) report six cases of late congenital syphilis of the joints. In addition to the classical osteo-articular type there exist also pure synovial forms which, owing to their polymorphism, may simulate acute, subacute, or chronic rheumatism. They may be accompanied by fever and be painful or indolent. In some cases the appearance of bilateral hydrarthrosis, whether simultaneously or not in both joints, points to a syphilitic etiology. Systematic examination of the synovial fluid brought to light the existence of a polymorphonuclear count of from 70 to 95 per cent.; the fluid was sterile, and animal experiments were negative. The Wassermann test was always positive. Congenital syphilis is believed to play an important part also in the development of some fibrous forms of chronic arthritis deformans. The authors think that the fixation of a fibro-ankyrotic character which occurs in gonorrhoeal arthritis may be referable sometimes to congenital syphilis.

Surgery.

119. Infections by Fusiform Bacilli and Spirochaetes.

I. PILOT and K. A. MEYER (*Arch. Derm. and Syph.*, December, 1925, p. 837) point out that putrid infections are often caused by the organisms of Vincent's angina, and the source of these infections is related to the normal distribution of the bacteria in the body. They report a case of gangrenous infection of a finger in which these organisms were found. A negro in the course of a fight was bitten on his left middle finger. The next day the finger was swollen; one week later a swelling on the radial side was incised. The lesion subsequently became deeper and discharged foul pus. A deep ulcer occupied the base and sides of the distal phalanx; it involved the entire circumference of the middle phalanx, and extended on to the dorsal surface of the proximal phalanx. The lesion was moist and dull green in colour, bone was visible in the centre of the base with a black irregular slough around. The margins were irregular and shaggy, and bled readily. The discharge was thick, blood-stained, and purulent, and had a putrid odour. The epitrochlear and axillary lymph glands were not enlarged; the Wassermann test was negative. The radiologist reported an old fracture of the middle phalanx with a deep destructive infection superimposed. Pathological examination showed many fusiform bacilli, spirochaetes, and a few streptococci and diphtheroids. Two doses of 0.6 gram of neo-arsphenamine were given intravenously, but as the distal part of the finger was hanging loosely amputation was performed through the middle phalanx. Two more doses of neo-arsphenamine were given later; following this the ulcer improved rapidly and was completely healed eight days after the operation.

120. A Pulsating Sacral Tumour.

M. BÉCLÈRE (*Journ. de Radiol. et d'Électrol.*, November, 1925, p. 503) describes the case of a girl, aged 13, who had a large irregularly rectangular swelling occupying the whole of the sacral area, apparently following a fall four months earlier. The skin was smooth and thin, but otherwise normal; the subjacent tumour appeared somewhat elastic and was distinctly pulsatile. The patient suffered from incontinence of urine and faeces. There was tactile and thermal anaesthesia over a saddle-shaped area comprising the buttocks, perineum, vulva, and inner surfaces of the thighs. The lower limbs were so wasted and weak that she could walk only a few steps when supported on either side. The abdominal and patellar reflexes were present, but the tendo Achillis reflex had disappeared on both sides. A skiagram showed almost complete decalcification of the sacrum. The Wassermann reaction was negative. She received four applications of x rays at intervals of two days, and fifteen days after the fourth irradiation the tumour was distinctly smaller and pulsation had ceased. Incontinence of faeces and enuresis occurred only at night, during sleep. The patient could raise herself and walk a few paces without pain. Three weeks after the termination of the first series of irradiations a second course of four was given over the suprapubic region in the direction of the anterior surface of the sacrum. Five months later the patient had gained 11 lb., and appeared to have recovered her health completely. She could stand and walk without pain, as before her fall. A slight ridge in the sacral region was the only vestige of the tumour. The lower limbs had recovered their normal size, but the saddle anaesthesia persisted and the tendo Achillis reflex had not reappeared. Incontinence occurred nocturnally at intervals of ten to fifteen days. A skiagram of the pelvis showed some deformity of the sacrum, but no other abnormality.

121. The Treatment of Keloid.

P. DEGRAIS and A. BELLOT (*Presse Méd.*, November 28th, 1925, p. 1531) describe the factors which predispose to keloid, which include a lymphatic area and a tendency to scorbhœmia; they then describe three methods of treatment. The first is surgical; its success is dependent on the extent and situation of the growth and it may be followed by recurrence; after-treatment by radium is recommended. The second method is to attack the scar directly by such methods as scarification, electrolysis, oscharotics, or carbonic acid snow. Most of these methods are painful and can therefore only be applied to small scars. The third method is the one of choice and consists of either x rays or radium, the latter being preferable because it is more easily controlled. The dose will depend on two factors—the depth of the scar and the tolerance of the patient. The object is to penetrate to the base of the growth and at the same time to avoid reaction in the adjacent tissues.

122. Tumour of the Carotid Body.

G. LECLERC (*Bull. et Mém. Soc. Nat. de Chir.*, November 28th, 1925, p. 982) records a case of a tumour of the intercarotid body in a woman, aged 37, which had been present for seven years. At the operation the common carotid was found to run through the tumour, which was firm in consistence, did not pulsate, and evidently arose from the carotid body. Its removal was difficult, and entailed ligation of the carotid artery and resection of a portion of the internal jugular vein. The post-operative course was complicated by dysphagia and aphonia, but there were no cerebral or paralytic symptoms. Her condition slowly improved, but there was still some difficulty in deglutition and weakness of the voice. These tumours of the carotid body histologically reproduce the structure of the normal gland; they are apparently benign in character. Operation for their removal is difficult, and a mortality rate of between 20 and 30 per cent. was reported in a series of collected cases.

123. Results of Sympathectomy in Angina Pectoris.

T. JONESCO and D. IONESCO (*Presse Méd.*, December 25th, 1925, p. 1697) have performed total resection of the sympathetic stellate ganglion in 32 cases of angina pectoris, partial resection of the cervical sympathetic in 24, and the Eppinger-Hoyer resection of the depressor nerve in 18. All three operations gave about the same mortality—namely, 20 per cent. The patients who recovered showed no cardiac disability, the pulse and blood pressure being unaffected and the heart responding to drugs such as adrenaline as before. One man with angina, operated on nine years previously, was now working seven days a week and did much walking; another had been a butcher for three years and felt well. A young man operated on for Graves's disease had been through the war since; and two epileptic women were now married and had large families, twenty-five years after operation. The authors state that the patient may have to remain in bed for four months after the operation. The

freedom from subsequent cardiac disability was to be expected in view of the physiological findings, it having been shown that the heart can meet all needs of the circulation by the automatism of its musculo, even when communications with the central nervous system are quite cut off.

Therapeutics.

124. Treatment of Scarlet Fever.

U. FRIEDEMANN and H. DEICHER (*Deut. med. Woch.*, November 13th, 1925, p. 1893, and November 20th, p. 1938) maintain that the organisms described by Di Cristina, Caronia, and Sindoni as the cause of scarlet fever are merely precipitates derived from the culture media and that the eruptions produced thereby are only anaphylactic reactions to foreign proteins. They agree that the scarlet fever streptococci described by the Dicks and Dochez fulfil Koch's postulates. The uncertain therapeutic action of the serum of scarlet fever convalescents is readily comprehensible, since there is no means of determining its antitoxin content. The serums of individual convalescents show great differences. Moreover, the difficulties of obtaining a sufficient quantity of serum in practice are very great. Lastly, the best convalescent serum cannot be compared for efficacy and antitoxin content with the scarlet fever streptococcus serum. Dochez's serum was used in fourteen cases of scarlet fever in doses of 40 to 50 c.c.m. intramuscularly; in very severe cases the injections were repeated on the following day. The warning is given that, owing to the large size of the dose, the risk of anaphylaxis must be borne in mind. The serum should be given as early as possible, but if it is injected within the first three days of the disease no difference can be detected in its action. It is only after the fourth day that its effect becomes less striking, though it is still distinct. In all but three of the fourteen cases the injection of serum was followed by a remarkable change in the clinical picture. In the course of twelve to fourteen hours the temperature fell by crisis to normal and the feeling of illness disappeared. Complications, if not present at the time of injection, did not occur. This remedy is described as being superior to any other therapeutic serum, including even diphtheria antitoxin. During the last ten years scarlet fever in Germany has assumed a remarkably mild form, but epidemics have occurred in which the mortality was as high as 20 or even 40 per cent., and in such epidemics it is suggested that the serum would be of the utmost value.

125. The Use of "Bipp" in Osteomyelitis.

A. P. MACKINNON (*Canadian Med. Assoc. Journ.*, November, 1925, p. 1222) states that the treatment of osteomyelitis is still far from satisfactory and urges the more frequent use of bipp. He believes that few cases of osteomyelitis are recognized by the general practitioner in the early stages, when they might be cured by simple drainage, and it is not until there are present discharging sinuses, bone cavities, and sequestra that the patient is referred for surgical treatment. At this stage MacKinnon uses bipp: the wound is thoroughly exposed and all sinuses traced to their origins. Sequestra are removed, the walls of the cavity levelled so as to allow the soft parts to fall in, or the cavity filled with fat grafts in order to leave no dead space. Bleeding must be stopped as far as possible; the wound thoroughly swabbed with alcohol-soaked gauze, and bipp then applied so as to leave a thin smear, the wound being closed in layers without drainage. Dressings were usually not removed for ten to fourteen days after the operation, when the stitches were taken out; this eliminated frequent painful dressings. MacKinnon states that there is no danger of serious poisoning, but healing by first intention has not been so frequent in his cases as in those reported by Rutherford Morison.

126. Boric Glycerin in Post-operative Urinary Retention.

TANT (*Bruxelles-Médical*, December 13th, 1925, p. 216) for the last five years has treated 175 cases of post-operative urinary retention by the following method, modified from that of Corborean. The bladder is first emptied by the catheter and then an injection is given of glycerin 50 grams, boric acid 5 grams, sterilized water 5 c.c.m. Power of micturition is established in a quarter to half an hour. In about three-quarters of all cases one injection suffices; if not, a second injection is nearly always successful, and only very exceptionally is a third necessary. Tant has known only one instance of failure; this occurred in a man suffering with erysipelas who died three days later. As the operations were of the most diverse kinds, ranging from resection of the rectum to the radical cure of varicocele, and as success was so constant, the author considers this method worthy of routine use.

127. Vaccine Treatment in Epidemic Encephalitis.

A. REMOND and H. COLOMBIER (*Arch. medecine*, December, 1925, p. 177) treated five cases of post-encephalitic Parkinsonism by intraspinal injections of the Levaditi-Poincoux vaccine. Only one patient appeared to derive definite benefit from the treatment, three after a slight improvement remanued in the same serious condition as before, and one developed severe symptoms after injection which at one time resembled Landry's paralysis. Poincoux, who used the vaccine in 50 cases, 7 of which were suffering from acute encephalitis and 43 from the sequelae, obtained complete cures in 3 and considerable improvement in 2 cases of the acute group, whereas the results in the chronic cases were not so good. Although improvement occurred in every case no actual cure resulted. The present authors conclude that in a condition so invariably fatal as post-encephalitic Parkinsonism there is justification for employing Levaditi's vaccine, even though its use is not without danger. The possibility of an occasional arrest of the disease, especially when the treatment is employed early, must be taken into consideration.

128. The Bromide Treatment of Epilepsy.

W. WEIGANDT (*Klin. Woch.*, December 10th, 1925, p. 2400) states that the combination of the three bromides presents no advantage over the potassium salt, while the latter is cheaper. He thinks that luminal is the better remedy and is invaluable if bromism supervenes, and it is not much more expensive. Many of the modifications or combinations of bromide for use in bromism are in his experience not only expensive but of doubtful value. Bromism can be prevented by administering the drug in capsules that dissolve in the intestine, not in the stomach. All medicinal treatment of epilepsy can be aided by attention to the diet, which should be poor in sodium chloride, although a complete deprivation cannot be borne. No salt should be taken on the plate, milk (the best vehicle for bromide) should be the chief drink, and white bread and meats should be substituted for brown bread and purine-containing flesh. Any exacerbation of symptoms may be treated by rest in bed.

Diseases of Children.**129. Renal Tuberculosis in Childhood.**

E. FALCI (*Journ. d'Urol.*, October, 1925, p. 301) discusses the incidence, clinical course, and prognosis in renal tuberculosis in the child as compared with the adult. The condition is less common in childhood, but increases in incidence with age, and the greatest frequency in the young is from the thirteenth to the eighteenth year. The number of cases of bilateral renal tuberculosis is greater in early life; in the first years of life its incidence is double that of later life, 28 per cent. of the cases being in children, 14 per cent. in adults. Bilateral disease is more frequent in the very young and decreases as the child grows up; its course in children is very rapid and soon proves fatal. After operative treatment in unilateral cases there is a mortality of 44 per cent.; in 16 per cent. the condition is aggravated, in 16 per cent. the patient's condition is stationary, and there are 24 per cent. absolute cures. In the adult the incidence of the disease is greatest between 19 and 30 years of age. In bilateral cases the course is not so rapid and there is a greater reaction on the part of the patient. After an operation in unilateral cases there is a complete cure in 56 per cent. of cases in adults. Falci concludes that in children the disease is very serious, and that it tends to spread generally; even after operation the prognosis is distinctly poor.

130. Brain Tumours in Children.

M. CRITCHLEY (*Brit. Journ. Child. Dis.*, October-December, 1925, p. 251) discusses the phenomena common to all varieties of cerebral tumour as seen in pediatric practice in a paper based on the analysis of 125 cases admitted to the National Hospital, Queen Square, between 1912 and 1925. The rarity of the disease in the first few years of life is shown by the fact that only three in this series occurred in the first thirty-six months. The frequency then gradually increases up to the age of 8, after which a fairly uniform level is maintained. As regards the localization 59, or 47.2 per cent., of the tumours were situated in the pons or cerebellum; 34, or 27.2 per cent., in the cerebral hemispheres; and 14 were classified as pituitary or suprapituitary. In other words, the more archaic and primitive areas of the brain tended to be affected by tumour growth rather than the younger and higher evolved telencephalon. As regards the various types of tumour tuberculomata were the most frequent, the masses being often multiple. Gliomata came next in frequency. Sarcomata were third in importance, while gammata, endotheliomata, and neuro-fibromata occurred in much smaller proportions. Carcinomata were very rare. Headache was

the most constant symptom of all, but varied greatly in severity, character, and position. An alteration in the child's disposition was often the earliest and most outstanding symptom in cerebral tumour. Somnolence was a marked and persistent feature from the onset, with tumours in certain localities, especially in the neighbourhood of the diencephalon and mesencephalon. Vomiting occurred in most patients sooner or later. In very slow-growing tumours, such as endotheliomata, it might be absent altogether. Papilloedema, often incorrectly described as optic neuritis, occurred in about 80 per cent. of all cases, being most intense in subtentorial growths. Convulsive attacks, with or without unconsciousness, might occur at any stage. In most cases the march of the disease was progressively downhill, but in some cases, especially in tuberculomata situated in the ponto-cerebellar region, one or two remissions might occur.

131. Pyelitis in the Infant.

G. LEMOINE (*Le Scalpel*, October 10th, 1925, p. 1049) holds that in infantile pyelitis the blood stream is the most frequent channel of infection of the kidney. The organisms commonly recovered, generally in pure culture, are *Staphylococcus pyogenes albus* and *citreus*, the pneumococcus, *B. typhosus*, *B. coli*, *B. tuberculosis*, *B. diphtheriae*, and the gonococcus, the one that appears most often being the colon bacillus. The clinical picture is of a severe general infection—high temperature, convulsions, cyanosis, vomiting, and diarrhoea. The pain may be either suprapubic or iliac. Two types are recognized, the primary and the secondary, the latter following gastro-enteritis in the summer, or affections of the upper respiratory passages in the winter. There is usually nothing to indicate renal trouble until the urine is examined and found to be acid and to contain pus. Treatment includes warmth, applied locally, a diet of milk, or milk foods, and fluid should be given freely. When vomiting occurs the author gives enemata, and subcutaneous, intravenous, or intraperitoneal injections of glucose serum. Helmholtz has recommended hexamine tetramine in doses of 3 to 5 grains four or five times a day for infants over six months. The treatment most generally adopted, however, is rapid alkalinization of the urine with potassium citrate, less commonly with the carbonate or bicarbonate of soda. For nurslings Helmholtz finds potassium citrate sufficient, either alone or with equal parts of sodium bicarbonate. To an infant of two months or more he gives 1½ drachms daily, increasing by 1 drachm daily till the urine becomes alkaline. The treatment should be continued for two weeks. With older children, if the symptoms have not improved after three days of alkalinization of the urine, it is necessary to give urotropine and acid sodium phosphate, which will render the urine acid again. Further changes may have to be rung on alkalinizing or acidifying the urine. In most cases material improvement follows on alkalinization of the urine. But after about ten days the urine should be rendered acid again with acid phosphate or benzoate of soda, kept acid for ten days, and then alkalinized again with potassium citrate. Cure should not be considered complete until the urine remains sterile after this test.

132. Hypoplasia Mandibulae as the Cause of Choking Fits.

E. LENSTRUP (*Acta Paediatrica*, October 22nd, 1925, p. 154) records three cases in infants a few weeks old who suffered from violent choking fits caused by a deficient development of the lower jaw, as the result of which the tongue could not be kept in its normal position in the mouth, but fell back into the pharynx, blocking the opening of the larynx. The patients were successfully treated by fixing the child in a lateral position by means of pillows, so that the tongue fell forwards by its own weight. Lenstrup quotes two similar cases reported by Shukowsky, who described them as examples of congenital stridor. One of these infants died of asphyxia. Cleft palate was present in all five cases, but did not appear to affect the clinical picture.

Obstetrics and Gynaecology.**133. Conservative Treatment of Eclampsia.**

S. BERNAN (*Boston Med. and Surg. Journ.*, January 7th, 1926, p. 7) compares the Stroganoff and Rotunda methods of the conservative treatment of eclampsia, and gives an account of his own modification of the former. Absolute quiet in a darkened room is provided. On admission the patient receives a quarter of a grain of morphine, followed by the Stroganoff routine of chloral hydrate, morphine, milk, and saline solution. All examinations are made under gas and oxygen anaesthesia, but so far as possible any disturbance of the patient is avoided. Magnesium sulphate is given intravenously after each convulsion, the dose being 20 c.cm.

of a 10 per cent. solution, and oxygen is administered during the convulsion. Magnesium sulphate is also given if the patient becomes restless some hours after a convulsive attack. Berman recommends having available a 25 per cent. solution of calcium chloride, 10 c.cm. of which can be given intravenously in the event of respiratory embarrassment after the magnesium sulphate injection. He has not experienced this complication himself, however. If the patient is comatose and not taking fluids by the mouth, he recommends the intravenous injection of 1 litre of a 5 per cent. glucose solution every six hours. He does not think venesection necessary as a general rule, and, unless there is no response to treatment, he postpones delivery of the patient until the os is fully dilated and convulsions have ceased. Transfusion may be necessary after delivery if shock supervenes.

131. Cornual Pregnancy.

J. L. GROVE (*Surg., Gynecol. and Obstet.*, January, 1926, p. 102) believes that there has been during recent years an increase in the incidence of tubal pregnancy as compared with normal gestation, possibly owing to more cases being recognized by the improved methods of diagnosis, and also owing to surgical treatment being now more common and facilitating diagnosis. He maintains also that gonorrhoea should be considered as an important etiological factor in ectopic pregnancy, and states that this infection was traced in eight consecutive cases of ectopic gestation in his clinic. He gives details of one case of cornual pregnancy, and suggests that the asymmetry of the fundus, when distinguishable by manual examination, is very suggestive, though it may be solid enough for a fibroid.

135. Pregnancy in Chronic Leukaemia.

R. CHIARI and F. DAUTWITZ (*Wien. Arch. f. inn. Med.*, November 1st, 1925, p. 475), who record an illustrative case, state that there are only twelve cases, including their own, of pregnancy occurring in leukaemia. As a rule the foetus is expelled dead, and in only five instances, including the authors' case, was a living child born. The authors' patient was a woman, aged 31, who had been suffering from chronic lymphatic leukaemia for eighteen months. She was treated by radium in the fifth month of pregnancy, which ran a normal course. A healthy child was born at full term, and there was no dangerous post-partum haemorrhage. Owing to a return of the leukaemic symptoms the patient underwent a second series of radium applications twenty-two months after the first, and rapid improvement followed as on the first occasion. A year after the delivery both the mother and child were in good health.

136. Perforation of the Uterus during Curetting.

MOLIN and DESJACQUES (*Lyon Méd.*, November 29th, 1925, p. 643) record four cases of accidental perforation of the uterus during operation for curetting. In two cases the instrument was a small Hegar's dilator (No. 1 and No. 2 respectively), and in the third case perforation by the curette was not suspected until an iodine injection had failed to return from the uterus. The authors suggest that in general these perforations of the uterus are best treated by incising and draining the posterior fornix, a large gauze drain being left for five days in the colpotomy wound. Against purely expectant treatment they urge (1) that complete aspsis is obtained with difficulty in a curetting operation; (2) that even with minute perforations there is always (as proved in their own colpotomy and in other surgeons' laparotomy cases) bleeding in the pouch of Douglas whereby an excellent culture medium is afforded to micro-organisms; (3) that colpotomy secures drainage at practically negligible operative risk. If the interior of the uterus is highly septic an abdominal operation, completed if necessary by hysterectomy, is indicated.

Pathology.

137. Serological Classification of the Haemolytic Streptococci.

S. ANDERSEN (*C. R. Soc. de Biologie*, January 5th, 1926, p. 1690) has made an examination of 88 strains of haemolytic streptococci obtained from human beings, of whom 61 were suffering from scarlet fever. After a preliminary attempt to employ the agglutination test in their classification, he abandoned this method on account of its technical difficulties and resorted to the complement fixation reaction. Immune sera were prepared by injecting rabbits with cultures killed by heat at 65°C. for thirty minutes, eight different strains being employed. Each serum was then absorbed with every strain in the series and then tested against its homologous antigen. The suspensions utilized were from ascitic agar

cultures, the growth of which had been washed twice with saline. The results showed that the 88 strains fell into five serological groups; one of these contained all of the scarlet fever strains. A serum prepared against a strain of endocarditic origin was absorbed only by its homologous organism. A serum prepared against an abscess strain was absorbed by three other strains of varying origin. A serum prepared against an erysipelas strain was absorbed by nine strains, five of which were isolated from cases of erysipelas. Three sera prepared against a strain of meningial, of phlegmonous, and of anginal origin respectively were absorbed by every strain except the endocarditic one. A serum prepared against a strain isolated from a patient with catarrhal angina was absorbed by all the scarlatinal strains, the anginal strains, and three others. Finally, a serum prepared against a strain of scarlatinal origin was absorbed by all the scarlatinal strains, and by only two others. The scarlatinal strains, therefore, form a fairly homogeneous group.

138. Chronic Intestinal Dyspepsia in Children.

A. BROWN, A. M. COURTNEY, G. A. DAVIS, and I. F. MACLACHLAN (*Amer. Journ. Dis. Child.*, November, 1925, p. 603) submit that the characteristic intestinal flora in the chronic intestinal dyspepsia of childhood is strongly suggestive of a bacterial influence in the etiology. There is a delay in the normal change from the Gram-positive (*Bacillus bifidus*) or aciduric group to the Gram-negative or colon group. The authors are not yet satisfied whether this aciduric group comprises several distinct organisms, or only one extremely pleomorphic organism, but tend rather to support Noguchi in the latter view. A spore-bearing bacillus was isolated from the faeces of two children suffering from chronic intestinal indigestion, which at first was proteolytic, but was found to change its nature greatly after long culturing. Some feeding experiments with white rats showed that they did not gain normally while being fed with milk cultures of the above spore-bearing bacillus, but resumed the normal rate as soon as the diet was changed. Lactic acid milk and milk cultures of *Streptococcus lactis* inhibited the growth-depressing effect. The proteolytic nature of this spore-bearing bacillus is of interest since abnormal putrefactive activity in chronic intestinal indigestion is general, as evidenced by the high ammonia content of the faeces. *Streptococcus lactis*, cultures of which are used therapeutically, was very active metabolically in casein-enriched, low sugar milk, and formed no harmful products. It establishes itself as the predominant organism of the faeces soon after its ingestion has been begun, but probably takes a long time to oust completely the pathological bacteria.

139. Cholesterol in Pleural Fluids.

C. MAININI (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 10th, 1925, p. 1534) states that rather more than twenty cases of pleural fluids containing cholesterol have been recorded, but the etiology has not been investigated. He now describes two new cases in men, aged 27 and 28 respectively, who had been treated with apparent success for pulmonary tuberculosis by artificial pneumothorax. In both cases the family history of tuberculosis was very bad, and the subsequent effusion was sterile and extensive. On standing, the pleuritic fluids showed three strata: the lowest was crystalline and fairly copious, the middle was pale, and contained sparkling crystals, while the highest stratum consisted of yellow opalescent fluid. There was no coagulum. Aspiration showed the pleurae to be thickened and tough, but without extensive adhesions. No tubercle bacilli were found, but the pulverized crystalline sediment proved to be pathogenic when injected into guinea-pigs. The soluble cholesterol of the exudates was much increased and both patients had hypercholesterinaemia. Repeated paracentesis was required in both cases, followed by irrigation with chlorine water.

140. Post-anaesthetic Hypoglycaemia.

H. JOSEPHS (*Bull. Johns Hopkins Hosp.*, December, 1925, p. 376) found that after short periods of ether narcosis in a series of tonsillectomies in children a moderate degree of hypoglycaemia occurred and was accompanied by an increased excretion of acetone bodies in the urine, more than would have been the case from an equal period of starvation without anaesthesia. This hypoglycaemia was usually, though not invariably, preceded by an increase in the respiratory quotient. Josephs concludes that anaesthesia may cause an increased oxidation of carbohydrate lasting for several hours, and that this is usually accompanied by a more or less parallel hyperglycaemia. He believes that the increased carbohydrate oxidation is in part at least responsible for the hypoglycaemia which occurs twelve to eighteen hours later, and is a factor in recurrent vomiting and post-anaesthetic acidosis.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

141. Heart Failure with Normal Rhythm.

J. PARKINSON and A. E. CLARK-KENNEDY (*Quart. Journ. Med.*, January, 1926, p. 113) investigated 100 unselected cases of severe congestive heart failure with normal cardiac rhythm between the ages of 20 and 70, with 84 deaths and 48 necropsies. Only the severe form in which the patient was confined to bed with breathlessness and oedema of the legs was studied, the object being to define the type of case in which auricular fibrillation might be expected if it were going to occur at all, recognized endocarditis and heart failure in the acute infections, such as pneumonia, alone being excluded. Pathologically failure was found attributable to cardio-vascular hypertrophy (high blood pressure) in 26 cases, to cardio-vascular syphilis in 20, to chronic pulmonary disease in 19, to chronic rheumatic heart disease in 7, to acute or chronic rheumatic endocarditis in 4, to atheromatous coronary occlusion in 4, and to congenital heart disease in one. Chronic rheumatic myocarditis and the toxæmia of exophthalmic goitre are undoubted factors in the production of auricular fibrillation, and intensive treatment with digitalis may occasionally produce it. In heart failure due to acute infections of the heart itself, such as rheumatic endocarditis, infective endocarditis, and diphtheria, normal rhythm usually persists. In hyperplegia (cardio-vascular hypertrophy) it was found that the blood pressure sometimes fell to normal during cardiac failure. The authors find that fibrillation is of value in the differential diagnosis of the pathology of a case of heart failure and it may assist in assessing the relative importance of different causes in a complicated case. The average duration of life after the onset of oedema was found to be only eight months, and the prognosis in cases of failure with normal rhythm was less favourable than in a corresponding degree of failure with auricular fibrillation, being least favourable in rheumatic cases and in those secondary to chronic lung disease.

142. The Prognosis for High Blood Pressure.

R. EHSTRÖM (*Ugeskrift for Læger*, November 19th, 1925, p. 1038), as the result of a study of over 300 cases of high blood pressure, finds that the average age at which this condition begins to make itself felt by the patient is 52 years, but that before this age the high blood pressure has existed for about ten years unobserved by the patient. The average age at death of this class of patient is about 62 years; thus, from the beginning to the end of this condition there is apparently about two decades of life. Life may, however, last as long as twenty-five to forty years, and in 20 of the author's cases in which he kept in touch with the patient for ten to sixteen years the blood pressure was seldom or never below 200 mm. of mercury, although most of the patients were well and fit for work during the greater part of this time. The author insists that the patient whose high blood pressure begins at the age of 50 and lasts for twenty years or more can hardly complain that this condition has shortened his life, seeing that, at the age of 70, he has already exceeded the average expectation of life. Factors affecting the prognosis unfavourably are an early onset of the high blood pressure, the coexistence of syphilis, and disease of the kidneys. In most cases it is impossible to decide whether the disease is progressive or not, and the physician is therefore not justified in giving a grave prognosis.

143. Mumps with Visceral Complications and Death.

M. BARBATO (*Rif. Med.*, November 23rd, 1925, p. 1103) reports the case of a man, aged 53, in whom inflammation of the left testicle developed one week after the onset of an attack of mumps. Seven days later he showed signs of acute uræmia (unconsciousness, high blood pressure, anuria, cardiac weakness), which yielded to bleeding and purging, the uræmia being probably an exacerbation of a previous underlying nephritis. Later on, when the acute symptoms of uræmia had passed off, the patient developed marked sleepiness, diplopia, and paresis of the third and sixth cranial nerves, probably of central origin, and possibly due to small thrombi in the arterioles, which were already affected with arterio-sclerosis. Consciousness was unaffected, and, although lumbar puncture showed considerable pressure, there was no headache. The heart became enlarged and gradually failed. Death followed vesical and respiratory paralysis. No autopsy was made. The author thinks that the later symptoms may have been due to mumps.

144. Late Perforation in Typhoid Fever.

DARAIGNEZ (*Journ. de méd. de Bordeaux*, December 10th, 1925, p. 1086), who records a personal case, states that intestinal perforations in convalescence from typhoid fever are rare, occurring in only 30 per cent. of all typhoid perforations according to Derle and Froment. As a rule they are situated at the lower end of the small intestine, and more rarely in the appendix and caecum. There is usually only a single perforation, but sometimes multiple perforations may be found. The condition may be mistaken for acute appendicitis. There is a striking contrast between perforations in convalescence, which are ushered in by violent symptoms in apparently healthy persons, and those occurring in the acute stage of typhoid fever, when the symptoms are masked by stupor and prostration, and often consist merely in a dissociation between the pulse and temperature. The ideal treatment would be resection of the whole terminal segment of the ileum, but usually the patient's state only permits of suture of the perforation. The prognosis is very bad. The few cases of spontaneous recovery on record are open to criticism, as there was no means of verifying the lesion. Success depends on early operation. Hardly any recovery has been reported when the operation was performed more than twenty-four hours after the onset of the symptoms. Daraigne's patient was a youth aged 17, who was convalescent from a severe attack of typhoid fever which had kept him in bed two months; he had had phlebitis of the left lower limbs three weeks before the onset of the perforation. He was awakened suddenly one morning by severe pain in the right iliac region. There was no vomiting, but there was passage of faeces and flatus. When Daraigne was called to see him, four days after the onset, he made a diagnosis of acute generalized peritonitis from perforation of a typhoid ulcer. Laparotomy was performed under a local anaesthetic, and generalized peritonitis, due to a perforation, was found. The perforation was sown up and the peritoneum drained. Death occurred the next day. The necropsy showed generalized peritonitis and a second perforation 20 cm. above the first.

145. Acute Parkinsonism at the Onset of Encephalitis.

H. ESBACH (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 10th, 1925, p. 1548), who records an illustrative case, states that acute Parkinsonism is rare at the onset of epidemic encephalitis. Lhermitte and Cornil, Thomas and Jumenté have noted it in old age, and Rimband, Ronquier, and Lacambre have also observed it. The associated symptoms in these cases showed that it was connected with epidemic encephalitis. Esbach's case occurred in a man, aged 28, in whom Parkinsonism developed in a single night. The patient, who had been drowsy the previous day, woke up the following morning with so marked a contracture that he was immobilized in bed in a position of semi-flexion, his mouth half open, and the muscles of the limbs rigid. The contracture was accompanied by continual tremor of the fingers. Death, which was preceded by delirium and mental confusion, occurred five days after the onset of the Parkinsonism.

146. The Incidence of Tuberculosis.

R. DÉRÉ and F. CORDEY (*Paris méd.*, January 2nd, 1926, p. 31) have studied the incidence of tuberculosis at different ages, and conclude that there is evidence that the resistance increases from birth onwards. Thus, whereas the newly born child appears to have little or no resistance, of older children up to 5 years of age exposed to infection only 50 per cent. will develop the disease. Between the ages of 5 and 10 the proportion that become diseased falls to one-third, and from 10 to 15 years to a quarter. In the case of adults similarly exposed to infection only one in twenty develop tuberculosis. This difference in susceptibility, they add, depends upon the power, acquired with age, of reacting to the bacillus by forming localized and fibrous lesions instead of by generalized granulations, as are found in infants and savage races. The occurrence of bone and joint tuberculosis at an earlier age than pulmonary disease indicates a low resistance to the bacillus, the interval between infection and the appearance of disease having been too short to allow the development of sufficient resisting power. The authors add that allergy or the altered reaction to fresh infections and to the injection of tuberculin must have been established for some considerable time before an effective degree of immunity can be developed.

147. Chronic Nasal Diphtheria and Atrophic Rhinitis.

A. ABRAHAM (*Deut. med. Woch.*, December 18th, 1925, p. 2114) records thirteen cases of atrophic rhinitis in which true diphtheria bacilli were found in the nasal cultures; eleven were females and two males. The ages ranged from 14 to 49. All the patients had the same symptoms, which consisted in nasal discharge of several years' duration, formation of crusts, headache, anosmia, and lassitude. With the exception of one case of chronic rhinopharyngitis sicca the clinical diagnosis was atrophic rhinitis. Infection of the nasal accessory sinuses was not present in any. Two patients had chronic otitis media. Two patients had had diphtheria, and another two gave a history of diphtheria in the family. Treatment consisted in administration of 4,000 to 6,000 units of diphtheria antitoxin for three days, combined with twelve to fourteen injections of an anto-vaccino prepared from an isolated strain of diphtheria bacilli, or in most cases from other organisms associated with the diphtheria bacilli, such as *B. proteus* and *B. mucosum*. The nose was also irrigated thrice daily with a 1/4 per cent. solution of chloramine. Abraham concludes that a previous attack of acute diphtheria was the cause of the atrophic rhinitis in these cases. Similar cases had been previously recorded by Pfeiffer.

148. Acute Ascending Myelitis following Chicken-pox.

D. P. WALDMAN (*Journ. Amer. Med. Assoc.*, November 21st, 1925, p. 1612) records a fatal case of this condition in a woman aged 32. The attack of chicken-pox was mild and accompanied by only slight fever. The vesicles were chiefly on the chest and back, with only a few on the abdomen, and none on the face and extremities. Zoster was excluded by the 2-year-old son of the patient having a typical attack of varicella immediately after the subsidence of his mother's eruption. On the tenth day of disease the woman suddenly developed loss of power in the lower limbs, with rapid onset of complete anaesthesia, retention of urine and faeces, and later incontinence of faeces. Clinically the case appeared like acute myelo-malacia, with an extreme degree of softening and degeneration of the spinal cord. Sacral bedsores rapidly developed, together with severe cystitis and diarrhoea. Death, which occurred in coma after three months' illness, was preceded for several weeks by progressive weakness and pain in the back of the neck. There was no necropsy.

Surgery.

149. Myositis Ossificans.

A. GRUCA (*Annals of Surgery*, December, 1925, p. 883) points out that though the appearance of parosteal bone within muscle following trauma has been known for over two centuries, yet its etiology and pathology are not fully understood. The traumatic variety follows a single severe injury and is the most frequent type. It affects the thigh and upper arm, and one form occurs after dislocation of the elbow, commonly in the brachialis anticus muscle. The condition is also seen in gunshot wounds and after clean incised wounds. The chronic variety is met with after repeated slight injuries and is found as "rider's bone" in the adductor muscles. Myositis ossificans is also seen in muscles the seat of a metastatic abscess and around joints affected with a chronic inflammatory process. The course may be divided into three stages. In the first typical traumatic symptoms are present, and are followed by pain and impaired movement and increase in size of the mass. Finally growth stops and pain disappears and the mass is clearly shown by the x-ray picture. The condition occurs in the thigh and on the arm near to joints commonly, and is usually seen in middle life. Conservative treatment is usually the best, unless the growth interferes with function; it has a tendency to disappear without any active intervention. In some cases simple excision of the mass may be advisable. Myositis ossificans is a reparative process within the young connective tissue originated by inflammation. It is possible that there may be a special tendency, congenital or acquired, for this excessive callus formation to take place.

150. Omental Strangulation.

E. SCHWARZ (*Zentralbl. f. Chir.*, January 2nd, 1926, p. 5) records a case of omental strangulation in which the symptoms suggested acute cholecystitis. He operated upon a somewhat obese woman, aged 48, for a large right inguinal hernia, and in the sac found loops of intestine and omentum which was adherent at two points. The patient made a rapid recovery, but five weeks later she was readmitted with very severe pain in the right hypochondrium, especially in the nipple line; there was obvious rigidity of the abdominal wall, and an oval tumour, moving with respiration, could be felt. A diagnosis of acute cholecystitis was made. On opening the

peritoneum a fibrin-covered tumour as large as a child's fist was seen in the gall-bladder region. This tumour was adherent to the anterior abdominal peritoneum and to the liver, and the fibrinous envelope formed a cap over the gall bladder; its surface was mottled with yellowish-green or bluish patches. On removal of the matted omentum the subjacent gall bladder was found to be healthy. The commencing gangrene of the omental mass was due to torsion of its pedicle through ten turns. The pedicle originated beneath the transverse colon, and the adhesion of the omental tumour to the gall bladder produced the clinical symptoms of acute cholecystitis when strangulation occurred. The patient made an uninterrupted recovery. Schwarz states that more than 100 cases of torsion of pedicles of omental masses have been recorded; he remarks that it is probable that most of these cases are traceable to the return to the peritoneal cavity of damaged adherent herniated omentum. The congestion persists, rendering the omental mass hard and heavy; peristaltic action twists the pedicle, and this movement, once started, continues until strangulation ensues. The author recommends that whenever the herniated omentum appears atrophic, adherent, and congested, it should be resected rather than returned to the abdominal cavity.

151. Congenital Dislocation of the Hip.

C. A. VELO (*La Chir. degli Organi di Movimento*, December, 1925, p. 1) reports an unusual sequel to the bloodless reduction of a congenital dislocation of the hip in a girl aged 10 years. After fortnight's massage the double dislocation was reduced by the Lorenz method and put up in a fixed position. Much oedema and cyanosis, especially of the left leg, followed, so that the apparatus was removed, and eventually it was seen that paralysis of the sciatic nerve had developed, which persisted for six months, when improvement was noted, and in another month complete recovery had occurred. Paralysis of nerves has been described before as a sequel to the treatment of reduction of congenital dislocation, but it is rare, and the author gives the statistics of 113 patients (151 dislocations) treated in his hospital in recent years. Of the 113 patients 103 were female; the ages ranged from 2 to 14, and in 75 the dislocation was unilateral (46 per cent. right, 20 per cent. left). The average length of treatment was seven months, and the case reported above was the only one in which paralysis occurred. In two other cases separation of the lower epiphysis of the thigh and upper epiphysis of the tibia were noted; otherwise no accidents occurred and the results were excellent. The author refers to other accidents in association with this operation, including ecchymosis, laceration of the skin, fracture, gangrene, crural hernia, rupture of the capsule, and convulsions, but adds that as experience is gained these complications get less and less common. A bibliography of some forty references to recent literature is appended.

152. Dilatation of Stenson's Duct.

T. BARSONY (*Klin. Woch.*, December 24th, 1925, p. 2500) reports the case of a man aged 70, with two years' history of recurrent swelling of the left parotid gland after eating. The opening of Stenson's duct was patent, and a probe was found to be freely movable in it. Pressure on the parotid swelling produced abundant saliva with some flakes of pus. A parotid calculus was suspected, but skiagrams were negative. A 20 per cent. potassium iodide solution was injected into the duct and skiagrams showed a widely dilated duct, extending into the gland, the filled duct being as large as the little finger. The author is unable to find a similar case in the literature, and attributes the condition to muscular weakness of the walls of the duct; he thinks it is comparable with idiopathic dilatation elsewhere in the alimentary tract. He suggests that the condition would be diagnosed more often if lipiodol was injected before examining Stenson's duct radiologically.

153. Gastric Acidity after Gastro-enterostomy.

K. NICOLAYSEN (*Norsk Mag. f. Laegevid.*, December, 1925, p. 1328) investigated the gastric acidity of fifteen patients who had been operated on for gastric ulcer, with the following results. The majority of those who had been cured after an operation several years previously were without free hydrochloric acid, whereas all those who had not been cured showed free hydrochloric acid in the stomach contents after Ewald's test meal. X-ray examination showed that an empty condition of the antrum pylori was associated with an absence of free hydrochloric acid, whereas filling of the antrum was accompanied by persistence of acidity. Nicolaysen's conclusions are as follows: (1) With few exceptions the effect of gastro-enterostomy is proportional to its power to reduce acidity. (2) Diminution of acidity is due partly to decreased secretion and partly to neutralization. (3) Decreased secretion generally coincides with rapid emptying of the stomach and depends among other causes on non-filling of the antrum pylori.

Recurrent Peptic Ulcer.

154. P. RIESS (*Zentralbl. f. Chir.*, December 12th, 1925, p. 2818) observes that in recurrent peptic ulcer there must be considered: hyperacidity of the gastric juice, pyloric spasm, and a neurotic temperament. The relative importance of these three factors is variable, and one or more may be absent. Riess describes the case of a man, aged 27, who was admitted to hospital with a perforated pyloric ulcer which had penetrated the pancreas. The ulcer was excised and an anterior gastro-enterostomy performed, but two and a half months later a second ulcer had perforated. The site of the gastro-enterostomy was normal, but the perforated ulcer was found in the distal loop immediately below the site of the gastro-enterostomy; this portion of bowel was resected. Six months later the patient was readmitted for a third perforation: the ulcer was as large as a pea and was found in the anterior surface of the proximal loop. The site of the former gastro-enterostomy was resected with the neighbouring portion of the stomach wall, and a fresh anterior gastro-enterostomy was performed. The excised portion contained two ulcers, a large perforated ulcer on the anterior surface of the proximal loop and a small shallow ulcer on the anterior surface of the distal loop. Two years later another perforated ulcer was found at an operation.

155. Pulmonary Carcinoma simulating Lung Abscess.

KRAMPF (*Deut. Zeit. f. Chir.*, December, 1925, p. 128), who records three illustrative cases, remarks that pulmonary cancer may assume a variety of forms according to its localization and extent. Thus carcinoma arising from a bronchus is characterized by the early development of a troublesome cough with occasional haemorrhage, whereas the less frequent solid carcinoma developing in the substance of the lung may remain latent for a long time. Cachexia, which is usually present in the subjects of cancer, is always absent at first, because the absorption of the toxic products of the tumour is much less in the lung than in the gastro-intestinal tract. Solid tumours in the substance of the lung usually do not make themselves apparent until they come into relation with the bronchial tree and thereby with the exterior. The tumour then rapidly undergoes necrosis, and portions of it are expectorated, the sputum being at first mucoid, later purulent, and occasionally haemorrhagic. An abscess cavity thus develops and increases in size as the necrosis continues. The process is usually accompanied by a rise of temperature and the growth gives rise to pneumonic changes in its neighbourhood. In the diagnosis of pulmonary cancer from pulmonary abscess most importance is to be attached to examination of the sputum, though it is only by good luck that tumour cells can be discovered in it. The opening of a doubtful abscess cavity may clear up the condition. After evacuation of a true abscess the lung can be seen, whereas the walls of a cavity caused by a tumour present a characteristic appearance due to the presence of necrotic tissue.

156. Congenital Dislocation of the Patella.

R. ZANOLI (*La Chir. degli Organi di Movimento*, December, 1925, p. 83) describes 13 cases of this rather rare affection, with numerous photographs and radiograms. He classifies the cases in two groups—permanent and habitual. Of his 13 cases, 10 occurred in females, but this was rather exceptional; as of 152 cases collected from various sources there was not much difference in the sexes. The condition is often hereditary and familial and frequently associated with other congenital deformities. The author discusses some of the more probable theories of pathogenesis—such as the presence of genu valgum, atrophy of the external condyle, flattening of the trochlear groove, small size of the patella, and arrested development. Most of these conditions he believes are effects rather than causes; he thinks the efficient cause is anomalous orientation of the bony parts of the knee, and especially external rotation of the tibia with slight internal torsion of the lower epiphysis of the femur. The fact that some cases are cured by operation without remedying the torsion he explains by the altered direction of the muscular pull. Incidentally he refers to recent views as to the morphological significance of the patella, which is not now looked upon as merely a sesamoid bone but as a regression of a primitive bone of which the proximal part remains as the patella, the distal as the os trigonum of Bardeleben, while the middle part has disappeared. The treatment is purely surgical and various operations are described. Zanoli prefers median transplantation of the patella tendon combined with capsulorrhaphy. The results are very satisfactory, and photographs are given of patients from three to sixteen years after operation. A bibliography of sixty references is added.

Therapeutics.

Treatment of Pulmonary Gangrene.

157. G. CAUSSADE and A. TARDIEU (*Bull. Soc. de Thér.*, November, 1925, p. 228), who record twelve illustrative cases illustrating the various methods of treatment of pulmonary gangrene, come to the following conclusions: (1) Serum treatment, and Weinberg's antigangrene serum in particular, gives only very inconstant results. None of the cases so treated showed an undoubted or permanent improvement. In his recent thesis Briault has come to the conclusion that antigangrene serum is not specific, and has shown that while temporary improvement is frequent a permanent cure is rare, only one such example, reported by Lemierre, being on record. (2) Arsenical treatment, advocated by Perrin of Nancy, also proved a failure in the authors' hands. Vincent's fusospirochill symbiosis is only transient in pulmonary gangrene, so that the indications for this mode of treatment are very restricted. (3) Auto-vaccines proved quite useless. (4) Tincture of garlic showed only a slight antiseptic action when given by the mouth. (5) Repeated intratracheal injections of gomecol oil in progressive strengths of 5 to 10 per cent. may produce slow but steady improvement. (6) Artificial pneumothorax is often difficult if not impossible owing to the early formation of pleural adhesions. Though it has been successful when employed at an early stage by Dinarest and Bonafé and Amévil and Tellesse, the present authors never derived any benefit from it. (7) The formation of a tracheal fistula deserves to figure in the therapeutics of pulmonary gangrene, as its indications, though limited, are real. (8) Intrapulmonary injection of drugs in oily suspension is valuable when other methods fail. (9) Surgical intervention is only rarely indicated. Death often occurs very rapidly after operation. (10) Phrenicotomy is chiefly indicated in bronchial dilatation. In the authors' experience it produced only a very temporary improvement.

Insulin Treatment.

158. L. HERTOGHE (*Le Scalpel*, January 9th, 1926, p. 25) remarks that though the value of insulin treatment remains indisputable, yet the difficulties associated with its administration are more obvious now than was the case hitherto, and its field of utility has diminished. Thus, apart from renal glycosuria, there are cases of pancreatic diabetes in which degeneration of the islands of Langerhans has gone so far that insulin treatment is ineffective. Again, a hyperglycaemia which is yielding to insulin may be complicated by the presence of renal glycosuria, which is resistant. Difficulty in assessing the value of insulin is caused by its cumulative action, which results in there being considerable delay after a course of treatment before the patient feels the full benefit or begins to relapse. The symptoms of developing hypoglycaemia Hertoghe puts in the following chronological order: first, disquiet and nervousness; then pallor, tachycardia, and sweating; and lastly, syncope, convulsions, and coma. He adds that there is no risk involved in the prophylactic use of sugar, and great care should be taken that this safeguard is available. The author recommends that a hypodermic syringe should be kept ready for injecting carbohydrate in an emergency.

159. Protein Therapy in Diabetes Mellitus.

G. SINGER (*Wien. Klin. Woch.*, January, 1926, p. 28) reports further cases of diabetes treated by protein shock. During the last two years 92 cases were treated, with the following results: considerably improved 51, improved 22, not improved 17, made worse 2. The first criterion of improvement was the increase in sugar tolerance. In one case before treatment started the ingestion of 60 grams of white bread produced 18 grams of sugar in the urine. After treatment, 180 grams of white bread were ingested without glycosuria. The second criterion was the duration of improvement; this had persisted for twelve to twenty-two months. The author found that skin complications, such as furunculosis and gangrene, were particularly favourably influenced. The patient is placed upon a low carbohydrate diet of sufficient calories, and is given 0.5 gram novoprotein as an initial dose. The dose is increased by 25 to 50 per cent. each time, and injections are given every other day at the commencement, later every fourth day. As the glycosuria diminishes or disappears carbohydrates are added to the diet. The author attributes the improvement to a better metabolism of sugar. In conjunction with A. Fischer he conducted experiments on dogs with phloridzin glycosuria, which when treated by protein shock therapy showed a marked decrease in the nitrogen-sugar ratio in the urine. The author considers this method an improvement on insulin treatment because of its simplicity and the lasting improvement.

160. The Therapeutic Use of Infra-red Rays.

C. BENOIT (*Revue d'Actinother.*, October-December, 1925, p. 61) states that the infra-red rays which immediately succeed the red or red-black rays in the spectrum have a much greater power to penetrate the tissues than the ultra-violet rays, their penetration being 1 to 3 cm., and even more when the irradiation can be prolonged. The penetration diminishes as the wave-length increases. The tissues show a varying degree of permeability by the infra-red rays. After the skin the muscular tissue is most readily permeated, and then the cellular tissue, aponeuroses, and bones. Blood, on the other hand, absorbs and arrests the rays. Serous membranes which contain a certain quantity of fluid, and especially morbid effusions, show considerable resistance to the rays. The penetration of the rays varies with the sensitiveness of the subject under treatment, some tolerating the sensation of heat better than others. Infra-red rays give rise to intense hyperaemia with redness of the skin in the zone irradiated. The redness is sometimes uniform, but may present dark streaks on a lighter background. The redness persists for a long time, as a rule two to three hours, and sometimes eight to ten hours, and then progressively fades, the darkest streaks being the last to disappear. The local temperature after cessation of the irradiation sometimes remains high for as long as two hours. Infra-red rays have an important action on the blood vessels and their contents, causing marked vaso-dilatation, a progressive increase in the number of red corpuscles, a marked diminution of the leucocytes, and an increase in the temperature of the plasma. Lastly, they exercise a remarkable analgesic effect, which is due partly to the hyperaemia and vaso-dilatation accompanying the irradiation and partly to the action of the radiations on the nerve endings in the dermis.

161. Dietetic Treatment of Gastric Ulcer.

A. J. JAROTZKY (*Therap. Gazette*, December 15th, 1925, p. 837) discusses the dietetic treatment of ulcer of the stomach and advocates a diet limited to white of egg in the morning and butter in the evening as giving the most perfect rest to that organ. The uncooked white of one egg, without salt and not beaten up, is swallowed in the morning and three-quarters of an ounce of unsalted fresh cream butter in the evening. On each of the following days the number of eggs is increased by one and the amount of butter by three-quarters of an ounce until eight eggs and six ounces of butter are being given; no other food, drink, ice, or medicine is allowed by the month. By the limitation of drinking the secretion of gastric juice is delayed and the deficiency of water in the organism can be overcome by the rectal administration of water and sugar. By such means the disadvantages of the milk treatment are obviated and the closure of the pylorus which occurs as soon as milk or yolk of egg reaches the duodenum is avoided. The time of retention of food in the stomach is thus reduced to a minimum and the stomach remains contracted instead of distended. Jarotzky claims that this method alleviates pain quickly and that the feeling of epigastric distension is soon abolished. Such a diet, he adds, can be given with advantage even in the presence of haemorrhage, and there is no need for it to be preceded by a period of starvation.

162. The Gold Treatment of Surgical Tuberculosis.

SIEDAMGROTZKY (*Zentralbl. f. Chir.*, No. 47, November 21st, 1925, p. 2642) has employed two German substitutes for sanocrysin—krysolgan and triphal; the gold content of both of the German preparations is similar. The largest single dose employed was 40 c.cm. of a 1 per cent. solution (0.04 gram of the solid gold preparation); this dilute solution had no injurious effect on the kidneys. Siedamgrotzky gives the results of treatment in 26 cases of various forms of surgical tuberculosis. In 6 cases the treatment was ineffectual; 15 patients improved under treatment; and 5 patients, with tuberculosis of the bones or joints, were cured. He used a 1 per cent. solution of the gold preparation in normal saline solution, and as the injection might be very painful infiltration anaesthesia was induced prior to injection. A very fine needle was used. In children the author did not administer more than 40 c.cm. as an initial dose, nor more than 10 to 20 c.cm. at subsequent injections, which were repeated at intervals of fourteen days.

163. Osmotic Therapy in Glaucoma.

W. S. DUKE-ELDER (*Brit. Journ. Ophthalmol.*, January, 1926, p. 30) describes four cases of acute glaucoma treated by intravenous injection of a 30 per cent. solution of sodium chloride. The dose was calculated as 1 c.cm. per kilo body weight and the average adult dose was about 50 c.cm. of this solution. The fluid was injected slowly and evenly for a period of ten minutes, with the patient recumbent so as to obviate any danger from the sudden drop in blood pressure

which occurred. The general dehydration of the tissues which followed appeared to cause little discomfort and was easily combated by free administration of fluids by mouth. The effect of this treatment was to reduce speedily and effectively the tension of the eye. The effect was not permanent and the tension tended to rise again in the course of the next twenty-four hours. Duke-Elder, however, considers it a very useful method of tiding over the emergency of an acute glaucoma.

Neurology and Psychology.

164. Mental Changes in Encephalitis Lethargica.

G. A. AUDEN (*Journ. Mental Sci.*, October, 1925, p. 647), discussing the psychological implications of encephalitis lethargica, points out that while its acute stages may be so indefinite as to render a diagnosis not always possible, the later manifestations are so constant that they form a syndrome which is characteristic of a distinct morbid entity. Limiting his observations to children between 5 and 15 years of age, attention is called to the frequency with which moral changes and failure of adjustment to their social environment supervene together with outbreaks of spitefulness and disobedience, noisy excitability at night, destruction of clothes, and frequent tics and habit spasms. Experience in juvenile delinquency points to the basic causal factor in many of these cases being a suppression of discrimination and intelligent self-control, so that it seems reasonable to conclude that the lesions in encephalitis lead to a reduction of such control comparable by analogy with the geological process of denudation whereby younger sedimentary rocks become removed by various physical actions laying bare the ancient primitive rocks upon which they had been deposited. Such changes in behaviour following an attack of encephalitis can be explained as regressions similar to those which sometimes follow other acute infections and disease or injury to the brain. If this explanation is correct little or no deterrent effect can be expected from punishment, which rather may produce disastrous results by the fixation of an antisocial attitude; commitment to reformatories is therefore deprecated. Auden maintains that one of the most pressing needs of the time is the establishment of special institutions in which, by a simple regulated life, these patients could regain self-control without being handicapped by the stigma of judicial proceedings.

165. Etiology of Dementia Praecox.

S. KURE and M. SHIMODA (*Journ. Nerv. and Mental Dis.*, December, 1925, p. 597) give the statistical results of an investigation of the various conditions which might have affected the brain before the onset of dementia praecox. In 47.2 per cent. of the cases there was evidence of heredity being a definite factor, and though different signs have been given by other observers all agree that this factor is traceable in a large percentage of dementia praecox patients. The present authors found that 46.2 per cent. of the patients had parents who were addicted to alcoholism; this contrasts with the percentages of 20, 25, and 26 of other observers. There was a previous history of convulsions in childhood in 8.4 per cent., while histories of trauma, poor development, and disease were obtained in a large number of cases. Poor intellectual development characterized 21.9 per cent., and 15 per cent. showed significant physical abnormalities. The authors conclude that at least 80 per cent. of the patients were abnormal prior to the onset of dementia praecox, which would appear to exclude coincidence.

166. The Plantar Lines in Mental Defectives.

T. BRUSHFIELD (*Brit. Journ. Child. Dis.*, October-December, 1925, p. 274) remarks that though the hands of mental defectives have been studied and their various characteristics described, especially in mongols, no similar description of the foot and its markings is available. In a study of the foot in the mongol and other varieties of mental defectives, of whom 618 in all were examined, Brushfield noted the following lines: *Crease lines*—(1) transverse, caused by flexion; (2) longitudinal, caused by the movement of bringing all the toes together; (3) a delicate network of lines. *Plantar lines or folds*—namely, the oblique plantar line, the transverse plantar line, and the transverse hallucal line. The oblique plantar line, which is an almost constant feature of the mongol, commences in the cleft between the first and second toes and runs obliquely outwards to end about the ball of the big toe. From this point the transverse plantar line and transverse hallucal line run outwards and inwards respectively to the outer and inner borders of the foot. In addition to the oblique plantar line a characteristic feature of the foot in the mongol is a wide gap between the first and second toes. In normal children, as was found by

examination of over a hundred cases, these lines are all rudimentary, and generally become obliterated after the third to the fifth year, whereas in mental defectives they persist up to the fourteenth year. Brushfield maintains that owing to the constancy and persistence of these lines in mental defectives they should always be looked for and their presence regarded as a stigma.

Obstetrics and Gynaecology.

167. Full-Term Ectopic Gestation.

J. M. H. ROWLAND (*Surg., Gynecol. and Obstet.*, January, 1926, p. 50) reports a case of extrauterine pregnancy which went to full term, and resulted in a living child. The diagnosis was made by a vaginal examination after the patient had been reported to have been in labour for two days, the head of the child being discovered in the pelvis, but not in the vagina. At the operation the placenta was found attached to the posterior surface of the uterus and the broad ligaments, some small extensions being fixed to the mesentery and folds of the small intestine by light adhesions. A well developed normal child, weighing 8½ lb., was delivered, and the patient made a good recovery, the only complication being a slight infection of the operation wound. Rowland believes that the development of the head must have been entirely in the pelvis in this case; the uterus had been completely displaced from the pelvis. The placenta, apart from a few small extensions, was an almost exact quadrilateral mass. Rowland adds that the case illustrates the importance of a very careful supervision of pregnant women and consideration for a history of irregular haemorrhage early in pregnancy. Pelvic examination at any time before labour would in this case have disclosed the absence of the cervix.

168. L. HERTZENBERG (*South African Med. Record*, December 26th, 1925, p. 560) describes a case in which an extrauterine pregnancy went to full term, the dead foetus being removed by operation from the abdominal cavity. He concludes that the extrauterine pregnancy had ruptured, but the ovum had survived and continued to live in the abdominal cavity up to full term, when spurious labour set in. The woman made a good recovery.

169. Insulin and Pregnancy Glycosuria.

H. ELIAS, J. GÜDEMANN, and R. ROUBITSCHKE (*Wien. Arch. f. inn. Med.*, November 1st, 1925, p. 567) state that hitherto two views have been held as to the pathogenesis of glycosuria in pregnancy. According to the first view, which is maintained by Porges, Novak and Strisower, Frank, Frank and Notbmann, Notbmann, Guggisberg, Roubitschek and others, it is mainly due to a greater permeability than usual of the kidneys, with relatively slight increase in the blood sugar. Others, such as Rosenberg, Umher, Lepinc, Hofbauer, von Noorden, and A. Gottschalk, hold that there is an hepatic insufficiency which causes a disturbance of carbohydrate metabolism, so that the liver is unable to store up as glycogen the sugar which has been brought to it. The present authors carried out an investigation on women in the third and fourth months of pregnancy and came to the following conclusions: (1) Small doses of insulin often increase the normal blood sugar. (2) After intravenous injection of sugar the blood sugar increases in the same degree in the normal and the pregnant woman. An intermediate factor in the form of damage to the liver could not be demonstrated to account for the glycosuria of pregnancy. (3) After injection of insulin the raised blood sugar level in pregnancy and menstruation sinks less than in normal subjects.

170. Surgical Treatment of Contracted Pelvis.

C. VERCESI (*Ann. di Ostet. e Ginecol.*, November 30th, 1925, p. 764) states that Costa's operation for contracted pelvis has now been performed about sixty times by Italian surgeons. The whole thickness of the symphysis pubis, including periosteum, cartilage, and ligaments, is now removed between the pubic spines and reaching from 1 to 1.5 cm. below the upper margin of the symphysis. The permanence of the consequent enlargement of the pelvic brim has been demonstrated radiographically and otherwise; there has been no maternal mortality, and difficulty in walking followed in one case only. Summaries are given of 16 cases operated on before and 42 during labour. Death of the foetus during or shortly after birth occurred in 11 instances. With regard to the scope of the operation, which has been almost entirely restricted to the flat type of pelvis, Vercesi is unwilling to define the precise arithmetical limits of the conjugata vera which are suitable or unsuitable. Each case demands separate consideration, especially with regard to the age, obstetric history, condition of the soft parts, and probable or ascertained foetal

dimensions. In general, he concludes, Costa's operation may be expected to give entirely favourable results with a conjugate not less than 83 mm.; with a conjugate of 83 to 80 mm. the operation is still definitely useful, especially if delivery is subsequently accelerated by forceps or version. With conjugates of 80 to 75 mm. Caesarean section is in general preferable, but may well be followed by Costa's operation in order to facilitate delivery in subsequent labours. In comparison with symphysiotomy or pubiotomy the operation, besides giving permanent pelvic enlargement, is easy, safe, and unattended with inconvenient sequelae. The alternative method of enlarging the bony pelvis consists in resection of the sacro-vertebral promontory, as suggested by Rotter in 1912, employed shortly afterwards by Schmid, and practised later by Mangiagalli: this demands a true conjugate exceeding 75 mm., and except as a complement to Caesarean section is inapplicable to cases in labour. Vercesi records two additional cases in which this operation has been successfully performed, giving rise to enlargements of the conjugate of 6 and 11 mm. respectively. He mentions that Fossati has twice seen spontaneous delivery follow an old operation of this nature.

171.

X Rays in Obstetrics.

R. MITCHELL and M. R. MACCHARLES (*Canadian Med. Assoc. Journ.*, November, 1925, p. 1202) discuss the value of x rays in the practice of obstetrics. They state that while numerous observers have found it possible to produce changes in the embryo by means of long exposures to the x rays, yet the momentary exposure necessary for the production of a radiogram is probably harmless, and the present authors have never had a single case of physical or mental maldevelopment result. They point out that x rays can be of great assistance in examining the general conformation of the pelvis. During pregnancy they have found the rays to be of greatest assistance after mid-term, which is usually the earliest time when the foetal skeleton can be distinguished. The position of the foetus and its presenting part can be determined, and a twin pregnancy be recognized. X rays can also be used in cases of illegitimate pregnancy or pseudocyesis. Foetal abnormalities, such as hydrocephalus and spina bifida, or death, can also be diagnosed by this means, and trouble in delivery may be avoided by perforation if necessary. After delivery x rays can be used to demonstrate injuries to the pelvis of the mother, or fractures and dextrocardia in the child. For the purpose of radiography the authors place the patient in the prone position with the chest and thighs supported; the factors used are 10 milliamperes current, 87 kilovolts, and 15 seconds exposure through a Bucky diaphragm.

172. Conservation of Menstruation after Hysterectomy.

ROUFFART-THIRIAU (*Bruxelles-Médical*, January 3rd, 1926, p. 316) discusses the value of the uterine transplantation of an ovary in preserving menstruation and a limited degree of fertility after double salpingectomy and states that the mortality of the procedure is negligible. Subsequent pregnancy may, he finds, be expected in up to 10 per cent. of cases, but more than one subsequent pregnancy has not been reported. Persistence of menstruation was observed in 26 out of 27 patients; in the one exception it was only possible to transplant a very small piece of ovarian tissue. Ten women complained later of pains in the side, and three of them were operated on again, when the implanted ovarian tissue was found to have become cystic. Four became pregnant, two aborted at the third or fourth month, and the other two gave birth to healthy children. One of Tuffier's cases developed acute intestinal obstruction after the lapse of nine months, and at a spot remote from the former pelvic operation. Hysterectomy was performed and histological examination of the implanted tissue showed that ovulation had occurred. The author thinks that the number of subsequent pregnancies would have been higher had more of the patients desired offspring.

173.

Tubal Insufflation in Sterility.

R. POLLART (*Bruxelles-Médical*, January 10th, 1926, p. 353), discussing the value of tubal inflation in the differential diagnosis of sterility and certain types of dysmenorrhoea, prefers filtered air to the more usual carbon dioxide. He finds that after injection of 100 c.cm. or more into the uterus and the peritoneum there is no reaction and the air is absorbed quickly. Careful preliminary examination of the pelvic organs is necessary in order to avoid the danger of forcing infective material into the peritoneum. When the tubes are normally patent air passes into them at a pressure of 80 to 100 mm. of mercury, but should the pressure rise to 200 mm. it is certain that the tubes are impermeable. It is possible to determine in some cases that one tube is patent and the other closed. The patients tolerated the procedure well as a rule, but some complained of abdominal pain for

two or three hours subsequently; these patients usually had impermeable tubes. Pollart gives details of its use in 22 patients, of whom only 3 had previously borne children; impermeable tubes were found in 16 cases. Of the other 6 patients one, previously nulliparous, became pregnant a few months later, and another, who had had one child, also became pregnant after insufflation. Although the remaining four patients had no tubal obstruction their sterility persisted.

Pathology.

174. Chemical Changes in the Intestine.

N. J. NOVELLO, W. WOLF, and C. P. SHERWIN (*Amer. Journ. Med. Sci.*, December, 1925, p. 888) have investigated the chemical defence of the animal and human body against the products formed in the process of intestinal putrefaction. They find that as a rule there is an initial effort to oxidize completely such products and if this is not successful an attempt at reduction follows. Should both fail the organism tries to attach the toxic substance to a compound or radiolo which will decrease the toxicity and increase the solubility, thus making possible the rapid elimination of the resulting compound in the urine. The authors believe that the products of intestinal putrefaction are much less toxic than has been generally thought and that some of these substances are harmless. The putrefactive products usually formed are indol, skatol, phenol, imidazol, and imidazol acetic acid. The authors fed individuals on these substances under experimental conditions, and their urines were examined at twenty-four hour intervals. Skatol was found to be slightly more toxic than indol, 0.1 gram producing a feeling of nausea but no vomiting, loss of appetite, belching, and a dull headache which lasted for at least twelve hours after the dose. Phenol caused no untoward effects. Imidazol compounds produced an increase in the pulse rate of 10 to 20 a minute. The authors consider that glycuronic acid serves only in a minor capacity as a detoxicating agent for indol and is apparently used only after the sulphate supply has been nearly exhausted. The greater part of the indol is excreted uncombined. They find Jolles's test superior to that of Obermayer for the estimation of indican. They state that skatol is mainly detoxicated by union with sulphuric acid, very little being excreted unchanged or in combination with glycuronic acid. Phenol is also detoxicated chiefly by sulphuric acid, which seems to be derived not only endogenously but also exogenously from cystine, so that the percentage of phenol excreted in this way is dependent on the amount of cystine in the diet, and, therefore, the amount of ethereal sulphate excreted is no indication of the amount of phenol present. Imidazol and imidazol acetic acid appear to be split into uric acid, urea, and ammonia.

175. Spirochaetal Infections in Vienna Rats.

I. TAKAKI (*Wien. klin. Woch.*, November 12th, 1925, p. 1231), of the State Serotherapeutic Institute at Vienna, states that the *Spirochaeta icterohaemorrhagiae* has been found in rats in most of the large towns in all countries. In Germany, for instance, Uhlenhuth and Zuelzer found it in 10 to 50 per cent. of the rats, while Noguchi in Quajaguil found an incidence of 67 per cent., and Smillie in Sao Paulo one of 75 per cent. In three out of eight healthy rats examined in Vienna Takaki found the *Spirochaeta icterohaemorrhagiae*. Spirochaetosis icterohaemorrhagica was successfully transmitted to healthy guinea-pigs by inoculation of the organs of the infected rats, and the spirochaete was demonstrated in the blood and organs of the inoculated guinea-pigs by dark-field illumination and Giemsa's stain. In another case after inoculation of the blood of a healthy rat into mice it was possible to find the *Spirochaeta morsus muris*, or organism of rat-bite fever, in the blood of the inoculated animals. It is therefore obvious that rats in Vienna, as in other countries, may be carriers of spirachetosis icterohaemorrhagica and rat-bite fever. Systematic measures for the destruction of rats are, therefore, required in Austria, and especially in Vienna, such as have been taken in other countries, including Great Britain and Denmark.

176. Stages in the Development of the Tubercle Bacillus.

F. BEZANÇON and A. PHILBERT (*Presse Méd.*, January 9th, 1926, p. 33), from a study of the structure of growing colonies of the tubercle bacillus, have come to the following conclusions as to the development of this organism. The surface membrane which is formed on liquid media was fixed in alcohol, embedded in paraffin, and cut into thin sections, which were stained either by Ziehl-Neelsen or by Fontès's method with Gram's stain, fuchsin, and methylene blue. Examination of these sections showed that the greater part of the membrane consisted of a network formed of fibrils arranged parallel to

the surface; they did not show true branching, and they were decolorized. For this reason they call it the cyanophilic substance. On the under surface of the membrane a variable number of acid-fast bacilli were seen lying parallel to the fibrils of the network; on the upper or free surface, and in that part of the membrane which extended up on to the walls of the flask, there were none to be seen. In some of the bacilli there were granules, similar to those described by Babès, which took on the Gram stain with great avidity; for this reason the authors call them the chromophilic corpuscles. The granules were not confined to the bacilli; they could often be seen lying free in the cyanophilic network, disposed in long rows. Examination of cultures of different ages showed that in very young membranes there was nothing but cyanophilic substance. After sixteen to twenty-five days acid-fast bacilli appeared containing chromophilic granules. In a culture aged sixty days the bacilli were few in number, but there were numerous granules lying mostly in the network. Finally, after two hundred days there were practically no bacilli; the cyanophilic membrane had lost its striation and was riddled with granules. From this they deduce that in the course of growth non-acid-fast filaments are first formed; these are transformed later, partly into acid-fast bacilli, which are finally replaced by chromophilic granules. The acid-fast bacilli appear to be only one stage in the life-history of the tubercle bacillus. The observations afford some explanation of the well known fact that acid-fast bacilli are often hard to find in tissue sections, and of the recent reports that tuberculous pus which has been filtered through a Berkefeld candle may yet be infective to guinea-pigs.

177. Action of Ultra-violet Light on Tissue Cultures in Vitro.

S. KIER (*C. R. Soc. de Biologie*, December 4th, 1925, p. 1389) exposed a pure culture of connective tissue *in vitro* to the action of ultra-violet light. The culture was placed in a water-bath at a temperature of 38°C., and was separated from the source of light—a Kromayer lamp—by 3 cm. of water, a quartz square, and 3 cm. of air, to exclude the heat rays. Exposure of a twenty-four hour culture for five minutes did not affect the subsequent growth of the tissue, but an exposure of eight minutes decreased the rate of growth during the next twenty-four hours; on subculture after this period the tissue grew normally. An exposure of one hour retarded the growth in such a way that the tissue did not recover its original rate of proliferation till after two or three subcultures had been made. Finally an exposure of two to three hours definitely killed the fibroblasts. It was expected that a very small dose might actually stimulate the growth, but this was never observed, even with exposures of 0.5 second. From these experiments it appears that the action of the ultra-violet rays is to injure the cells; the lethal dose is about ten to fifteen times the inhibitory dose. In another paper (*ibid.*, p. 1391) the author describes the use of embryonic chick heart. With this tissue he found that a small exposure of fifteen seconds to two minutes increased the rate of contraction. After a short lag period the heart cells began to beat faster; return to the normal rate occurred in three to twenty minutes. To show that this accelerating action was due to the ultra-violet rays themselves, he replaced the quartz square by a piece of glass which would filter off the rays; exposure under these conditions was without effect. Further, by covering the tissue with China ink, he found that the rays had no effect, showing that the action was not due to the production of a change in the surrounding medium. It may be concluded that the accelerating action of the rays on heart muscle is the result of the ultra-violet light itself.

178. Glycaemia in the Newborn.

L. AURICCHIO (*La Pediatria*, December 1st, 1925, p. 1274) examined the blood sugar in 18 normal newborn children aged from 1 to 10 days, investigating the alimentary glycaemia in 10 and the adrenalinic glycaemia in 8. The alimentary glycaemia was tested by giving the infant a gram of glucose per kilo of body weight in 10 c.cm. of distilled water, and the adrenalinic glycaemia by intramuscular injection of 0.2 per cent. of 1 in 1,000 adrenalinic solution. The results were as follows: The newborn child even before it has received its first feed has a glycaemia almost equal to that of the adult. Ingestion of glucose produced an increase in the amount of glycaemia, which became appreciable in fifteen minutes, and reached its maximum in half an hour, and then diminished. Two hours later the glycaemia had returned to its original level. The maximum increase was from 50 to 100 per cent. Injection of adrenalinic was followed by a marked and prolonged increase of glycaemia. Fifteen minutes after injection the initial value was doubled, and it was not until two hours later that the glycaemia began to diminish. These findings show that in the normal child the regulation of glycogen starts at birth.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

179. Tuberculous Peritonitis in Children.

C. GIAUME (*La Pédatrie*, January 1st, 1926, p. 1) has investigated 450 cases of tuberculous peritonitis in children. He found the disease most common between the ages of 4 and 6 and relatively rare in infancy; 60 per cent. of his patients were boys, and the disease mostly started in the earlier months of the year, rarely in the summer. It was usually associated with other tuberculous manifestations, and the infection seemed to be traceable to the circulation or to primary tracheo-bronchial tuberculosis. A family history of tuberculosis could be traced in 40 per cent. of the infantile cases and in 16 per cent. of the older children. The importance of measles and whooping-cough as predisposing causes was clearly shown, even allowing for the great prevalence of these diseases. Giaume finds that in diagnosis the von Pirquet reaction is helpful, though it was negative in 32 per cent. of the children under 1 year and in 25 per cent. of the older children. In early infancy the symptoms are often obscure, the course more rapid, and the prognosis worse; in many cases ascites was the only symptom. The ascitic type was present in about 70 per cent. of children between the ages of 2 and 5, while in those under 1 the ascitic and fibrocascous forms were about equally present. In a third of the cases some other tuberculous localization was clinically demonstrable. The mortality in the ascitic type was as high as 75 per cent., but the prognosis in the ascitic forms was fairly good. Surgical treatment of the ascitic form is now reserved for prolonged and obstinate cases. Heliotherapy and tuberculin therapy have given good results, but the former is contraindicated in rapidly progressive cases with high fever. The author refers to the pseudo-ascites due to collections of intestinal fluids in loops of bowel.

180. Recrudescence of Encephalitis in the Parkinsonian Stage.

J. FROMENT and P. DELORE (*Lyon méd.*, December 20th, 1925, p. 753) record the case of a woman who, two years after the onset of Parkinsonism and seven years after the onset of encephalitis, developed a fresh attack of somnolence and fever. The amount of sugar in the cerebro-spinal fluid during this stage rose from 0.65 to 0.85 gram per 1,000. There was a considerable increase of rigidity. Injections of nrotropine, which had been employed in the primary attack, were resumed, with the result that the fever and somnolence disappeared and the rigidity became less pronounced. This case may be compared with that previously reported by Guillaïn, Alajouanine, and Célèce, illustrating the contagiousness of epidemic encephalitis in the Parkinsonian stage. The present authors conclude that epidemic encephalitis, which is a chronic disease, should be subjected to a prolonged treatment, and that nrotropine, which in the absence of a specific remedy is a really active drug, should be administered for several years with short interruptions.

181. Relapsing Cerebro-spinal Fever.

C. ZOELLER (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, November 26th, 1925, p. 1473) records a case of cerebro-spinal fever in a young sailor in whom the disease ran its course in three successive stages. The first, in which the symptoms assumed the form of a meningeal reaction, lasted a week, the cerebro-spinal fluid being clear and aseptic and containing only a few lymphocytes, a slight and transient excess of albumin, and sugar not below 0.62 per litre. After an interval of twenty days the disease recurred, the cerebro-spinal fluid now containing numerous leucocytes and a few diplococci. In each of these two stages signs of general infection were present in the form of herpes facialis and purpura in the first stage and of herpes facialis alone in the second stage, without it being possible to find meningococci in the blood. The lowest amount of sugar in the second stage was 0.56 gram per litre. Finally, after an interval of two and a half months, a fresh attack occurred which lasted about a month and was much more severe in character. An organism was isolated from the cerebro-spinal fluid and proved to be meningococcus A. Recovery followed repeated lumbar puncture, serum treatment, and vaccine therapy. The case was therefore a typical example of relapsing cerebro-spinal fever. Zoeller states that it is not exceptional to find a clear cerebro-spinal fluid in meningococcal

meningitis, either at the onset or at an advanced stage of the disease, as has been noted by Depter and Netter and Dobré. In the first attack the meningococci were probably localized in some part of the cerebro-spinal axis or in the accessory nasal sinuses, and produced a meningeal reaction which subsided of itself. In the second stage the meningeal reaction was more violent and gave rise to a puriform effusion with a few meningococci. In the third stage there was typical meningitis with the presence and persistence of meningococci in the cerebro-spinal fluid. The changes in the cerebro-spinal sugar in the case were of interest. During the first two stages it was remarkably high, and in the last stage very irregular, ranging from 0.17 to 0.50 gram, according as the first or last cubic centimetres of the fluid withdrawn were examined. Zoeller thinks it probable that the specimens of fluid came from different parts of the cerebro-spinal axis, in some of which the inflammatory process was still active, while in others it was tending to subside.

182. Diagnosis of Congenital Syphilis.

SABOURAUD has maintained since 1917 that the "mamillary eminence," a supernumerary cusp springing from the palatine surface of the first upper molar, is an indication of hereditary syphilis if it is well developed, pointed, and separated from the tooth by a subjacent groove. E. JANÉ (*Ann. de Derm. et de Syph.*, December, 1925, p. 734), who has been working in Sabouraud's laboratory, now reports the examination of 29 patients with this dental peculiarity. In 17 cases the Wassermann reaction was positive, and in 12 other cases in which it was doubtful or negative 9 patients exhibited other stigmata of syphilis. Jané concludes, therefore, that confirmation is provided of the truth of Sabouraud's suggestion, and draws attention to the absence of variation in skeletal structures when no congenital infection, such as syphilis, is present, which produces such malformations by interference with ossification. Some of the signs attributed to congenital syphilis appear to be reversible to prehistoric ancestral types: thus the sabre-shaped tibia was normal in the Cro-Magnon race. Jané claims that the mamillary eminence is a special transformation of the tubercle of Carabelli, which is an abnormal development of the primitive enamel belt on the internal surface of the first upper molar. A fifth cusp may have existed normally on this molar in prehistoric races. Janssen has shown that the rudiment of this tubercle is recognizable in many other teeth than the first upper molar, and that it is a normal feature in lemurs, whose dentition, like that of chimpanzees, resembles most closely the human type.

Surgery.

183. Ligation of the Jugular Vein in Pyæmia.

P. RIESS (*Zentralbl. f. Chir.*, December 5th, 1925, p. 2755) describes three cases of pyæmic sinus thrombosis treated by tying the jugular vein. In a man aged 26 severe left tonsillitis was followed by diffuse cellulitis of the same side of the neck, high pyrexia, and rigors. Under ether anaesthesia the internal jugular vein was tied just above its junction with the left subclavian vein, since the tissues were so inflamed that it was impossible to isolate the internal jugular vein in the neck. The vein was then opened, the septic thrombus removed, and a rubber drainage tube was inserted. The wound healed in six weeks. In the second case, a man aged 21, severe pyæmic infection followed the removal of adenoids; there were frequent rigors and high pyrexia, with much brawny infiltration and cellulitis of the right side of the neck. The right internal jugular vein was ligatured at its deepest part. The rigors ceased immediately after the operation, but there was protracted suppuration in the wound and the patient had pyæmic abscesses in the sacral and femoral regions. He finally recovered. The third patient, aged 29, was admitted with cellulitis in the left temporal region, following a carbuncle which had been opened four weeks previously. The swelling returned three days before admission, and was accompanied by rigors and headache. The swelling was incised. The patient was very ill; he was semiconscious, with high temperature and rapid pulse, and was evidently suffering from thrombo-phlebitis. The left jugular vein was ligatured and the mastoid process was explored, but no focus of suppuration was found. The patient

had recovered completely five weeks after admission. Riess observes that the number of these patients who recover under expectant treatment is so small that early surgical intervention should be regarded as routine treatment.

184. Acute Typhoid Cholecystitis Forty-one Years after Typhoid Fever.

L. A. POMEROY and J. K. SHEN (*Amer. Journ. Med. Sci.*, December, 1925, p. 881) record the case of a man, aged 57, who had had an extremely severe attack of typhoid fever at the age of 16 complicated by intestinal haemorrhage, when he was attended by Pomeroy's father. He remained in good health for the next forty-one years, and then developed symptoms of acute cholecystitis which required operation. The gall bladder was found to be acutely inflamed, and on aspiration yielded a mixture of blood and pus. Owing to the patient's condition it was considered better to drain the gall bladder than to remove it. Cultures of the bile yielded a pure growth of *B. typhosus*, but the Widal test was negative for *B. typhosus* and *B. paratyphosus* A and B. Cultures from the stools were also negative. The authors believe that this case presents the longest interval on record between the original attack of typhoid fever and the recovery of *B. typhosus* directly from the gall bladder. When the patient was last seen, two months after the operation, the sinus still discharged slightly at intervals a fluid containing *B. typhosus*, while the stools remained negative.

185. Rectal Diverticula.

G. FANTOZZI (*Arch. Ital. di Chir.*, October, 1925, p. 418), who records an illustrative case, states that the first example of this rare condition was described in 1762 by Morgagni, who spoke of a diverticulum "somewhat smaller than a fig situated two fingerbreadths above the anus." Physick of Philadelphia in 1836 gave the name of "encysted tumours" to formations which subsequent writers called ulcers of a tuberculous, syphilitic, or dysenteric nature affecting the solitary follicles. Under the name of "saciform disease of the anus" Gibson and Gross described a dilatation of the anal region corresponding to the crypts of Morgagni. Fantozzi's patient was a woman, aged 56, who for the last two years had noticed a small round painless swelling in the left labium majus. Eighteen months later some other small swellings appeared and all united to form a single lump. The part then became painful, there was an evening rise of temperature, and some oedema of the lower limb occurred. There was no disturbance of micturition or defaecation. Examination of the vagina was negative. Rectal examination, on the other hand, showed on the anterior wall above the sphincter a depression which appeared to be the opening of a cavity connected with the tumour in the labium. Under ether anaesthesia the labium was incised and the diverticulum containing a coprolith was removed. Complete recovery took place. The histological and clinical study of the case showed that the diverticulum originated in a congenital anomaly. Fantozzi has been able to find only two similar cases on record, reported by Terrier (1889) and Neumann (1896) respectively.

186. Ectopic Thyroid Tumours in the Neck.

F. FEDELI (*Arch. Ital. di Chir.*, September, 1925, p. 167), who has collected 53 cases from literature as well as 3 which came under his own observation, states that cysts and tumours presenting the structure of the thyroid may develop in regions of the neck which are not the usual site of the thyroid gland. Of these cases 80 per cent. are found in females and 20 per cent. in males. The ages of the patients ranged from 10 to 76 years. Malignant changes never occurred before the age of 40. Goitrous inheritance, prolonged coughing, and various infections have been incriminated as causes of the condition. The symptoms may be classified into positive and negative. The positive are: (1) Their situation on the side of the neck; (2) position beneath the sterno-mastoid muscle; (3) roundish form; (4) multiple character; (5) lobulated surface; (6) slow development for a long period; (7) mobility in all directions; (8) independence of movements of deglutition; (9) soft consistency; (10) transient increase in size during menstruation; (11) frequent, sudden, and considerable increase in size; (12) transmitted pulsation; (13) presence of murmurs; (14) obstruction to circulation; (15) tendency to involve the vessels of the neck. The negative symptoms are: (1) absence of pain and tenderness; (2) absence of subjective symptoms; (3) absence of symptoms of hyper- or hypo-thyroidism; (4) absence of any effect on the general state of nutrition; (5) absence of glandular metastases. The growths must be distinguished from lymphosarcoma, aneurysm of the carotid or subclavian artery, fibroma, lipoma, and branchiogenic carcinoma. Treatment is exclusively surgical and consists in removal of the growth as soon as possible.

Therapeutics.

187. Subcutaneous Injection of Milk in Infants.

A. B. MARFAN and R. TURQUETY (*Paris méd.*, November 7th, 1925, p. 377), who have employed injections of milk on a large scale in the treatment of infants, though inclined to regard the early enthusiasm for the method as unwarranted, maintain that it may be of value in the following groups of cases: (1) the severe form of prurigo, or strophulus of former writers, when the ordinary methods of treatment have failed; (2) more or less generalized erythrodermia exfoliativa; (3) the very rare cases in which diarrhoea in breast-fed babies interferes with growth. In these cases the injection of milk hardly ever causes a violent or early reaction, so that there is no doubt as to their anaphylactic origin. Whether cow's milk or woman's milk is to be employed will depend on the mode in which the child has been fed. If combined feeding has been employed, cow's milk should be injected alternately with woman's milk. Woman's milk should be drawn off as aseptically as possible and injected undiluted. If there is a fear of its being contaminated, it is best to sterilize it. Cow's milk should be boiled for at least five minutes, but it is preferable to employ milk which has been completely sterilized in the autoclave. As it is impossible to determine beforehand the child's degree of sensitiveness, only a very small dose, such as 4 or 5 drops diluted in normal saline, should be given on the first occasion. If this dose does not produce any reaction, 1/2 c.c.m. may be injected next day. Subsequent doses ranging from 2 to 5 c.c.m. may be injected every two days until improvement has been obtained, but if none occurs after five injections it is useless to continue.

188. Blood Transfusion in Potassium Chlorate Poisoning.

A. BÉCART (*Bull. Soc. de Thé.*, November 11th, 1925, p. 254) reports the case of a woman, aged 55, who accidentally took 40 grams of potassium chlorate in mistake for sodium sulphate. The following morning she was awakened by severe abdominal pain; she vomited everything she took, and had suppression of urine. Numerous wet cups were applied to the lumbar region and gave issue to a thick brownish-black viscid blood which coagulated at once. Bécart, who was called to see the patient the next day, transfused 200 c.c.m. of whole blood, and a few hours later she evacuated a few drops of black urine and spontaneously passed a motion of the same colour. The following day she passed 38 grams of urine which was less dark in colour. A second transfusion was performed three days after the first, and eight days after the accident the total amount of urine in the twenty-four hours was 165 grams. Improvement was gradual, and eventually complete recovery took place. Bécart adds that the case is of interest, first, in view of the rarity of recovery after so large a dose of potassium chlorate, and secondly, on account of the rapid destruction of the red corpuscles. Examination of the blood twenty-four hours after the drug had been taken showed that the red cells had fallen to 2,500,000.

189. Protein Therapy in Syphilis.

S. S. GREENBAUM and C. S. WRIGHT (*Arch. Derm. and Syph.*, December, 1925, p. 858) recall that a rise in the body temperature may serve to hasten the involution of the cutaneous manifestations of syphilis and that injections of protein may cause such a rise. They have, therefore, tried protein injections in conjunction with neo-arsphenamine for the treatment of syphilis. They treated 25 patients with injections of milk protein and neo-arsphenamine and 25 with the drug alone. The average number of injections of neo-arsphenamine required in the first series to produce a negative Wassermann reaction was 4.7, but in the second series the average number of injections was 7.5. The number of failures was less with the combined treatment than with the neo-arsphenamine alone. They found that protein injections alone produced involution of the skin lesions in some cases, and think that such non-specific therapy stimulates the natural defensive forces of the body. They believe that the combined treatment will be found of greatest service in latent syphilis where a strongly positive Wassermann reaction is the only symptom.

190. Ovarian Extract in Graves's Disease.

M. LAEMMER (*Bull. Soc. de Thé.*, October 14th, 1925, p. 216) states that when he first treated cases of Graves's disease he attributed more importance to preparations of the blood of animals from which the thyroid had been removed than to the ovary, whereas at present he does exactly the reverse, for the following reasons. A woman suffering from exophthalmic goitre has a genital sign, which is hardly ever absent—namely, irregular menstruation and often amenorrhoea. This fact is so important that some endocrinologists, especially Marañón, are of opinion that in the overwhelming majority of

cases of Graves's disease in women ovarian disturbance is also present, at least at first. This fact accounts for the predominance of the disease in the female sex. Moreover, it is well known how frequently symptoms of Graves's disease develop at the menopause. Guided by these considerations Laemmer has made a systematic use of ovarian preparations in the treatment of Graves's disease with very successful results, as shown by considerable improvement in the cardinal signs, and almost complete disappearance of the secondary signs. The method consisted in a series of fifteen to twenty injections of the fresh product, 0.20 to 0.25 gram being injected daily. Sympathicotonus being the rule in Graves's disease, the injections were associated with the administration of hyoscyamus, which has a depressing action on the sympathetic. As regards the therapeutic action of ovarian preparations on the thyroid Laemmer points out that ovarian insufficiency may give rise either to hyperthyroidism or hypothyroidism, according as the patient shows a tendency to sympathicotonus or vagotonus.

191. The Effect of Tobacco in Post-encephalitic Tremor.

G. HERRMANN and E. WOTKE (*Med. Klin.*, December 4th, 1925, p. 1842) have noticed a remarkable improvement in post-encephalitic tremor from the employment of tobacco derivatives. The first case of the kind seen by them was in a man, aged 27, whose tremors improved so much after smoking a cigarette that he was able to write a letter. The authors have now treated altogether fourteen cases, and with three exceptions have found that tobacco exercised a favourable action on the tremor, although the result was not so striking as in their first case. Of the three exceptions one was an example of true paralysis agitans and another a severe case of post-influenzal encephalitis. A nicotine salt in the form of nicotine tartrate had only a very slight action in no way comparable to that of smoking a cigarette. The authors add that the question of what constituent of tobacco is the active agent must first be decided before nicotine can be employed therapeutically. Nicotine is found in the leaves of *Cannabis indica* and picurin isolated from the leaves of the Australian solanaceous plant *Duboisia hopwoodii* is said to be identical with nicotine. Duboisin is well known to have an action similar to that of hyoscyne in the treatment of true and pseudo-Parkinsonism.

Dermatology.

192. Thrush Infections of the Skin.

B. SHELMIER (*Arch. Derm. and Syph.*, December, 1925, p. 789), who records five illustrative cases, states that during recent years a great many skin eruptions formerly regarded as "eczema" have been shown to be due to *Oidium albicans*. They occur either as disseminated lesions over large areas of the skin surface as in water-bed treatment, after wet dressings, in nursing infants, or are found localized in the contact areas of the skin (anus, genitals, under the breasts, the axillary and interdigital folds), where the warmth and moisture are especially favourable for the growth of the fungus. In water-bed treatment the sites of predilection are those areas of the skin which are alternately exposed to water and air, such as the axillae, knees, and hands. The genital and anal regions are often much involved, and sometimes the greater part of the body may be affected, the areas being thickly studded with papules and vesicles. In nursing infants the favourite site for the lesions is the circumanal region, whence they extend to the thighs, genitals, abdomen, and buttocks, consisting of superficial punctate vesicles, which frequently become pustular, or lentil-sized areas of erythema, with branny scales in the central portions. Mycotic infections following wet dressings show no typical localization and are characterized by the presence of vesicles and pustules, often in herpetetic arrangement. Thrush infection beneath the breasts is often seen in nursing mothers whose infants are suffering from stomatitis due to *Oidium albicans*. There is only one case on record, reported by Engelhardt, of thrush infection of the axilla. Interdigital thrush infection is seen in one or more spaces of the hands and feet, the third interdigital space being the site of predilection in the hand. Women, and especially those engaged in house work, are particularly prone to this infection. Other localizations of thrush infection are the nails, in which hyperkeratotic changes, abscesses or chronic paronychia may occur. Thrush infections are very resistant to treatment, salves, wet dressings, and the quartz lamp being unavailing. In Riehl's clinic at Vienna the only satisfactory results have been obtained from radium treatment, by which complete healing of the lesions is usually effected.

Eczema and Focal Infections.

193. J. W. VISHER (*Amer. Journ. Med. Sci.*, November, 1925, p. 723) points out that most authorities regard sensitization to various foods as being the most important cause of infantile eczema, and that since most children slowly improve and eventually recover without dietary restrictions it would seem likely that immunity to food substances is gradually acquired. But, he states, in the adult one group of cases of eczema appears to be due to external irritants and in another group this condition seems to be a result of some focus of infection. He reports five cases in which when a focus of infection was removed the existing eczematoid condition rapidly cleared up. In three of these recovery followed the removal of diseased teeth, in one the eczema ran its course concurrently with an attack of acute pharyngitis, and in the other case the condition appeared soon after the onset of puerperal sepsis, and subsidence of the eruption accompanied improvement in the pelvic infection. In each patient careful search was made to discover some other possible cause of the skin lesions, but with no success. Local treatment had little success, and the eczema appeared to improve in spite of, rather than because of, it. Visser suggests that the eruption is due to the patient becoming sensitive to the end-products formed in the focus of infection.

Pityriasis Rubra.

194. IN view of the obstinate character of pityriasis rubra H. GOUGEROT (*Bull. de Derm. et de Syph.*, November 8th, 1925, p. 374) publishes the following case. A girl, aged 5, was seen in May, 1925, covered with an extensive eruption of pityriasis rubra pilaris, which had proved very resistant to treatment. In addition to the local application of salicylic ointment, dieting, small doses of calomel and arsenic, injections of Vaudremet's antituberculous vaccine were given, and by the end of June the child was completely cured and remained so. The author believes that the vaccine was the effective agent in producing so speedy and satisfactory a cure; he does not think that spontaneous regression occurred. He had previously used this vaccine with success in the treatment of cutaneous tuberculosis.

Obstetrics and Gynaecology.

Prognosis in Uterine Cancer.

195. BÖHM and ZWEIFEL (*Zentralbl. f. Gynäk.*, January 2nd, 1926, p. 30) describe various efforts which have been made to find which histological types of cancer of the uterus are most amenable to x-ray or radium treatment. Bergonié's law, according to which tumours possessing less highly differentiated cells show the greater radio-sensitivity, has not been confirmed by certain recent observers, who attach more importance to the relative amount of connective tissue present, to the quantity of effused blood, and to other factors. Adeno-carcinomatous tumours have been described as being refractory in the cervix, but in the corpus uteri as responding favourably to radiation, but Döderlein found that cases which were cured had always shown solid and never glandular carcinoma. The investigations of the present authors show that the prospect of cure is relatively favourable where the stroma of the tumour is richly infiltrated with leucocytes. Other favourable signs are relative "unripeness" of the tumour cells, a large amount of cytoplasm with abundant vacuolation, and rich leucocytic infiltration of the tumour epithelium; these conditions, however, rarely coexist. They find the medullary type of tumour more favourable and attach little importance to the frequency of mitoses. Formation of epithelial pearls is not discouraging if other histological criteria are favourable. Comparing the prognosis formed on histological grounds in 122 cases (before radiation) with the subsequent clinical course Böhm and Zweifel found that they corresponded in at least three-quarters of the cases.

Removal of Fibroids during Pregnancy.

196. R. SCHOCKAERT (*Bruxelles - Médical*, January 17th, 1926, p. 378) points out that during the early months of pregnancy fibroids, especially of the interstitial type, grow larger and also softer, owing to the hyperaemia of the pelvic organs generally. The consequent infiltration may go so far as to produce a cystic condition, and even a central cavity, in which case pressure on the fibroids causes flattening, and tension results in lengthening, so that the course of pregnancy is little disturbed. Rapid hypertrophy of a pedunculated fibroid often gives rise to pressure on the diaphragm and intestines, or, if the fibroids are impacted in the lower pelvis, to interference with the rectum and bladder. Schockaert removed one such fibroid from a primigravida by cutting the pedicle, and the pregnancy went to term; this fibroid was

as large as a man's head. He maintains, however, that unless symptoms are urgent no surgical intervention is desirable. Impacted fibroid is an indication for treatment, and pressure on the intestine caused by a hardish fibroid of the anterior uterine wall with much pain. In another patient with a fibroid which involved the whole thickness of the uterus, so that its removal left a two-inch hole in the wall, the author by rapid suture averted expulsion of the ovum and the pregnancy continued.

197. The Virulence of Vaginal Organisms.

E. PRIHAM (*Zentralbl. f. Gynäk.*, January 16th, 1926, p. 137) refers to the attempts of Ruge and of Philipp to determine the virulence of the micro-organisms, especially the streptococci, present in the vagina and cervix. An increase in the number of streptococci, after a mixture of the discharge and the blood of the patient has been allowed to stand for some hours, is taken to indicate a relatively high degree of virulence of the organism. At certain clinics so great importance has been attached to the Ruge-Philipp reaction that a positive result has been considered to prohibit operative treatment of cancer of the cervix and to render the risk of a Caesarean section unjustifiably great. Priham's study of a hundred gynaecological and obstetrical cases leads him to conclude that many patients suffer no severe infective phenomena in spite of a high degree of virulence of the cervico-vaginal flora as shown in the Ruge-Philipp test. E. M. FUSS (*ibid.*, p. 140) records 238 cases of radiological treatment of uterine carcinoma, comparing the course of events in those patients locally infected with virulent and non-virulent organisms respectively as shown by the Ruge-Philipp test. In the latter group treatment was followed by septic complications in 6 per cent., with 1.2 per cent. mortality; where virulent organisms were present severe infectious processes (such as protracted fever, peritonitis, and parametritis, occurred in 42 per cent., with a 10 per cent. mortality. In the Berlin Universitäts-Frauenklinik cases showing a positive Ruge-Philipp test are rarely submitted to operation; of the "negative" series of 65 cases surgically treated infection was absent or very slight in 91 per cent. Mortality and morbidity in a series of 180 cases were definitely less if febrile conditions following labour or abortion were associated with a negative Ruge-Philipp test. Fuss concludes that the presence of "virulent" organisms is a significant warning sign, and thinks that when severe infection follows operative or radiation treatment in spite of a negative Ruge-Philipp test the micro-organism responsible is probably an anaerobe which has eluded the test.

198. The Etiology of Eclampsia.

ZANGEMEISTER (*Med. Klin.*, January 2nd, 1926, p. 38) puts forward the theory that eclampsia is caused by cerebral pressure which is due to an oedematous swelling of the cerebral tissue, part of a general dropsy occurring slowly in the pregnant, and more rapidly in the parturient woman. He ascribes the albuminuria to a corresponding oedema of the kidney. The symptoms of eclampsia are ushered in by a rise in blood pressure; this should be treated by rest in bed, control of diet, and lumbar puncture; a later symptom is a rapid increase in weight. In the event of these symptoms not responding to treatment, the author considers it justifiable to empty the uterus. Employing this preliminary treatment he has had only one death from eclampsia during the last three years.

Pathology.

199. Infectivity of Tuberculous Filtrates.

T. YEGER (*C. R. Soc. de Biologie*, January 15th, 1926, p. 8) describes a case of artificial pneumothorax in which a pleural effusion appeared six weeks after the operation, large numbers of tubercle bacilli being found. Later the effusion became purulent, and the bacilli diminished in numbers till after five months they were no longer to be found. Nine months after the operation 5 c.cm. of the fluid was withdrawn, incubated at 37° C. for three days, mixed with 45 c.cm. of saline, and filtered through a Chamberland L2 candle. Two guinea-pigs were inoculated subcutaneously with 15 c.cm. of the filtrate. One of these animals died in four months, and at necropsy was found to have enlarged tracheo-bronchial glands; no tubercle bacilli were demonstrated. The other animal was killed a few days later, and also showed marked enlargement of these glands; tubercle bacilli presenting the usual acid-fast characteristics were found in the gland pulp. Yeger concludes, therefore, that in a pleural fluid containing no visible tubercle bacilli there may exist certain forms which are capable of passing through a Chamberland filter, and which on inoculation into guinea-pigs can give rise to a type of disease differing from the

usual experimental tuberculosis in the confinement of the lesions to the tracheo-bronchial group of glands. In the same journal (p. 46) F. ARLOING, A. DUFOUT, and MALARTRE describe the production of an atypical tuberculosis in guinea-pigs by the injection of filtered suspensions of tubercle bacilli. The material that they worked with consisted of extracts passed through a Chamberland L3 candle, from thirty human cases of tuberculosis of diverse nature. To all appearances these filtrates were sterile, but after injection fourteen of them gave rise to tuberculosis. As a rule the infected animals remained well for three or four months, then became cachectic and died. At the necropsy no macroscopic lesions were seen, but tubercle bacilli were found in smears from the glands. In two cases the animals developed the typical inoculation disease.

200. The Morphology of *B. melitensis* and *B. abortus*.

G. FAVILLI (*Lo Sperimentale*, January, 1926, p. 1041) has tried to distinguish morphologically between *B. melitensis* and *B. abortus*. Working with 20 strains of Bang's bacillus and 7 strains of *B. melitensis*, he found that both organisms were pleomorphic, presenting in one and the same preparation coccoid, coccobacillary, and definite bacillary forms. The use of Amato's brilliant cresyl-blue stain demonstrated the presence in each bacillus of a very tiny round granule, stained dark blue, and situated either at the equator or near one end. No difference was established between the granules of the two species of organism. By means of a stain for flagella he was able to make out a short prolongation of the protoplasm at one end of the bacillus. This was considerably thicker than a flagellum, and was no longer than the bacillus; sometimes it stretched backwards, sometimes it curled round to touch the side of the organism. Careful examination for motility under dark-ground illumination failed to show any true movement of the bacilli; the very active Brownian motion was not hindered by the presence of weak solutions of antisoptics. Further, using Rovid's sand tube, he failed to demonstrate any movement of the bacilli. It is doubtful, therefore, whether the protoplasmic prolongation can be regarded as a true flagellum. The main point of interest is that the two species of bacilli are alike in respect of their pleomorphism, their granule formation, their flagellum-like bodies, and their non-motility. Morphologically they must be considered indistinguishable.

201. Immunization against *B. melitensis*.

E. SANFILIPPO (*Biochimica e Terap. Sperimentale*, December, 1925, p. 493) has obtained some successful immunization results in white mice by the use of a vaccine consisting of organisms treated with gold chloride. Cultures of *B. melitensis* grown for forty-eight hours at 37° C. were suspended in a 1 per cent. solution of gold chloride; after one hour the suspensions were centrifuged, the supernatant fluid drawn off, the organisms washed repeatedly with distilled water, and finally suspended in the same medium. The gold chloride appeared to have a detoxicating action, for after treatment with this salt the organisms could be injected in large quantities (two agar slope cultures) intraperitoneally into white mice. Similar injections of organisms sterilized by heat killed the animals in two or three days. Mice injected with the bacilli treated by gold chloride were found able to resist without any injury ten lethal doses of a living virulent strain of *B. melitensis*. Mice injected with heat-killed organisms succumbed to a similar dose of living bacilli in twenty-four hours. The author believes that the use of this detoxicated vaccine confers a definite protection on mice.

202. The Action of Mixtures of Rabies and Herpes Virus.

P. REMLINGER and J. BAILLY (*C. R. Soc. de Biologie*, December 18th, 1925, p. 1486), in view of the resemblance between the viruses of rabies and herpes febrilis, determined to study the action on animals of a mixture of the two viruses. Two quarters of the brains of rabbits which had died, one of herpetic encephalitis and the other of paralytic rabies, were crushed together in a mortar and made into a fine emulsion with 40 c.cm. of normal saline. The emulsion was kept twenty-four hours in the ice-chest and then inoculated into the brains of rabbits, guinea-pigs, and cats with the following results: The rabbits died on the third or fourth day of an encephalitis indistinguishable from that due to inoculation of herpes virus. In three days' time the virus of rabies had not had time to develop. The cats usually died on the eighth to the tenth day after inoculation of a disease impossible to distinguish from paralytic rabies. In guinea-pigs the symptoms were not characteristic either of rabies or herpes, death occurring five to eight days after inoculation. The authors conclude that there is no antagonism between the virus of rabies and that of herpes, and that they are capable of developing in the inoculated animal in a manner without affecting one another.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

203. Rheumatic Fever and Chorea in Children.

H. C. BUSSIERE and L. J. RHEA (*Canadian Med. Assoc. Journ.*, January, 1926, p. 35) record the results of an analysis of 100 cases of acute rheumatic fever and chorea in children, undertaken to determine the clinical picture and the results of treatment in the two diseases. Before the sixth year both diseases are rare and occur most frequently between the sixth and the twelfth, females being more susceptible than males, especially as regards chorea. In both there was a high percentage of cardiac lesions, though such involvement was more frequent in acute rheumatic fever than in chorea. Acute or chronic disease of the tonsils was of frequent occurrence; only 3 per cent. of cases of chorea were without an associated tonsillitis, acute rheumatic fever, or cardiac involvement. The treatment adopted in acute rheumatic fever comprised rest in bed between woollen blankets, with a mixture of 1 grain of sodium salicylate a day for every pound of body weight, sufficient sodium bicarbonate to reduce the acidity, and 10 to 30 minims of tincture of nuxvomica. In cases showing cardiac weakness tincture of digitalis was given commencing with five minims three times a day and gradually increasing. A similar line of treatment was followed in chorea with isolation and as complete quiet as possible for at least a month, even in mild cases, and as soon as the acute stage had subsided removal of the tonsils if diseased. The authors add that while the prognosis in both diseases is generally good as regards life, the prospect of a return to complete health is poor if there has been any involvement of the heart; if attacks of chorea are repeated, or are of long duration, the children may become nervous and their intellectual ability be impaired.

205. Irregularity of the Pulse in Epidemic Encephalitis.

Y. HANNEMAN (*Nederl. Tijdschr. v. Geneesk.*, January 2nd, 1926, p. 12), who records four illustrative cases, draws attention to the occurrence of irregularity of the pulse in epidemic encephalitis, and states that this symptom is sometimes present in the early days of the disease. Some patients may complain of palpitation. L. BOUMAN (*ibid.*, January 16th, 1926, p. 293), on the other hand, remarks that he has never observed this symptom in epidemic encephalitis, and that it has not been described in the literature as in any way characteristic of the disease. Slowing or quickening of the pulse has been recorded, usually corresponding to the temperature. In the examination of 100 cases Nellis found only one patient who showed any change in the pulse—namely, slowing. Achard alone states that extra-systoles may occur. He thinks it, therefore, very remarkable that Hanneman had found irregularity of the pulse so frequent in epidemic encephalitis, and adds that further observations on this point are required.

208. Infectious Mononucleosis or Glandular Fever.

J. G. HISLOR (*Med. Journ. of Australia*, November 7th, 1925, p. 557), who records four cases, three of which occurred in children aged 1 year and 8 months, 5 years, and 10 years, and one in a nurse, states that Filatow of Moscow first described the disease in 1886 as glandular inflammation of the neck without inflammatory changes in the month, nose, or pharynx. Pfeiffer in 1889 gave the first clear account of the disease. Dawson Williams in 1897 also gave a full description of it, but it was left for the later writers to describe the accompanying blood changes. The leucocytes may range as high as 26,000 per cubic millimetre, but one observer says that there may be a leucopenia. According to Longcope, 80 to 90 per cent. of the leucocytes are of the non-granular type, and may appear as (1) small mononuclear leucocytes identical with the small lymphocytes seen in normal blood; (2) large mononuclear cells identical with the large mononuclear and transitional cells of normal blood; (3) mononuclear cells of a type not usually seen in normal blood. All observers agree regarding the acute onset with malaise, anorexia, obstinate constipation, pain and stiffness in the neck, abdominal pain, and high fever. The glandular enlargement occurs early, the usual site of the first enlargement being just beneath and posterior to the left sterno-mastoid. The glands then become enlarged on both sides of the neck anteriorly and posteriorly; the axillary and inguinal glands may also be enlarged. The acute symptoms subside about the fifth day and the glands then begin to resolve. The liver is almost invariably enlarged,

and the spleen in about half the cases. The mediastinal and bronchial glands may be affected, and their enlargement accounts for the cough which accompanies the infection and may persist for some time. The disease is rarely fatal, but may be severe. Hislop's cases were of a mild type. The glands may take from a fortnight (Dawson Williams) to a month (Koliert) to subside. Acute nephritis, which occurs in about 6 per cent., is the commonest complication. The disease must be distinguished from tuberculosis, syphilis, and Hodgkin's disease, which have not a sudden onset and are more chronic. Acute leukaemia is excluded by the low leucocytosis or leucopenia.

206. Prophylaxis in Tuberculosis.

B. WEILL-HALLÉ and R. TURPIN (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 24th, 1925, p. 1589) describe an attempt to obtain active immunity from tuberculosis in the case of infants. They used the special vaccine of Calmette known as "B.C.G.," which is a living culture. It was given by mouth on the fourth, sixth, and eighth days after birth. Bacilli were passed in the excreta for a few days, but no ill effects were observed. The authors have treated a series of 254 patients, some with a healthy and others with a tuberculous parentage. The mortality in the whole series was 13; 5 children died within the first month of gastro-enteritis, but in the institution where the tests were made 5 deaths occurred from the same cause among non-vaccinated infants. There were 8 deaths between the ages of 1 month and 1 year, but in no case was the death traceable to the vaccination. Certain infants born of healthy parents, and who became exposed to infection for the first time at the age of a few months, lost no weight and showed no clinical evidence of the disease, but the von Pirquet reaction became positive and pulmonary nodules were seen on x-ray examination. The question now confronting the authors is that of revaccination, since the immunity lasts only about two years. The original method is no longer suitable, since the child's intestine differs from that of the infant at or shortly after birth. The difficulty lies in the fact that to establish the success of a subcutaneous injection the child's von Pirquet reaction must have been negative for at least one month beforehand.

Surgery.

207. Sequels of Prostatectomy.

R. H. HERBST (*Journ. Amer. Med. Assoc.*, January 9th, 1926, p. 93) discusses the causes of interference with urinary function after removal of the prostate, and emphasizes the importance of the pre-operative examination from this point of view. Diverticula of the bladder, which are frequently associated with prostatic obstruction, may be congenital or acquired, and if overlooked retard convalescence by maintaining cystitis with frequent and painful micturition. The author recommends strongly that in every case of prostatic obstruction the bladder should be distended before the operation with a 15 per cent. solution of sodium iodide and a radiogram taken; the bladder should then be emptied, air injected, and a second radiogram taken. In this way diverticula which do not retain urine can be recognized and need not be removed, though the retention type must be excised when the prostate is dealt with or soon after. Examination of the central nervous system is also recommended in order that any nerve or circulatory lesions may be detected. Fibrosis of the internal sphincter may interfere with the urinary function after prostatectomy, and prostatic tags left behind and attached to the internal urethral orifice may be large enough to obstruct the flow of urine. Another cause of obstruction is the barrier produced by the trigone crossing the internal urethral orifice at a high level. This can be detected after enucleation of the prostate and may be corrected by a V-shaped excision of the bladder wall at this point. Urethral polyps developing in the prostatic bed may be the cause of impaired function; they can easily be removed by diathermy. Careful bimanual palpation of the prostatic bed and the trigone will reveal the presence of any deep-seated, enlarged submucous glands. Retention and infection of the upper urinary tract is not uncommonly overlooked and is usually corrected quickly by pelvic lavage and instillation of silver nitrate. Other possible causes of impaired function after prostatectomy include infection of the seminal vesicles; formation of a stone in the bladder; the incomplete removal of a prostatic adenoma; and malignancy in the lower segment

of the prostate, with benign hypertrophy in the upper one. Adhesion of the posterior surface of the gland to the lower segment should arouse suspicion of the existence of this last condition, and bimanual palpation of the prostatic bed after enucleation will usually reveal some hard nodules in the so-called surgical capsule of the gland.

208. Treatment of Surgical Tuberculosis.

DURING the past two years G. B. RHODES (*Journ. of Lab. and Clin. Med.*, December, 1925, p. 227) has performed a number of experiments to discover a substance that could be injected into a tuberculous abscess cavity and exert an antiseptic action on the causative bacilli. The best results have been obtained with cod-liver oil. As this substance is too acid to be tolerated by the healthy tissues, it must first be hoiled with an equal quantity of an aqueous suspension of magnesium hydroxide; the mixture is then centrifuged, and the supernatant fluid, which contains the oil, is removed. In this form it may be introduced into an abscess cavity without causing irritation. The success that has followed the evacuation of tuberculous abscesses and replacement of the pus with this oil has led the author to inquire into the manner in which it acts. Campbell and Kiefer found that cod-liver oil exerts a bactericidal effect on virulent strains of tubercle bacilli; Kugelmass and McQuarrie showed that the oil possesses the property of emitting ultra-violet rays. An attempt to confirm the latter statement has cast doubt on the ultra-violet nature of the rays. An x-ray film enclosed in black paper and placed over a metal dish containing cod-liver oil, when developed after forty-eight hours, was found to have a perfect representation of the oil upon it; rays must have emanated from the oil to affect the sensitized film. It seems probable that these rays are not of one type, but are composed of different wavelengths.

209. Intracranial Abscess.

SIR W. MILLIGAN (*Journ. of Laryngol. and Otol.*, January, 1926, p. 1) remarks that the bony walls of the middle ear and mastoid act as a barrier against acute infective processes, but that chronic inflammation in time makes a breach in this barrier and some extradural complication arises. If the infective process is virulent and comparatively acute, meningitis is one of the commonest complications, but in more chronic cases adhesions form and some kind of abscess results. Intracranial abscesses occur as an almost invariable rule only after many years of suppuration and may be classed as cerebral and cerebellar. It is usually accepted that cerebral are commoner than cerebellar abscesses, but the author's experience is that the proportion is one cerebral abscess to two cerebellar. Many cases of infection arise from the labyrinth, the usual path being along the internal auditory meatus, or the aqueductus vestibuli. An extradural abscess or sinus thrombosis and suppuration may convey the infection through the meninges. The author stresses the importance of cholesteatoma which opens up the spaces of the internal ear and allows the infection with which it is almost invariably associated to enter. Cerebellar abscesses are never large because of the proximity of the cardiac and respiratory centres. They usually run a latent course and then cause sudden death. Intracranial pressure is the rule, with the classical triad of headache, vomiting, and papilloedema. There may be homolateral hemiparesis and ataxia. Nystagmus in early stages is directed towards the affected side, but later towards the sound side. Dysidiadokokinesis is a common symptom. The abscess should be drained at once on account of the danger of sudden death.

210. Surgical Treatment of Angina Pectoris.

S. A. LEVINE and F. C. NEWTON (*Amer. Heart Journ.*, October, 1925, p. 41) give detailed reports of seven patients upon whom cervical sympathectomy was performed for the treatment of angina pectoris. These patients were all alive three months to two years after operation. Of the seven, three were completely and immediately cured, three were considerably improved, and one was neither better nor worse; three of these last four later responded to medical treatment. An eighth patient died a few hours after the operation, which was only performed as a last resource in a moribund case at the patient's request; necropsy showed an occlusion of the left coronary artery. The authors emphasize the importance of proper selection of patients in diminishing the immediate mortality and increasing the number of successes. In estimating the patient's suitability they lay stress on accuracy of diagnosis, with special reference to cardiac infarction; the myocardium must be sound, and preferably there should be no valvular disease. Coronary thrombosis, they add, may be distinguished from an ordinary anginal attack by its longer duration, greater severity, and resistance to medical treatment. In thrombosis also the pulse tends to become rapid and to change in rhythm, whereas in angina it remains essentially unchanged. Moreover, the blood

pressure rises during an anginal attack and falls with thrombosis, in which latter fever and leucocytosis are common. In order to assist the establishment of indications for this operation the authors suggest that all reports of cases should be in full detail. They believe that with a proper selection of patients, so as to exclude cases of cardiac infarction and congestive heart failure, this method of treatment is of distinct value.

Therapeutics.

211. Treatment of Pulmonary Tuberculosis with Metal Salts.

N. LUNDE (*Ugeskrift for Læger*, January 7th, 1926, p. 1) has tested at the Lyster Sanatorium in Norway Walbum's statements as to the therapeutic action of small doses of certain metals in a variety of infectious diseases, including tuberculosis. The best results were achieved with manganese chloride, intravenous injections being given at intervals of four to seven days. Injections of small doses of salts of calcium, gold, and beryllium were also given, from ten to twenty-six injections being given in each case. Of the 58 tuberculous patients whose treatment was completed, 31 were in the third stage of the disease, and 25 of them benefited from the treatment. Of the remaining 27 patients who were in the first or second stage of the disease, 24 derived benefit from the treatment, which in no case seemed to be injurious. In 22 cases the rate of sedimentation of the erythrocytes was investigated, and in as many as 16 of these cases there was an improvement, the rate of sedimentation being reduced by an average of 13.1 mm. in an hour. Among the same 22 patients there were 5 who gave a positive nrochromogen reaction at the beginning of the treatment, and in 2 of these cases this reaction became negative under the treatment. As many as 51 of the 58 patients had tubercle bacilli in the sputum at the beginning of the treatment, and in 8 cases the bacilli disappeared. Comparing Walbum's system of small, carefully graduated doses with Moclgaard's system of massive dosage, Lundé argues that the former is a process which stimulates the reactive properties of the tissues, and thus promotes an active defence of the body by its own mechanism, whereas the processes concerned when the dosage is massive are largely passive, the high concentration of the salt in question being sufficient in itself to interfere with the action of microbes in the body. Lundé believes that Walbum's system could be developed into a very effective weapon against tuberculosis.

212. Acriflavine in Epidemic Encephalitis.

C. E. RIGGS (*Minnesota Med.*, December, 1925, p. 753) records three cases of epidemic encephalitis in patients aged 24, 40, and 33, treated by intravenous injections of neutral acriflavine. Each patient received eight consecutive injections. The dosage was 10 c.cm. of a 0.5 per cent. solution. In order to avoid distressing symptoms the injection was given slowly at the rate of 10 c.cm. in five minutes. If the injection was given more rapidly there would be gasping respiration with air hunger, associated with a sensation of heat, affecting the mucous membrane of the respiratory tract, and intense lacrimation. After two or three injections the patients experienced great relief, and after eight injections the improvement was really remarkable. The Kernig, Babinski, and other objective signs disappeared slowly.

213. Prostatic Massage in Gonorrhoeal Urethritis.

A. L. VOLBARST (*Med. Journ. and Record*, January 6th, 1926, p. 3) calls attention to the value of prostatic massage in acute gonococcal infections of the anterior urethra. In forty cases so treated there was no extension of the inflammation to the posterior urethra, and very often the pre-existing congestion was relieved. In about 30 per cent. of cases of first infections of acute anterior gonococcal urethritis in which there was no clinical evidence of posterior involvement the prostate was found to be enlarged, soft, and congested; there was unmistakable evidence of a chronic low grade, non-venereal prostatic inflammation with similar evidence in some cases of chronic inflammation in the seminal vesicles. The existence of such a low-grade inflammation accounts for those cases in which a mild anterior urethritis suddenly develops an acute or subacute prostatitis tending to chronicity and complications. Volbarst recommends the routine examination of the prostate and seminal vesicles in every case of anterior urethral infection, and in the event of prostatic congestion being present, as evidenced by a large, soft, and boggy prostate, he advocates gentle massage carefully performed as a protective measure against the extension of the inflammation and for the reduction of the pre-existing chronic congestion. Such massage should be given every four or five days as long as signs of chronic inflammation exist.

214. Refined Therapeutic Serums.

J. M. DUBREUILH (*Thèse de Paris*, 1925, No. 515) states that a refined serum can be obtained by the following method. To a fixed quantity of dried serum are added increasing quantities of distilled water. The dried serum is dissolved in water in the proportion of 1 to 10, the solution being all the more viscid the less water is present. The different solutions of serum are then put in the coagulator for half an hour at 60°C. Part of the albumin is precipitated and becomes insoluble. The maximum quantity (0.53 gram) of protein substances or residual serum is thus obtained with a syrupy fluid consisting of two parts of water and one of serum. The most favourable dilution is consequently 1 gram of serum for 2 grams of water. By this method a refined serum is obtained freed from more than 50 per cent. of its albumins. Refined serum is five times less toxic experimentally than the original serum, and the more the process of refinement is repeated the less toxic does the serum become. The preventive and curative value of refined serum is about the same as that of the original serum. This fact has been proved experimentally in the case of anticholera, antitetanic, and antidiphtheritic serums, and clinically as regards its prophylactic action in the case of antidiphtheritic serum.

215. Stovarsol in Vincent's Angina and Ulcerating Stomatitis.

J. A. VOSS (*Tidsskrift f. d. Norske Lægeforening*, December 15th, 1925, p. 1227) has tested at the municipal fever hospital in Oslo the efficacy of stovarsol in Vincent's angina and ulcerating stomatitis. There were 10 patients suffering from the former disease and 2 from the latter. No other treatment, general or local, was employed. The drug was administered by the mouth, the first two tablets, each of 0.25 gram, being given on an empty stomach in the morning with a glass of water. In the absence of diarrhoea four tablets were given on the second day, and this dose was repeated till the membranes had almost completely disappeared. In 9 of the 10 cases of Vincent's angina recovery was complete when twelve to twenty-eight tablets had been given. Only in one case was it necessary, after twenty-eight tablets had been given, to resort to an injection of neosalvarsan. As stovarsol is excreted slowly, it is not necessary to continue giving it till the ulceration has cleared up completely. The author recommends this treatment in general practice, on the grounds that it renders local applications superfluous and saves the patient the cost and loss of time entailed by admission to hospital. The patient can, he adds, continue at work while taking the stovarsol. For patients already in hospital the author prefers the older method of local applications of salvarsan in glycerin, since this is cheaper and as effective.

Radiology.**216. Radiography of the Gall Bladder.**

W. BAETZNER (*Med. Klin.*, January 2nd, 1926, p. 18) describes his method of examining the gall bladder radiologically. After purgation the patient is given 5 grams of tetra-iodo-phenolphthalein sodium or 3 grams of tetra-bromo-phenolphthalein sodium dissolved in 40 c.cm. of distilled water and boiled for twenty minutes; the intravenous injection of this solution should be spread over ten to fifteen minutes. The preparation may be given by the mouth, 0.1 gram for each kilogram of body weight, but the result is said to be less satisfactory as some of the dye passes through the intestine. After fourteen to eighteen hours the patient is x-rayed and a shadow of the gall bladder will be seen. A faint shadow suggests partial obstruction of the ducts, while a mottled appearance indicates the presence of stones. A completely negative picture—that is, the absence of any shadow—points in most cases to a stone in the duct or a severe degree of inflammation. There is a possibility of error, however, and Baetzner mentions four cases in which, on the strength of a negative picture, the patients were operated on and were found to possess healthy gall bladders. Two proved to be cases of acute pancreatitis, one of acute appendicitis, and one of spastic colitis.

217. X-ray Treatment of Malignant Granuloma.

N. VOORHOEVE (*Nederl. Tijdschr. v. Geneesk.*, October 10th, 1925, p. 1677) records the results of x-ray treatment of 19 cases of malignant granuloma; 11 were in women and 8 in men. The ages ranged from 3 to 49, the average age being 29. Apart from purely symptomatic treatment no therapeutic measures were employed. The results were as follows. The average duration of life and good health was considerably prolonged. Voorhoeve points out that it is essential that all the localizations of the process should receive a sufficiently large dose, and that any recurrence should be treated at

once. He frequently observed that a few hours after the first application of x rays, especially when there was a sudden and considerable absorption of the granulomatous tissue, there was a rise of the already elevated temperature, which subsided in one or two days, when an improvement of the general condition and a fall of temperature occurred. Leucopenia in patients under treatment might reach a considerable degree without any permanently bad effect resulting. The lowest number of leucocytes found was usually between 3,000 and 5,000. The prognosis was unfavourable in cases where the malignant granuloma was situated in the lung and abdominal lymphatic glands, in cases of pleural effusion, and in those complicated by diffuse tuberculosis of the lymphatic glands. X-ray treatment is contraindicated in the following conditions: association with pulmonary tuberculosis when the malignant granuloma is situated in the mediastinum or lung, amyloid disease, multiple metastases in the bone marrow, and acute infective processes in the neighbourhood of the malignant granuloma.

218. Radiography of the Lungs.

L. H. CLERF (*Surg., Gynecol. and Obstet.*, December, 1925, p. 722) has used bismuth subcarbonate and lipiodol as radiopaque substances for radiological examination of the lungs in a large series of cases. He has found that the broncho-scopic insufflation of bismuth subcarbonate into the tracheo-bronchial tree is devoid of untoward effects, but although the introduction of lipiodol was harmless in all his cases there has been one reported instance of acute iodism with oedema of the larynx following it; Clerf advises, therefore, that lipiodol should not be used in persons susceptible to iodine. His investigations have shown that in an adult 1 ounce of bismuth subcarbonate can be safely used, as the greater part is rapidly expectorated within forty-eight hours. The quantity of lipiodol required in an adult is usually about 20 to 25 c.cm. and several days elapse before it all disappears. Clerf considers such radiological examination of great assistance in the diagnosis and localization of foreign bodies, neoplasms, and suppuration in the lungs.

219. Radiographic Diagnosis of Cervical Spinal Caries.

É. SORREL and G. MAURIC (*Journ. de Radiol. et d'Électrol.*, November, 1925, p. 497) state that the pharynx, larynx, and trachea form, in profile, in a skiagram a clear column, easily visible in front of the vertebral column; this is displaced forwards when an abscess due to cervical caries is present, and constitutes a simple means of diagnosis which is a valuable sign in some cases when there are no clinical signs of abscess. Occasionally, subsequent skiagrams show regression of the abscess. The relations of the "clear column" with the cervical spine indicate also the best route for its evacuation. In one case of compression of the oesophagus and trachea of uncertain origin, the skiagram showed displacement of the soft tissues, and indicated indirectly the presence of an abscess.

Obstetrics and Gynaecology.**220. The Low Cervical Operation in Caesarean Section.**

L. C. CONN (*Canadian Med. Assoc. Journ.*, January, 1926, p. 32) reports two cases in which the low cervical operation for Caesarean section was employed without difficulty and with satisfactory results. In discussing the relative values of this operation and the classical method he points out that after the latter there is considerable danger of rupture and that there is doubt whether regeneration of muscular tissue occurs. In favour of the low cervical operation are the facts that the cervix resists infection better than the fundus; healing is also more rapid owing to the absence of the repeated contractions which affect the upper uterine segment, and the active involution and fatty degeneration of the uterine wall after delivery. There is also less danger of leakage into the peritoneal cavity during the operation or after it, and the risk of adhesions being formed is reduced to a minimum. Conn adds that an uninterrupted convalescence after operation is characteristic when the low method is used, and intestinal complications are rare. The method cannot, however, be recommended for the obviously infected case. The mortality of the classical operation increases with every hour after the commencement of the pains, and especially after rupture of the membranes, whereas the low cervical operation has been stated to be easier when the patient has been in labour for some time. Where speed is a vital factor the classical operation retains its supremacy, because the low cervical operation takes fifteen to twenty minutes longer. Conn also reports a case in which uterine rupture followed two previous Caesarean sections of the classical type. Although there was only slight pain, the abdomen was opened and it was found that the whole of the uterine scar had ruptured

and a dead child was floating free in the abdomen. There was evidence that the scar had been gradually giving way and only required a few labour pains for the process to be completed. Conn, therefore, emphasizes the importance of avoiding such dangers by performing the low cervical operation whenever possible in preference to the classical method.

221. Lymphangioma of the Fallopian Tubes.

L. W. STRONG (*Amer. Journ. Obstet. and Gynecol.*, December, 1925, p. 853) reports two cases of lymphangioma of the Fallopian tube—a rare condition, of which only five previous cases appear to have been recorded. These two tumours gave rise to no clinical symptoms, and were only discovered during the course of operations for inflammatory conditions of the uterus; one was 5 mm. and the other 1/2 cm. in diameter. Subsequent microscopic examination showed the tumours to be typical lymphangiomas. Their small size and the absence of any clinical manifestations causes Strong to suggest that these tumours are not so rare as was previously thought. These two cases differ from the others reported in that they were unassociated with myomata, thus controverting the original belief in this relation. The Fallopian tubes were otherwise normal in all respects and there was no evidence of any malignant process. Both Strong's patients were married: one was aged 48 and had a large fibrous tumour of the ovary; the other, aged 52, had a retroverted uterus and cystic changes in both ovaries.

222. Absorption from the Vagina.

R. ROSENTHAL (*Zentralbl. f. Gynäk.*, January 9th, 1926, p. 122) describes the case of a woman who committed suicide by introducing three mercury sublimate tablets into the vagina. The whole of that organ sloughed, thus facilitating absorption of the poison from the wound. Rosenthal states that deposits of mercury albuminate may also be formed in the periproctal tissue, for which reason a good immediate treatment is to inject milk into the tissue lying between vagina and rectum, as a neutralizer. Remote lesions are severe parenchymatous nephritis and fatty degeneration of the heart. He adds that it is advisable to supervise the propagation of vaginal discharges until the patient becomes thoroughly familiar with the correct procedure, since there is a real danger of the solution being too concentrated.

Pathology.

223. The Bacteriological Diagnosis of Botulism.

V. DE LAVERGNE and E. ABEL (*Rev. d'Hygiène*, November, 1925, p. 950) summarize the methods available for the bacteriological diagnosis of botulism. A suspicion of the suspected food should be heated to 70° C. for half an hour to destroy all vegetative bacteria, and inoculated in decreasing quantities into ten or twelve Veillon tubes of agar, which are incubated at temperatures varying from 25° to 55° C. After eight days suspicious colonies are picked off, planted in broth, gelatin, and glucose broth and incubated anaerobically. If a growth is obtained of organisms morphologically similar to the *Clostridium botulinum*, cultures should be put up in peptonized bullock's heart broth and tested for the presence of the specific exotoxin. This toxin varies according to whether it is secreted by Type A or Type B of the bacillus. With either type ingestion of the toxin will produce mydriasis, and pharyngeal and laryngeal paresis in the cat. If Type A is present, ingestion of the toxin produces muscular paralysis of the neck in fowls, followed by generalized paralysis, coma, and death in twenty-four to forty-eight hours. Type B does not affect fowls. If the result is negative, the filtered toxin should be injected subcutaneously into a guinea-pig. The result with either toxin is to produce abdominal paralysis, paralysis of the hind legs, dribbling, and death in two or three days. A similar result occurs with injected mice. Having proved the presence of a toxin, the next step is to ascertain if it is the toxin of the *Cl. botulinum*, and, if so, to which type it belongs. This is effected by injecting three guinea-pigs or mice—one with antitoxin A, one with antitoxin B, and one with normal serum; at the same time an equal dose of toxin is given to each animal. Provided that the control mouse and one of the antitoxin-injected mice dies, it may be concluded that the toxin injected was the toxin of the *Cl. botulinum*, and that it was of the type corresponding to that of the protecting antitoxin. Similar animal experiments are conducted on a suspension of the original food. From the human patient an attempt should be made to recover the organism from the faeces or vomit, and from the intestine after death. Occasionally it is possible to demonstrate the toxin in the circulating blood by animal injection.

224. Relation between Herpes Zoster and Varicella.

A. NETTER and A. URBAIN (*C. R. Soc. de Biologie*, January 22nd, 1926, p. 98) have examined the blood serum of 100 patients suffering from zona and 24 from varicella. They used the complement fixation test, preparing their antigens from the crusts of the skin lesions. In some tests the antigen was derived from herpes, in others from varicella; in other tests both antigens were used. The reaction was positive in 93 per cent. of the serums from zona patients and in 91.7 per cent. from patients with varicella. Where both antigens were used the results were qualitatively identical and quantitatively similar. The authors conclude that the antibodies in both diseases behave in exactly the same way. They add that during the first few days of the attack they are in very low titre; their maximum is reached at the end of the second week, and after the attack they may persist for several months. Clinical evidence of the connexion between the two diseases was obtained in sixteen cases of zona. Netter and Urbain consider the zonal virus to be a mutation form of the chicken-pox virus, standing in much the same relation to this as the virus of vaccinia stands to that of variola. The zonal virus has a strong affinity for the nervous system, the chicken-pox virus a low one. The human body destroys the chicken-pox virus rapidly; the zonal virus is much more resistant and may remain latent for a long time, presenting in this respect a close analogy with the herpetic virus. Under the influence of various causes, of which arsenical intoxication is the best established, the zonal virus may resume its activity, and give rise to the typical eruption.

225. Structure of the Nasal Polypus.

G. BUSACCA (*Arch. Ital. di Otol., Rinol. e Laringol.*, November, 1925, p. 696) has investigated the structure of the ordinary polypus of the nose, and has drawn the following conclusions. The liquid in the glandular acini, in the cysts, and in some of the cells of the epithelium is normal mucin. The liquid in the mesh of the stroma is not mucin; van Gieson's stain indicates the presence of amyloid material, but no other stains confirm this, and the author considers that the substance must be hyaline. Fibria is found in amorphous masses or in a definite reticulum of fibres. Elastic fibres are not found in a well formed state, but small fragments of fibrin are scattered through the sections, due, the author suggests, to the breaking up of the elastic fibres by oedema. Plasma cells are fairly numerous and are particularly grouped round the vessels. The epithelium shows in many cases a mucoid degeneration, in others a change to a pavement epithelium. The stroma consists of a fine connective tissue network containing fluid, leucocytes, and some stellate and fusiform cells. The glands have irregular acini which are often dilated and may form large cysts. The vessels, and especially the arteries, present a hyaloid degeneration and a notable thickening of the outer coat. The author concludes that the nasal polypus is not a myxoma, an oedematous fibroma, or a simple hydrops of the nasal mucosa, but an inflammatory condition resembling granulation tissue.

226. The Influence of Fatigue on Infection.

A. E. BOYCOTT and C. PRICE-JONES (*Journ. Path. and Bact.*, January, 1926, p. 87) have investigated the generally accepted belief that fatigue predisposes to infection. Rats were exercised in drums which were rotated quickly so as to cause them considerable difficulty in maintaining their equilibrium. There was a fall in the rectal temperature roughly corresponding to the degree of fatigue. Both the fall in the temperature and the onset of fatigue were slower in rats exercised at a temperature of 25° to 30° C. than at one of 4° C. In the first series of experiments ten batches of rats after exercise were injected intraperitoneally with Gaertner's bacillus; another eleven batches were first injected and then fatigued, the exercise being repeated on the next and sometimes on the following days. A similar number of control animals in each case were injected but not fatigued. The mortality among the exercised and the control animals was closely similar, indicating that fatigue did not lower the resistance to infection. In another series of experiments the rats were fed on Gaertner's bacillus, fatigued daily for several days, and killed after about a fortnight. The results were unexpected. Of 27 exercised rats 24 became ill and 13 died; of 28 non-exercised rats fed with the bacillus only one showed slight symptoms of illness and not one died. Fatigue after infection increased both the morbidity and the mortality, but this result did not seem to be due to the case with which the bacilli penetrated the alimentary mucosa, since in both the exercised and the control animals the bacillus was recovered from the spleens of about 90 per cent. of the survivors. Similar experiments were made with the tubercle bacillus, but no evidence was obtained that the resistance of the animals was diminished by fatigue.

Medicine.

227. Hypogentital Ascites.

P. STANGANELLI (*Rif. Med.*, January 11th, 1926, p. 25), while recognizing tuberculous peritonitis in the young, simple idiopathic peritonitis at all ages, and abdominal scrofulosis with conspicuous lymphoid masses, describes a fourth form with the following characteristics. It occurs at or about puberty and is frequently associated with genital defects, such as amenorrhoea and monorchidism. There is no family history or predisposition to tuberculosis; the general condition of the patient is good, and there is complete absence of the tuberculous type of constitution. The patients belong to the lymphatic type and have short limbs, large abdomen, short neck, small pupils, open mouth, and an expressionless face. They are dull and apathetic, and the urine is scanty with a low urea content. The ascitic effusion forms rapidly; it is very obvious, very thin, and unassociated with any friction rub or adhesions. There is no pain and no fever, no night sweats, and no tuberculous foci in other organs. The fluid has the characteristics of a transudate, being serous with a specific gravity of 1008 to 1015; it rarely coagulates and contains 18 to 20 per cent. of albumin. It is not toxic for guinea-pigs, and tubercle bacilli are not present. There is no concomitant pleurisy. The author suggests that this type of essential ascites is due to an endocrine deficiency, especially of the thyroid and thymus and the lymphatic system. Working on this hypothesis good results were found to follow treatment with polyglandular substances and opotherapy, including a mixture of extracts of both ovaries and testes.

228. Anomalous Forms of Recklinghausen's Disease.

F. WISE and J. J. ELLER (*Journ. Amer. Med. Assoc.*, January 9th, 1926, p. 86) report three anomalous cases of Recklinghausen's disease, and summarize the literature, referring particularly to the reports of Parkes Weber, Trimble, and Levin. Regarding the propriety of including these anomalous types under Recklinghausen's disease, they state that they are found usually in the children of a family in which one or other parent has the classical signs of disease. Their cases were two brothers, aged 11 and 9, the older having many scattered light brown freckles on the neck, trunk, and extremities, together with a number of large café au lait spots. The pigmentation had been present since birth, and there were no line spots. On the upper aspect of the left scapula there was a soft elevated tumour about an inch in diameter, which appeared at the age of 8. The younger brother had many small pigmented light brown lesions on the neck, trunk, and extremities, together with a few large café au lait spots of irregular shape and size. In both cases subjective symptoms were absent, and the testes were undescended. The father had an eruption, including numerous tumours, distributed irregularly over the trunk and extremities and varying in consistence. Almost the entire skin was covered by pigmented macules, chiefly dark or light brown; there were no blue spots. The eruption in his case appeared first at about the age of 5. There were no subjective symptoms and no history of Recklinghausen's disease in any of his ancestors. In none of the patients was there any deficiency of mentality.

229. Exanthema Subitum.

S. SALOMON (*Deut. med. Woch.*, December 25th, 1925, p. 2152) refers to the cases of this condition recently reported by von Bokay (*Epitome*, December 19th, 1925, para. 558), and records four cases from his own practice in female infants, aged from 5½ to 9 months, one of whom was his own daughter. The course of the disease was the same in all. The children, who had hitherto been perfectly well, suddenly became peevish, refused their food, and became restless in their sleep. The temperature ranged between 100.4° and 103.2° F. Nothing was to be found on physical examination beyond considerable injection of the posterior pharyngeal wall and slight conjunctivitis. After seventy-two hours in three cases and forty-eight hours in the fourth a morbilliform eruption appeared on the scalp, face, trunk, and extremities, the temperature falling to normal immediately after its appearance. The rash faded in another forty-eight to seventy-two hours, and complete recovery took place. As regards the diagnosis, Salomon states that a toxic rash, measles and rubella, can easily be excluded, but anaphylactic phenomena are more difficult to distinguish. Exanthema subitum has

only a very slight degree of contagiousness, and apart from amnesia, which may last several months, leaves no sequelae. Salomon considers the term "exanthema subitum" less suitable than Zahorsky's term "roscola infantilis" or Glanzmann's term "exanthema irritium." D. BARS (Wien. med. Woch., October 31st, 1925, p. 2435), director of the children's department at the Hadassa Hospital in Haifa, records three sporadic cases of exanthema subitum in infants aged 2½ months, 8½ months, and 11 months. No similar cases have been described before as occurring in the East, and particularly in Palestine.

230. Arthropathy as an Initial Symptom of Tabes.

R. ZANOLI (*La Chir. degli Organi di Movimento*, October, 1925, p. 613), who records two illustrative cases, states that the incidence of bone and joint complications in tabes is estimated at 4 to 5 per cent. by Marie and twice as high by Lotheissen. In both Zanoli's cases arthropathy was a very early symptom of the disease, as neither showed ataxia or disturbance of the tendon reflexes. The first patient was a man, aged 52, who had contracted syphilis at 18 and had remained in good health until 51, when, after a slight injury to the left knee, he developed a painless swelling of the joint. The suspicion of tabetic arthropathy was confirmed by changes in the pupils and superficial sensibility as well as by x-ray examination, which showed the typical appearances of a tabetic joint. Zanoli's second patient was a man, aged 33, who had contracted syphilis at 22, and ten years later, without obvious cause, developed slight pain in the right hip, shortening of the limb, and a limp. The diagnosis of tabetic arthropathy was confirmed by the presence of typical disturbance of superficial sensibility and characteristic changes of the head of the femur on x-ray examination.

231. Lumbar Puncture in Meningitis.

REICHE (*Med. Klin.*, January 2nd, 1926, p. 37) describes his procedure in lumbar puncture. He introduces two needles; fluid passes out through the lower one and air is forced in through the upper one. From 60 to 200 c.cm. of the spinal fluid can thus be removed. Disinfectants may also be introduced through the upper needle and a 40 per cent. solution of urotropine is suggested. Reiche thinks this treatment should be beneficial in all forms of meningitis except the tuberculous type. It also facilitates the x-ray diagnosis of internal hydrocephalus.

Surgery.

232. Intermittent Joint Effusion.

H. SCHLESINGER (*Wien. klin. Woch.*, January 15th, 1926, p. 68), who in 1903 published a monograph on intermittent effusions into joints, now reports nine additional cases of this condition, which appears as a recurrent articular swelling at regular intervals, without inflammation, endocardial disease, or permanent changes in the joint. The condition usually affects one knee, but sometimes both are involved; any other joint may be simultaneously affected, even the mandibular or an intervertebral articulation, as in one of the new cases reported. The effusion returns in the same joint with constant regularity for each patient, so that the date of the next attack can be predetermined; the interval varies in different individuals from a few days to several weeks. Paraesthesia or severe pain may precede its appearance by a few days or accompany it. The maximum extent is reached in two or three days, when the normal contour of the joint is lost; the skin is often pale and slightly oedematous, but not hot, while pressure is painless. Usually in four or five days the swelling subsides, without leaving residual periarticular or osseous changes. Fever is occasionally present at the commencement. The condition has been observed in patients over periods of twenty and even thirty years; it is more common in women and the neurasthenic. The onset has followed trauma. Pregnancy has some influence on the condition in women. It sometimes starts soon after parturition, and may continue until the next pregnancy, when it disappears until after parturition. An hereditary or familial factor is sometimes present, but often other members of the family suffer from some other disturbance of the vasomotor system, such as angioneurotic oedema, to which the author thinks the condition is analogous. He suggests that it is caused by a metabolic toxin which affects the vasomotor system, and that the gonads influence the disease in some way, since

it has not been reported before puberty or after the reproductive life of the individual is over, while it is influenced by pregnancy. He has found no treatment effective, but two of his patients recovered spontaneously.

233. The Wrist Mobility in Diagnosis.

E. F. CYRIAX (*Journ. Anat.*, January, 1926, p. 199) calls attention to a possible fallacy in testing the extent of pronation and supination when the elbow is fixed. He has demonstrated the existence of a considerable amount of passive rotation of the wrist by placing the hand, with the fingers abducted, flat upon a table and immobilizing it by holding it with the other hand while alternate pronation and supination at the wrist are performed. By a series of studies of dissected and undissected arms the amount of rotation of each of the carpal bones was found to average 24.5 and 19 degrees respectively, though considerable variations existed, especially in the case of the semilunar bone. In the living subject the range of passive rotation of the wrist, as elicited by fixing the radius and ulna with one hand and rotating the hand alternately in both directions, was found to be about 45 degrees. Cyriax adds that in attempting to break down adhesions passive rotation will frequently accomplish results unattainable by other passive movements of the wrist.

234. Haemangioma of the Breast.

B. LUBARSKY (*Zentralbl. f. Chir.*, January 9th, 1926, p. 77) states that Kormmann (Odcssa) has collected eleven cases of the rare condition of mammary haemangioma, in which the diagnosis was confirmed histologically. Lubarsky now reports the case of a nullipara, aged 26, who had had a painless tumour of the inner quadrant of the right breast as large as a plum for four months. The tumour was removed under local anaesthesia: it was nodular and contained one large and a few small cysts filled with a yellowish-red fluid. The stroma consisted of firm connective tissue with few nuclei and areas of apparently hyaline degeneration; some islands of fat were seen, within and around which round-celled inflammatory infiltration had occurred. No gland tissue was found, but some excretory ducts were seen. The parenchyma of the tumours consisted of a mass of dilated capillaries, lined with swollen endothelial cells and filled with blood corpuscles. These tumours have been classified as (1) cutaneous angioma involving the nipple or areola, (2) subcutaneous haemangioma, (3) glandular haemangioma; but Klebs denied the possibility of the development of a haemangioma in glandular tissue. Other authors have stated that these tumours originate during childhood, and that trauma hastens their development. Both sexes are affected equally; according to Kormmann haemangioma is found three times more frequently in the right than in the left breast, and ranges in size from that of a nut to that of an orange or more. The tumour may be fluctuating or tense; the skin is usually unaltered, but it may be tightly stretched over the tumour and colourless, or it may exhibit numerous telangiectases. The ordinary haemangioma is usually single and painless, but in one case it was tender; it has a well defined capsule of connective tissue, but the cavernous form has none; it is diffuse, and penetrates the glandular tissue. Removal is the only treatment. Recurrence has not been reported.

235. Post-encephalitic Tic of the Diaphragm.

G. J. GAMBLE, O. H. P. PEPPER, and G. P. MULLER (*Journ. Amer. Med. Assoc.*, November 7th, 1925, p. 1485) record a case in a man aged 38, whose attack of epidemic encephalitis was followed by marked tachypnoea with nothing to explain it in the heart or lungs. The respirations were 84 to the minute. There was tremor of the outstretched hands, especially the left, and some ataxia and weakness of the left hand. Simultaneous pneumographic tracings of the chest and abdomen showed that the rapid breathing was due, not to frequent normal respiratory movements, but to definitely abnormal spasmodic contractions of the diaphragm. Chemical analysis of the blood confirmed the view that there was overventilation as a result of the tic with the synchronous and rapid respiratory movements. The respiratory centre was not receiving normal stimuli to respiration and was not sending out strong rhythmic impulses. It seemed probable that there was no actual damage to the respiratory centre itself, but that the respiratory disturbance was entirely secondary to the overventilation induced by the diaphragmatic tic. As relief had been obtained in cases of post-encephalitic hiccup by blockage of the phrenic nerves by injection of procain or alcohol, or by freezing, the authors determined to employ blockage of the phrenic nerves in the present case, which presented a similar condition. An incision was made on each side of the neck, and the phrenic nerves exposed and frozen with ethyl chloride spray. During the operation the respirations fell from 90 to 20 a minute, and the relief at the time of publication had lasted seven months.

Therapeutics.

236. Insulin in Diabetic Coma.

J. GRÉ (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, January 10th, 1926, p. 7) observes that acidosis is of far greater import than hyperglycaemia, which may exist for a long period without the onset of coma. Acidosis has been attributed to destruction of the acid-base equilibrium in the blood, and it is generally recognized that it may arise from many causes, such as starvation, nephritis, pregnancy, cyclic vomiting of children, shock, and anaesthesia. Acetone bodies are produced by defective oxidation of hydrocarbons and proteins. Gré states that importation of foreign insulin is prohibited in France, and that the various French products are insufficiently standardized, which may account for the fact that insulin has not received in France such approval as in England and America. He believes that the best results are obtained from subcutaneous or intramuscular injection; only in cases of extreme urgency should it be given intravenously, and then it must be injected very slowly. Rectal administration, he finds, is useless. In "intensive" treatment 40 units should be injected at the beginning, followed by 20 units every two hours, as long as coma persists and the percentage of sugar does not fall. If the patient's condition improves doses may be given at longer intervals, but the patient should receive 200 to 300 units during the first twenty-four hours. At the same time glucose should be administered (in 4 per cent. solution) subcutaneously, or in urgent cases intravenously. Gré points out also that American authorities insist on the great importance of such adjuvants as hot-water bottles, administration of fluids by Einhorn's tube, and hot coffee or broth every fifteen minutes to arrest vomiting. After two hours lemonade sweetened with glycerin should be given, since glycerin checks the formation of ketone bodies. Orange juice may also be administered when the patient can swallow. If vomiting persists the stomach may be washed out with tepid saline solution. To stimulate the heart, digitalis, caffeine, or camphor in oil and subcutaneously should be administered. Frequent examinations of the urine should be made, the estimation of the degree of acidosis being much more important than that of the glucose content of the urine.

237. Hepatic Symptoms during Arsenical Treatment.

BERTRAND (*Bulletin Médical*, January 17th, 1926, p. 380) remarks that the distinction between the toxic conditions produced by arsenic and syphilis is not always clear, particularly in the case of hepatic symptoms. Early jaundice during the arsenical treatment of syphilis may be due to the massive destruction of spirochaetes (Herxheimer reaction), or to reactivation of the spirochaetes in the liver tissue—in either case of syphilitic origin. Jaundice occurring near the end of the course of treatment is much more likely to be due to the arsenic. Bertrand considers, however, that exceptions to these generalizations are not infrequent. In his experience ten out of fifteen patients gave a history of liver disease, five of them being Africans; others gave a family history of gall stones, while one had had malaria. When the jaundice appeared late in the course it could be checked readily by stopping the arsenic. The author thinks that arsenic in large doses may cause toxic hepatitis, and that the optimum therapeutic concentration lies near the toxic limit. Therefore if the latter be lowered, as by a tendency to hepatic disease, the hepatic cell may become more susceptible to the drug than is the treponema itself.

238. Chloralose in the Insomnia of the Insane.

A. MARIE and V. KOHEN (*Bull. Soc. de Thér.*, December, 1925, p. 272) state that since Richet and Haariot demonstrated the hypnotic and anaesthetic properties of chloralose and its homologues in 1893, numerous clinicians have emphasized its hypnotic effects as well as the uncertainty of its action and the occasional appearance of nervous disturbances which have given rise to its being abandoned as a hypnotic. The uncertainty of its action must be attributed to its insufficient purification. Chevallier and Cherhuliez have shown that these drawbacks were principally due to the presence of parachloralose, from which it could not be completely freed by the old method of preparation. Since the work of Aguilhon, however, a chemically pure chloralose has been obtained in the form of fine crystalline needles with a bitter taste, which are only slightly soluble in cold water, more soluble in hot water, and very soluble in oil. Richet has shown that the action of chloralose is confined to the grey matter of the cortex without affecting the bulb and spinal cord. The present authors have given the drug by mouth to 20 patients in the Sainte-Anne Asylum in doses of 0.10 to 0.60 gram for from two to eight weeks with or without interruption. The patients were suffering from various forms of mental disease in which their insomnia was not affected by

other hypnotics. Hypodermic or intramuscular injections in doses of 0.10 to 0.40 gram were given in cases where chloralose was ineffective by the mouth. The injections were not painful, but often no effect was obtained until a dose of 0.30 or 0.40 gram had been reached. When chloralose was injected intravenously in doses of 0.05 to 0.40 gram sleep accompanied by anaesthesia was obtained in fifteen to twenty minutes. The authors conclude that with the exception of the last stage of general paralysis, in which the sleep centro appears to be destroyed, clinically pure chloralose seems to be of great benefit in nervous insomnia.

239. The Use of Oil in Artificial Pneumothorax.

G. DESMET (La Vie Méd., December 18th, 1925, p. 2039), discussing the pneumothorax treatment of tuberculosis, suggests the injection of oil into the pleural cavity. He states that it is a better compressor of the lung than air and therefore refills will be less frequently required. It can also be combined with antiseptics which have a deterrent action on the development of effusions. Desmet uses a mineral oil and adds to it goménol, a French proprietary balsamic preparation. This antiseptic is absorbed by the pleura and fresh quantities must be introduced from time to time in order that the oil may remain completely sterile. He injects the oil also in cases of pleural effusion, and finds that the emulsion which it forms with the pleural fluid is inimical to the growth of secondary organisms.

240. Treatment of Posterior Gonorrhoeal Urethritis.

M. MICHAÏLOVSKY and P. M. BUTTERFIELD (Urol. and Cut. Rev., November, 1925, p. 662) believe that the incidence of posterior urethritis in gonorrhoea amounts to as high as 90 per cent. In their own cases it occurred in 63 per cent. The average date of its onset in their cases was the twelfth day, the earliest date being the fourth day and the latest the twenty-eighth day. The authors recommend the following method of treatment, based on a series of fifty cases. In each case a concentrated non-irritating antiseptic solution was instilled into the posterior urethra with a No. 10 Gnyon catheter. A 10 per cent. solution of silvol was the most satisfactory solution. Acrilavine in a solution of 1 in 4,080 was also largely used and in most cases well tolerated. In resistant cases solutions of protargol and argyrol and silver nitrate from 1/4 to 2 per cent. were used. Patients with acute posterior urethritis were treated twice daily, the solutions being retained in the bladder as long as possible. As the urine clears and the discharge lessens the number of injections may be reduced. Patients with chronic posterior urethritis need only one injection daily. Old and new strictures must be dilated as soon as the urine clears and gentle massage given to the prostate and seminal vesicles if their secretions show more than a normal white blood cell content. The authors' patients treated by instillations of the posterior urethra were free from infection on the eighteenth day and clinically well on the twenty-eighth day of treatment.

Ophthalmology.

241. Glaucoma in Myopic Eyes.

A. KNAPP (Arch. Ophthalmol., January, 1926, p. 35) records 32 cases of glaucoma in myopic eyes, controverting the widespread—though erroneous—idea that the myopic eye is immune to glaucoma. In all these cases the glaucoma was of the chronic type with a deep anterior chamber, no great rise in tension, some excavation of the discs, which, however, was often somewhat disguised by the surrounding myopic change, and definite and characteristic field changes. The results of operation were on the whole satisfactory and compared well with the operative results of chronic glaucoma in emmetropic and hypermetropic eyes.

242. The Treatment of Painful Blind Glaucomatous Eyes.

H. NEAME and WAJID KHAN (Brit. Journ. Ophthalmol., December, 1925, p. 618) describe their investigations into the occurrence of new growth of the choroid in blind painful glaucomatous eyes. In 402 cases in which glaucomatous eyes were excised 16 (4 per cent.) proved to contain sarcoma of the choroid. In all these cases there was not the least suspicion of new growth prior to excision. In this series the average age of the patients at the time of excision was well above the average age of appearance of sarcoma of the choroid and near the middle of the age period of the onset of congestive glaucoma (50 to 70). They come to the conclusion that the treatment of cases of blind painful glaucomatous eyes should be enucleation, excepting possibly in the few cases in which the media of the eye are sufficiently transparent to allow of complete examination of the fundus.

243. Inflammation of the Cornea caused by Silver Nitrate.

J. FEJER (Amer. Journ. Ophthalmol., November, 1925, p. 863) describes the case of a newly born infant into whose eyes the midwife instilled silver nitrate drops as a prophylactic measure. Instead of a 1 per cent. solution a strength of 10 per cent. was used in error. Three months later the right cornea showed a round diffuse opacity the size of a pin's head in the lower and inner quarter, and the left cornea a widespread diffuse nebula in the central zone. Fejer claims that silver acetate is a much safer antiseptic for routine prophylaxis. He asserts that silver acetate prevents ophthalmia neonatorum as well as silver nitrate, that it causes less catarrh, and does not become concentrated on standing. An additional and most important recommendation is that at room temperature it is only soluble to a 1 per cent. strength, the remaining salt being thrown out of solution. It is impossible therefore for an overdose of silver acetate to be given.

244. Unilateral Proptosis due to Scurvy.

E. CLIFFORD PLACE (Amer. Journ. Ophthalmol., December, 1925, p. 955) describes a case of unilateral proptosis coming on suddenly in a male infant aged 8 months. The possibility of this being due to scurvy was recognized at once, but an erroneous report of the infant's diet directed attention elsewhere. Eventually an incision was made into the orbit and the remains of a large subperiosteal haematoma situated along the orbital plate of the ethmoid was found. The child rapidly improved on a suitable diet. The ocular signs of scurvy, which may be the first and in the early stages the only signs, are protrusion of the eyeball and haemorrhage beneath the skin of the lids. The proptosis usually occurs suddenly, and often after a fit of crying.

Obstetrics and Gynaecology.

245. Pregnancy complicated by Pyelitis.

J. T. WILLIAMS (Amer. Journ. Obstet. and Gynecol., December, 1925, p. 765) reports twelve cases of pyelitis complicating pregnancy, and expresses the opinion that this condition is not due directly to the pregnancy, but pre-exists in most cases. He thinks that a chronic infection is brought to a state of acute activity by the pregnancy and persists after it, the stages of development being as follows. The kidney becomes prolapsed and the pelvis dilates with or without kinking of the ureter. The excretory apparatus is strained during pregnancy, with later some compression of the ureters by the foetal head; urinary stasis follows, and infection with *B. coli*. In eight of the author's patients the right side alone was involved, and in two both sides. This preponderance of involvement of the right kidney is possibly attributable to the right lateral torsion of the uterus which is common in pregnancy; the abnormal mobility of the right kidney; the fact that the foetus more commonly occupies the right oblique diameter of the pelvis; and the close relation of the ascending colon and its lymphatics to the right kidney. Pyelographic examinations confirmed the presence of kinking of the ureter and dilatation of the pelvis. The author adds that catheterization usually proves effective.

246. Puerperal Sepsis.

E. A. SCHUMANN (Med. Journ. and Record, December 16th, 1925, p. 722) observes that puerperal sepsis begins almost always as a localized endometritis which may remain localized with little systemic disturbance, be followed by systemic absorption of bacterial endotoxin, or by an entrance of the invading organisms into the blood stream. The infection may spread by continuity, involving the veins of the broad ligaments, or small necrotic masses may enter the tubes and cause salpingitis. General peritonitis may occur. In a few cases the infection is autogenous. The diagnosis of these several types of puerperal sepsis is most important, the author states, since any hope of success in treatment depends on interpreting correctly the exact pathological condition. Repeated physical examinations are necessary in order that the right moment for the evacuation of a localizing collection of pus may be recognized. The general mortality is about 30 per cent., but when the *Streptococcus pyogenes haemolyticus* is the causal organism the death rate is from 60 to 80 per cent., and in general peritonitis from 85 to 90 per cent. Sepsaemia, localized infection, cellulitis, and salpingitis, carry a low mortality. The author recommends the use of pituitrin and a combination of ergot and strychnine. Septic material accumulating in the vagina should be removed

by gentle irrigation at frequent intervals. Where the infection remains apparently localized in the uterine cavity attempted sterilization by Dakin's fluid is advocated. A small rubber tube with minute perforations is introduced into the uterine cavity, a light gauze plug applied to the cervix, and Dakin's solution instilled by the continuous drip method. The gauze is changed daily, and should not be placed too firmly to allow free return of the fluid by seepage through it without distension of the uterus. The author maintains that the curette, the placental forceps, and even the gloved finger have no place in the treatment of septic endometritis in the puerperium. Repeated blood transfusions and rectal injections of 5 per cent. sodium bicarbonate solution are advised. For the sterilization of the blood stream the use of a 1 per cent. mercurochrome solution in sterile water is advocated. An initial dose of about 30 c.cm. is slowly injected intravenously with a salvarsan syringe, and a violent reaction occurs in thirty minutes to six hours. Shock during the reaction is met by the administration of adrenaline, strychnine, or other cardiac stimulants; diarrhoea by the administration of opium, belladonna, and bismuth; and chill is treated by local external heat. The symptoms of reaction usually subside within forty-eight hours, when another injection of 30 to 35 c.cm. of mercurochrome solution is given. Surgical intervention is indicated, according to Schumann, only when definite evidence of localization of pus is present.

247. Treatment of Leucorrhoea.

S. RECASSENS (*Arch. de med., cir. y esp.*, January 30th, 1926, p. 207) states that leucorrhoea may or may not be of microbial origin. Before puberty the vagina contains only cocci which produce an alkaline reaction, but subsequently the invasion of the genital tract by various saprophytes causes the alkaline reaction to become acid, with the result that pathogenic organisms find it more difficult to grow in this medium. The acidity becomes more pronounced in certain circumstances, such as pregnancy, when the need for a defensive reaction is greater. The production of some forms of amicrobial leucorrhoea, in which the glycogen stored up in the genital cells plays an important part, depends on biological causes, and often on changes in the composition of the blood. Thus chlorotic girls suffer from leucorrhoea which is connected with nutritional changes in the vaginal cells, and in such cases considerable quantities of glycogen are found in the leucorrhoeal discharge. Rational treatment of leucorrhoea depends on the recognition of the nature of the process; 75 per cent. of all leucorrhoeas are due to the gonococcus. Strong solutions of the antiseptics most commonly used, such as thymol, carbolic acid, potassium permanganate, and iodoform, increase leucorrhoea, while weak solutions have no bactericidal action, but cause a swelling of the epithelium and consequently an abnormal increase of secretion. Moreover, repeated irrigations may give rise to the antiseptic fluid used being converted into a culture medium. The inefficacy of vaginal irrigations has led to the use of the so-called "dry cure" of leucorrhoea, in the form of application of aluminium oxide powder or silver nitrate. Treatment of gonorrhoeal leucorrhoea with silver salts often yields satisfactory results, but sometimes very obstinate cases are encountered in which the infection has invaded the blood stream. Recassens adds that the employment of such drugs as sandalwood oil, copaiba, cubebs, and arretol, on the ground that they are eliminated by the kidneys and so come in contact with the infected urethra, is illusory, as in 90 per cent. of the cases gonococcal leucorrhoea is not accompanied by urethritis, and it is only in cases in which the bladder is involved that the use of these drugs is justified. Treatment by intravenous injection of various antiseptics, such as gold or colloidal copper, has not yielded the desired results, but has merely given rise to the appearance of casts in the urine.

248. Treatment of Gonorrhoea in Women by Diathermy.

P. J. VAN PUTTE (*Nederl. Tijdschr. v. Geneesk.*, January 30th, 1926, p. 437) states that, in addition to local antiseptic measures, a local non-antiseptic treatment has been introduced in the form of diathermy, which produces surprisingly good results in chronic gonorrhoea. Owing to anatomical conditions diathermy is more suitable for the treatment of the disease in women than in men. One electrode is introduced into the vagina up to the posterior fornix and the other is placed on the abdomen or on the flanks. The whole genital apparatus, including the urethra and bladder, is treated at one sitting, which lasts two hours the first day and one hour each of the three following days. The patients are irrigated twice daily with an astringent, such as potassium permanganate or copper sulphate solution. The strength of the current is not more than 1.5 amperes. The rationale of the treatment is that the application of heat to the infected tissues produces an increased formation of antibodies which destroy the gonococci.

Pathology.

249. The Presence of a Transmissible Lytic Agent in Water.

F. ARLOING and SEMPÉ (*C. R. Soc. de Biologie*, January 29th, 1926, p. 191) have found that the water of certain of the French rivers has an inhibitive or actually destructive effect on the growth of the intestinal bacteria. As examples may be quoted the antagonistic action to *B. coli* of the Saône, to *B. typhosus* of the Rhône, to *B. paratyphosus A* of the Isère, and to *B. dysenteriae* Shiga of the sea in the port of Havre. An extensive series of observations has been carried out on waters in different parts of the world. The results show that many streams possess the power of lysing one or more of the pathogenic bacteria, and that the lysis can be carried over from one culture to the next for a considerable number of passages. It is possible that this lysis may be of chemical nature, but the fact that its action is often unimpaired after several passages, and may even be exalted by this procedure, renders this supposition unlikely. Moreover, it is unusual to find purely chemical agents with the degree of specificity obviously possessed by this lytic agent. The authors consider that the lysis is probably of a similar nature to that described by Twort and by d'Herelle. If this is so it is important from a hygienic standpoint as being a hitherto unrecognized means, by which the self-purification of waters is attained. It may also serve to explain why certain regions and certain persons are immune to water-borne diseases.

250. Basal Metabolism in Pulmonary Tuberculosis.

M. REALE (*Il Morgagni*, January 3rd, 1926, p. 9) has estimated the basal metabolism in 116 cases of pulmonary tuberculosis. The methods employed were the indirect calorimetric method and the more precise one of Zuntz-Geppert. In this way not only was the consumption of oxygen estimated, but also the amount of carbon dioxide produced. Most of the patients examined were undergoing the ambulatory treatment, but the clinical and pathological types of the disease from which they were suffering varied considerably. The results showed that the majority had a basal metabolism closely approximating the normal, varying generally within 10 per cent. above or below this value. In the favourable cases the values tended to be below normal; in the serious cases above normal. In some of this latter type of case the values obtained were as high as 64 per cent. above the normal. The patients with a low basal metabolism as a rule gained weight; those with a high basal metabolism lost weight. In patients with a low basal metabolism there was a slight or moderate degree of allergy, whereas in those with a high basal metabolism a state either of hyperallergy or of complete absence of allergy was noted. An increase in respiration was observed in advanced cases of pulmonary tuberculosis, generally accompanied by a rise in the basal metabolism; in less advanced cases showing an increase in respiration the basal metabolism was normal or even depressed.

251. The Chemical Nature of Tuberculin.

J. H. MUELLER (*Journ. Exper. Med.*, January, 1926, p. 1) states that "old tuberculin" is a complex product containing one substance which is responsible for the precipitin and complement fixation reactions and another which produces the skin reaction. It was observed that a solution of old tuberculin treated by peptic or tryptic digestion gradually lost its power to provoke a skin reaction in tuberculous guinea-pigs but retained its precipitating power unimpaired. Similarly, precipitation of the protein with acetic or tannic acid had the same effect. This suggested that the factor responsible for the skin reaction was of protein constitution, while the one giving the precipitin test was of non-protein constitution. This surmise was proved to be correct. By growing tubercle bacilli in a synthetic medium, and precipitating the partly evaporated fluid with alcohol, a residue was obtained consisting of a non-protein gum that gave the precipitin but not the skin reaction. By treating the culture fluid with 5 per cent. acetone, dialysing, and subsequently precipitating with dilute acetic acid, the protein fraction was obtained, and was found to give the skin but not the precipitin reaction. These two reactions are therefore caused by different substances in the tuberculin—the skin reaction by a protein fraction (or at least a fraction containing a considerable quantity of protein), the precipitin reaction by a non-protein gum. In another paper (p. 9) the preparation of the non-protein gum is described in detail. The deduction is drawn that, as the substance responsible for the toxic action of tuberculin is different from that concerned with the precipitin and complement fixation reactions, the present methods of standardizing tuberculin by *in vitro* tests must be revised.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

252. The Clinical Course of Diabetes.

H. F. ROOT and S. WARREN (*Boston Med. and Surg. Journ.*, January, 1926, p. 45) believe that regeneration of the pancreas plays a greater part in the clinical course of diabetes than has previously been realized. They have collected a series of 26 cases of diabetes, including 6 of a very chronic type and others of an acute nature. Death in 22 of the cases was due to complications, and it is thought that the fatal issue might have been prevented in 10 cases. Arterio-sclerosis was present in 10 cases, while fibrosed coronary arteries existed with myocardial change in 11 cases. Cholelithiasis and cholecystitis occurred in 32 per cent. of cases over 25 years of age. In 13 cases hyalinization of the islets of Langerhans was found, and a variable degree of sclerosis of the islets was present in 5 instances. In 3 patients there was a slight lymphocytic invasion of scattered islets and in 5 more no obvious lesions could be found, although the number of islets was decreased in two of these five. Normal islets were present in all the pancreatic glands examined, and in 2 cases treated by insulin over a period of five months the number of normal islets seemed greater than in those patients who had received dietetic treatment alone. Root and Warren suggest that the pathological lesions in the islets are due either to prolonged functional strain or to some toxic process of a chronic nature. They point out that in haemochromatosis the type of diabetes is the same as that in diabetes mellitus, and both acinar and islet units exhibit evidence of regenerative changes. In the case of diabetes they believe that long-continued strain, either functional or caused by chronic toxæmia, slowly destroys the islets and in certain cases the acinar tissue also. Regeneration occurs, but it is followed by destruction of the newly formed units, and again new cells are formed. The rarity of uncomplicated deaths in diabetes suggests the presence of some regenerative power; the first two years are the danger period and coma is the condition to be most carefully prevented. The disturbance of the carbohydrate metabolism in diabetes mellitus, giving rise to abnormal fat and protein metabolism, may, they add, be a contributing cause of the high incidence of vascular disease.

253. Tertian Malaria with a Long Latent Period.

V. FOSSATI and C. SALVO (*Rev. Sud-Am. de endocrinol.*, December 15th, 1925, p. 871) record a case in a man, aged 29, who contracted malaria while living in an infested district in Italy during 1919-20. The disease, however, was not manifested at the time by fever or any other symptoms, and it was only after the patient came to Buenos Aires, five years later, that symptoms of benign tertian developed and *Plasmodium vivax* was found in the blood. Cases of latent malaria were first described by Koch, who observed them in natives of Africa. Other writers, especially during the world war, found that actual malaria carriers exist, as occurs in other diseases, such as typhoid fever, cholera, etc. These carriers have been discovered by methodical examination of their blood. The present authors' patient was undoubtedly an example of the kind. His absence of symptoms was due to a natural immunity which was diminished by a combination of circumstances, which included a change of life, work, and climate. Such cases of prolonged latency are rare, and are of considerable epidemiological and social importance. Treatment by quinine is very efficacious, and should be continued for a long period.

254. Sea-Sickness.

P. H. DESNOES (*Journ. Amer. Med. Assoc.*, January 30th, 1926, p. 319) believes that sea-sickness in the healthy adult is usually due to excessive stimulation of the labyrinth. The effects on the body as a whole are, he thinks, most plausibly explained by radiation of these stimuli from their receptive centres in the brain to such associated centres as the vasomotor, respiratory, and vagal. Other factors in the condition are fatigue of the eye muscles, disturbance of the meniscular sense reflexes, irritation in the gastro-intestinal tract, and certain neurotic or psychic reactions. The immunity of a healthy adult to the effects of the ship's motion, which is usually established after three or four days, is said to be due to the brain having learned to inhibit the irritating sensations or to be less affected by them. This immunity is not permanent, but is more readily acquired on a second voyage than on a first. After many voyages complete freedom from sea-sickness may be expected, with the exception of slight

relapses during severe weather conditions. Failure to acquire such immunity may be due to the presence of low-grade, chronic inflammatory foci in the gastro-intestinal tract such as colitis or gall-bladder disease; anatomical malformations and congenital anomalies; improperly balanced diets; and a possibly inherited inferiority of the adaptive mechanism of the brain. Since stimulation of the horizontal semicircular canals is the least objectionable; the recumbent position is often found to be beneficial. When the condition does not respond to treatment, careful examination is required, since a slight pre-existing cardiac incompetence may be aggravated by the efforts of vomiting and cause passive congestion of the abdominal viscera. In treatment Desnoes places main reliance on the use of scopalamine and strychnine; he has, however, obtained good results from sedatives and centrally acting hypnotics, such as chloralhydrate and veronal. When viscerospasm exists, an elastic belt or adhesive plaster support may be very valuable. In cases of excessive vomiting that resist treatment, morphine combined with atropine must be used, and after the sleep so induced is ended the patient must not be allowed to raise his head for several hours. Careful attention must be paid to the diet and to the regular action of the bowels.

255. Active Immunization against Diphtheria.

W. BAYER (*Jahrb. f. Kinderheilk.*, November, 1925, p. 272) has recently employed the method introduced by Böhm and Ricbold of using living Klebs-Loeffler bacilli for immunization against diphtheria. From January, 1924, to February, 1925, 87 infants, aged from 4 to 12 months, with positive Sebek reactions, were inoculated by this method at the Berlin University Children's Clinic. The skin of the thigh or upper arm, after previous disinfection, was scarified to an extent of 1 to 2 cm. and the contents of a capillary tube containing the bacilli were rubbed in. No constitutional symptoms or sequelae were observed. The local reaction consisted in slight redness at the site of inoculation and pustule formation, which subsided in five or six days without leaving any trace. Of the 87 children inoculated 63 gave a negative Sebek reaction on the tenth to twelfth day after inoculation. Nine months later 39 children were examined: 10 in whom the positive reaction had at first persisted were now found to be negative, and the remaining 29 continued to be negative. None of the children had had an attack of diphtheria in the interval. Bayer concludes that the method is inexpensive, readily applied, and yields the same results as those hitherto employed. The lack of exactness in the dosage is its only drawback.

Surgery.

256. Dupuytren's Contraction.

P. COKKALIS (*Dent. Zeit. f. Chir.*, January, 1926, p. 256), who records an illustrative case, states that Dupuytren's contraction, which usually affects only the palmar fascia, may also involve the plantar aponeurosis. Such cases, though very rare, have been described by Dupuytren himself and by Madelung. Cokkalis's patient was a man, aged 52, whose hands had been affected for the last nine years. One year after the onset of the disease in the hands the patient noticed a feeling of tension on walking, first in the left sole and later in the right. On examination both hands showed typical Dupuytren's contraction, all the fingers of the left hand being affected, and the third, fourth, and fifth fingers of the right hand. In both soles, especially the left, a tough cord could be felt beneath the skin on the mesial border of the foot and became particularly prominent on dorsal flexion of the great toe, the movement of which was decidedly less than that of the other toes. G. SPROGIS (*ibid.*, p. 258) reports the occurrence of Dupuytren's contraction in three generations. The genealogical tree showed 17 cases of the disease, of which 15, or 88.24 per cent., were in males and 2, or 11.76 per cent., in females. Sprogis's cases confirmed the investigations of Krogius that apparently healthy women can transmit the disease. In addition to typical cases of Dupuytren's contraction there were six examples of induration of the extensor tendons of the fingers; one patient besides Dupuytren's contraction showed marked thickening of the nails, and two were imbeciles. There were no examples of os priapi, or formation of bone in the penis, which according to Hans Sniend is sometimes associated with Dupuytren's contraction.

257. The Subsequent History of Benign Mammary Tumours.

P. WALZEL and F. STARLINGER (*Deut. Zeit. f. Chir.*, January, 1926, p. 152) state that from January 1st, 1903, to December 31st, 1922, 248 women and girls were admitted to the First Surgical Clinic of Vienna University with benign tumours of the breast. In 216 the tumours were classified as adenofibroma or fibroadenoma, and in 32 as chronic mastitis or papillary cystadenoma. Sixty-seven, or 27 per cent. of the 248 patients, presented themselves for subsequent examination, consisting of 53 whose tumours had been classified in the first group and 14 in the second. The first group of patients were mostly in the third, fourth, or fifth decennium when they came under treatment. Both breasts in this group were affected with almost equal frequency. The same is to be said of the upper two quadrants. The lower and outer quadrants were affected in 11 cases, and the lower and inner in only 4. Bilateral involvement was found in only 3. The size of the tumour in the first group ranged from that of a hazel nut to that of a hen's egg. Most were the size of a walnut or slightly larger. There was no marked difference in the size of the tumours in married and unmarried women, or in nulliparous women on the one hand and multiparous women on the other. The second group of patients were mainly in the third or fourth decennium. In 7 both breasts were affected; with four exceptions, in which the tumour was the size of the first, it was almost always the size of a hen's egg. There was no essential difference in the frequency with which the different quadrants of the breast were affected, apart from the fact that the lower internal quadrant always escaped. One case showed evidence of carcinoma of the nipple. Operation was performed in 48 and refused in 5 cases of the first group; in the second group 8 cases underwent operation. In several instances in which operation had been refused the tumours subsided spontaneously. The operation, which was almost always performed under local anaesthesia, consisted in excision of the breast with preservation of the nipple, a good functional and cosmetic result being obtained.

258. The Treatment of Recurrent Dislocations of the Shoulder and Patella.

S. S. GIGOLAFF (*Zentralbl. f. Chir.*, January 16th, 1926, p. 138) refers to the operations devised by Plummer, Potts, Joseph, and Wülfing (see *Epitome*, August 29th, 1925, para. 157) for the treatment of recurrent dislocations of the shoulder, and describes his own procedure, which aims at strengthening the atrophied and relaxed capsular ligament of the shoulder-joint by means of a broad strip of fascia lata. The deltoid is split vertically so as to bring into view the surgical neck of the humerus below the attachment of the capsular ligament and to permit of the exposure of the acromion and coracoid processes. The shaft of the humerus is then drilled through in an antero-posterior direction; the strip of fascia lata is passed through this canal and crossed over the outer aspect of the capsular ligament. The ends of this fascial strip are then sutured to the two processes, that from the posterior surface of the humerus being brought forward and fixed to the coracoid process, while that from the anterior surface of the humerus passes backwards and is attached to the acromion process. A suture is fixed in the fascial band at its crossing and the ends are sutured to the capsular ligament and periosteum. Gigolaff performed this operation upon three men and one woman during 1925. He reports that so far the functional results are excellent, but the operations are too recent for judgement as to the permanence of the benefit. He has employed the same method of fixation in recurrent patellar dislocation. The patient was a powerfully built seaman, who, after the operation, recovered full movements of the joint without recurrence of the patellar dislocation.

259. Lumbar Pain treated by Sympathectomy.

O. BITTMANN (*Lyon Chir.*, November-December, 1925, p. 757) points out that pain in the lumbar region is one of the most common affections met with in females after puberty. Not only the gynaecologist but all practitioners meet them, and the condition is very difficult and unsatisfactory to treat; opinions differ widely as to their cause and pathology. The pain is usually situated in the lower part of the body, specially in the lumbar region, and varies considerably in character and duration. In a large series of cases the condition was found to be associated with a considerable variety of other affections, the most frequent one being that of general asthenia. This is an affection accompanied by a general visceroptosis, associated with nervous dyspepsia, and defined as neurasthenic dyspepsia. This asthenia may be congenital or acquired. Nine cases of this disease are recorded in detail. The treatment adopted was laparotomy together with periaortic sympathectomy; it is based on the

opinion that there is some chronic inflammatory disease present in one or other of the abdominal organs—in these cases usually in the pelvic region. The nerve fibres of the sympathetic are reflexly irritated by this condition, causing pains in different parts of the body. Interruption of the nervous arc by removal of the sympathetic plexus is stated to be a simple procedure, free from danger, and apparently followed by encouraging results.

Therapeutics.**260. Treatment of Malignant Pustule.**

M. SALOMONE (*Studium*, January 20th, 1926, p. 12) states that since the introduction of antianthrax serum the mortality from the disease in Italy has been reduced to 5.3 per cent., and that if the diagnosis is made early and the treatment properly administered it should be reduced to nil. Out of sixty cases of malignant pustule treated by himself and two colleagues during the last few years only two, which came under treatment late, were fatal. Salomone always uses the thermo-cantery and has abandoned excision, as this procedure opens up the blood vessels and allows the organisms to enter the circulation. In some localizations of malignant pustule, such as the eyelids, the cantery should not be employed and the specific serum only should be used, as the scar left by the malignant pustule is less disfiguring than that caused by the cantery. An ointment composed of copper sulphate and yolk of egg is very effective when there is no constitutional disturbance. When the pustule is well developed and accompanied by oedema the cantery should be used, followed by hot fomentations containing boric acid in the case of the eyelids and 1 in 1,000 perchloride for other parts. Injections of 5 per cent. carbollic acid should be made all round the oedematous area. The dose of specific serum is determined by the pulse and temperature. If the temperature is below 102.2° and the pulse under 130, 20 to 30 c.c.m. is a sufficient dose for an adult; it should be given daily until the temperature becomes quite normal. If the temperature is high and accompanied by severe constitutional disturbance, the dose should be increased, and 20 c.c.m. should be given intravenously. Digitalis is useful in these cases in view of the tendency for the vagus to become paralysed.

261. Iodine in Exophthalmic Goitre.

R. R. FITZGERALD (*Canadian Med. Assoc. Journ.*, February, 1926, p. 159) reports an investigation into 148 cases of goitre which, in addition to operative treatment, had received administrations of iodine, either in the form of Lugol's solution or of resublimed iodine in hydriodic acid. Lowering of the basal metabolic rate occurred in nearly all the cases, irrespective of the kind of iodine used, and the two forms of iodine produced practically the same amount of diminution in the rate, and within the same length of time. It was found necessary, however, to give nearly four times as much resublimed iodine as Lugol's solution to produce the same clinical result. Lugol's solution was given in daily doses of from 6 to 20 minims, and the resublimed iodine dissolved in hydriodic acid in doses of 100 to 200 mg. of iodine daily. The advantages gained by the use of iodine were the shortening of the period of pre-operative rest that was necessary, and the abolition of distressing post-operative reactions. Many cases previously considered inoperable were rendered suitable for surgical treatment.

262. Protein Therapy in Resistant Syphilis.

R. D. HERROLD (*Journ. Amer. Med. Assoc.*, February 6th, 1926, p. 413) reports that the intramuscular injection of gonococcus protein, combined with the intravenous injection of neo-arsphenamine, exerts a markedly favourable influence on the reduction of the Wassermann reaction and on the clinical course of resistant syphilis, especially in the case of glandular enlargements. His patients had had three previous courses of treatment—with neo-arsphenamine intravenously, mercuric chloride intramuscularly, and potassium iodide by the mouth—and the Wassermann reaction was still positive in each case. The protein used consisted of a clear extract of gonococci in normal saline solution, its strength being 500 million per cubic centimetre. Four injections, each of 15 to 20 minims, were given intramuscularly in the gluteal region at intervals of three days and five days. After the last injection a combined administration of neo-arsphenamine intravenously and protein intramuscularly was continued twice a week for four weeks. In each case the Wassermann reaction either became completely negative or was markedly decreased in degree after one course of the combined treatment, and the lymph nodes diminished in size. No adverse symptoms of any kind were observed as a result of the combined treatment.

263. Vaccine Treatment of Typhoid Fever.

L. Y. ESPINOSA (*Druzelles-Méd.*, January 10th, 1926, p. 357) states that as a general rule the first doses of typhoid vaccine should be determined by the patient's sex, age, and fever, and the stage of the disease; subsequent doses should be estimated from the amount of reaction caused by the first. Small doses should be employed at first and their strength gradually increased; 50 million as a rule should be the initial dose. The vaccine should be given as soon as the clinical diagnosis is made, without waiting for bacteriological confirmation. When the patient's condition permits vaccine treatment should be preceded by a purge or an intestinal disinfectant such as calomel. Hitherto the only serious contraindications for vaccine treatment have been a hyper-toxic infection or hyperpyrexial attacks of the ataxo-adydynamia variety of typhoid fever. Cardiac complications are not a contraindication, except during the early stage. The presence of pulmonary complications requires reduction in size of the doses, and on the occurrence of intestinal haemorrhage the treatment must be temporarily suspended. Hyperpyrexia, syncopeal attacks, and much enlargement of the spleen also require suspension of the treatment. The unpleasant effects of vaccine therapy consist in a local reaction at the site of injection which is soon relieved by hot applications, a slight rise of temperature which becomes less marked after subsequent injections, and sweating. The good effects are a sensation of well-being and increase in strength, return of appetite, and shortening of convalescence.

264. A. GAVAZZUTI (*Il Policlinico, Sez. Prat.*, October 26th, 1925, p. 1485) treated 23 typhoid patients with antityphoid serum. Three injections, each consisting of 10 c.cm., were given, with one or two days' interval between; 16 recovered and 7 died. He also treated 24 patients with antityphoid vaccine. Of these 13 had previously received antityphoid serum without any improvement, and 11 were given the vaccine only. Only 3 of the 24 cases died. Apart from slight rashes and pain in the joints no bad effects were noted from the use of antityphoid serum and vaccine. Gavazzuti recommends that the vaccine should be given early in the disease and its use continued after the fall of the temperature so as to avoid relapses.

Dermatology.

265. Attenuated Forms of Acne Varioliformis.

R. SABOURAUD (*Paris méd.*, January 16th, 1926, p. 59) describes atypical forms of acne which occur on the scalp as well as on the body, affecting more severely the middle of the face and chest and the vertebral groove. The crusted top of the lesion comes off, leaving a little ulcerated cone covered with clear exudation which then cicatrizes like a small-pox papule. The morbid process is a necrotic one affecting a hair follicle, sometimes with its attendant sebaceous gland. The course is characterized by successive crops, each preceded by local discomfort. In children local medication is quickly effective, but in the middle-aged the disease may be much worse and more intractable; it has even led to suicide. In young subjects, also, the characteristic distribution on the forehead and temples may lead to a suspicion of the syphilitic "corona veneris." In most patients every form of bread should be strictly excluded from the diet. As with all acnes, sulphur has proved to be the sheet-anchor in local treatment, and the author recommends that it be applied in an ointment of lanoline, vaseline, and resorcin.

266. Treatment of Acne by Testicular Implantations.

L. L. STANLEY (*Urol. and Cut. Rev.*, January, 1926, p. 6) remarks that the sexual organs have a certain influence on the skin, as is shown by the following occurrences. Ringworm of the scalp is nearly incurable in children, but at puberty disappears without any treatment. A dermatitis symmetrica dysmenorrhoeica has been described. All kinds of skin diseases have been influenced by menstruation. Pigmentation during pregnancy is well known. Seborrhoea often disappears in pregnancy. In myoma of the uterus loss of the hair has often been observed. Scleroderma beginning at the menopause has been described. All these facts point to the existence of relations between the skin and the general condition. Stanley, who records 17 illustrative cases, with photographs showing the condition before and after treatment, treated 66 cases of acne in men aged from 18 to 65 by transplantation of testicular substance. The experiments, which were first made in 1918 with testes from executed criminals, were sufficiently encouraging to warrant further investigations. In 1921 a method for transporting testicular substance from animals to man was devised, the glandular substance of the testis, including the interstitial cells and the seminiferous tubules,

being injected beneath the skin of the abdomen. As the result of the treatment 54 patients, or 82 per cent., were benefited, and 18 per cent. showed no change.

267. The Etiology of Psoriasis.

R. BERNHARDT (*Ann. de Derm. et de Syph.*, January, 1926, p. 27) dismisses the theory of the bacterial origin of psoriasis as being incapable of proof and does not consider the disease hereditary in the strict sense of the term. The statistics (varying, according to different writers, from 15 to 44 per cent. of familial cases of psoriasis) show that there is some innate and latent inherited predisposition of familial type which causes the skins of these persons to react to a variety of stimuli. Bernhardt draws an analogy between psoriasis and freckling of the skin, in which such an hereditary predisposition is manifested under the influence of solar rays. Similarly, in psoriasis there is, he thinks, some hereditary specific property of the skin to react, and certain external causes which act as irritants can be defined. Anaphylaxis is also apparently a preponderant factor, since, without this, it is impossible to understand why some members of these families remain free from psoriasis, although living under similar conditions; why psoriasis may appear in elderly patients; why certain patients have recurrences at definite periods; and finally, why untreated psoriasis may disappear completely. He defines psoriasis as a congenital, hereditary, and familial tendency to react to different agents, both exogenous and endogenous, after sensitization of the skin; among the endogenous causes endocrine defect must be considered. Bernhardt's statistics show thyroid deficiency in 42 per cent., gonad deficiency in 22 per cent., and thymus deficiency in 21 per cent. of cases; but the physiology of the endocrine glands is not yet sufficiently understood for any etiological conclusions to be drawn.

268. Salicin in Psoriasis.

G. PERNET (*Arch. Derm. and Syph.*, January, 1926, p. 111) advocates the use of salicin in the treatment of psoriasis. He states that it should be administered in solution, being ineffective in tablet form, commencing with 1 gram in 30 c.cm. of water approximately 15 grains to the ounce, increasing to 1.2, 1.5, or even 2 grams three times a day immediately after meals, frugacanth for its suspension being necessary in the larger doses. During its administration only soothing local applications of lead lotion and occasional sodium bicarbonate baths should be used, chrysarobin and tar preparations being avoided. A case is recorded in which salicin taken regularly and perseveringly had given an interval of eleven years' freedom from an attack, after failure under arsenic and salicin in tablets. The drug does not terminate eruptive attacks, but it was found that fresh elements ceased to appear and the earlier ones became involuted. It has no effect upon old chronic patchy psoriasis. Not being a prophylactic its indefinite continuance is useless after its effects have been obtained in an acute or subacute attack. Pernet has found it useful in attacks of spreading psoriasis in children, young women, and in nursing mothers in whom psoriasis may become acute and generalized as the result of lactation. Those severe and extensive cases seen in elderly people are benefited by rest in bed, and soothing oily calamine applications with salicin internally in increasing doses combined with nuxvomica if necessary. In the acute generalized form associated with rheumatoid arthritis in women whose nutrition was lowered it was found that the rash was diminished and the joints were improved by its administration.

Obstetrics and Gynaecology.

269. Treatment of Severe Uterine Prolapse.

E. SOLMS (*Zentralbl. f. Gynäk.*, January 30th, 1926, p. 263) quotes Stoeckel as stating that failures result in 87 per cent. of severe cases of uterine prolapse treated by operations which, without involving fixation of the uterus to the vagina, the abdominal wall, or the pelvis, consist simply in shortening of the uterine ligaments. He thinks that little advantage is to be gained by such surgical shortening in young women suffering from severe prolapse, in whom, because of the risk of sterilization, vaginal or other forms of interposition are avoided. Rather than perform a ligament-shortening operation in these cases he advises treatment for a time by pessary. In order that this may be retained in the worst cases, he sutures folds of skin from the labia majora over the perineum—a procedure that can also be employed in senile atrophic subjects in whom operation is dangerous. In thirteen cases of severe prolapse he has had lasting success from an operation consisting of fixation of the fundus of the uterus to the symphysis pubis, the uterine body being fixed to and

between the bladder and the recti abdominis muscles, with the cervix directed towards the umbilicus. The action of the intra-abdominal pressure, he states, can only result in a raising of a uterus which has been fixed in this position.

270. Varicose Veins of the Female Pelvis.

L. A. EMGE (*Journ. Amer. Med. Assoc.*, November 28th, 1925, p. 1690) gives a statistical report of twenty-four cases of varicose conditions in the female pelvis, and states that a definitely circumscribed varicocele is of rare occurrence. Venous disturbance causes temporary or permanent dilatation is usually of a varicoid nature and involves one or more divisions of the ovarian and uterine circulation; it is therefore not easily dealt with by surgery. He believes that this condition is mainly due to damage of the fibro-elastic supporting tissue and is only occasionally produced by degenerative changes in the actual walls of the veins. The author's treatment is based on the intimate attachment of the pelvic peritoneum to the suspensory tissue. He has found that by shortening the sacro-uterine and associated ligaments, together with transplantation of the round ligaments, traction can be exerted on the peritoneum and control of the veins obtained with disappearance of large varicose vessels. This method has given freedom from symptoms for from one to seven years and has also removed varicosities due to childbirth. He thinks that resection of the veins is only necessary when some organic disease of the vein walls is present.

271. Thymus Extract in Obstetric Practice.

N. TEMESVÁRY (*Zentralbl. f. Gynäk.*, February 6th, 1926, p. 322), after an intensive trial of thymus extract, reports that it is no more potent in inducing abortion than any other single medicament. At most it produces slight pain, and must be supplemented by such agents as laminaria tents before useful uterine contractions ensue. Sometimes, but not always, when an abortion has already started, thymus extract will hasten its conclusion. With regard to premature birth the same rule holds—namely, that the extract will act only on a uterus made sensitive previously. Its chief use is in encouraging early contractions, at which stage hypophysis is either without action, or else, by producing a continuous pain, involves the risk of uterine rupture or of asphyxiation of the child. In practice the author uses a mixture of both drugs, and claims that complete safety is thereby secured. The preparation acts as well in a first as in later pregnancies, but the pains must be true pains, and not those sometimes felt three or four weeks before the onset of labour. He adds that thymus extract is unsuitable as a substitute for ergot after expulsion of the placenta because the contraction induced is clonic, not tonic.

272. The Value of Radiography in Pregnancy.

S. GENELL (*Gynéc. et Obstét.*, January, 1926, p. 41) refers to a case recorded by Essen-Møller in 1920 in which a skiagram, taken immediately before delivery, showed three foetal heads. He reports a somewhat similar case. A primipara, aged 29, was admitted to hospital when seven months pregnant. There was generalized oedema, especially of the lower extremities, and albuminuria. Two foetal heads could be felt and foetal heart sounds were heard in each flank, with a "silent area" in the mid-line. The diagnosis of "twin pregnancy" was made. Skiagrams of the abdomen and pelvis showed two foetal heads and the shadow of a vertebral column between those of the heads, which obviously belonged to neither. One week after admission labour commenced, and three female children were born alive, but in spite of injections of pituitrin and ergot the uterus failed to contract. The patient lost about 1,200 c.cm. of blood, and died ten hours after the termination of labour. The author emphasizes the value of skiagrams in all doubtful cases of multiple pregnancy.

Pathology.

273. Experimental Transmission of Leprosy.

J. REENSTIERNA (*Ann. Inst. Pasteur*, January, 1926, p. 78) reports the experimental transmission of leprosy to two species of monkeys—*Macacus sinicus* and *M. rhesus*. The infective material was derived from two untreated patients who during the preceding year had developed generalized leprosy of the nodular form. A saline suspension of the ground-up lepromata was injected in the supraorbital and malar regions of both sides of the face, in the pubic region, and into both nostrils. Three days later all signs of the inoculations had disappeared. On the thirty-ninth day a small round hard nodule was visible over the right malar bone. Similar swellings appeared later over the other sites of inoculation with the exception of the nasal mucosa, which

remained intact. The nodules increased in size till on the seventieth day they varied from a small pea to a nut. Pieces were excised from some of them and were injected into guinea-pigs and monkeys; both sets of animals remained well. Microscopic examination of the excised tissue showed typical leprosy bacilli in films. Sections demonstrated the presence of granulation tissue containing large mononuclear, often vacuolated, cells; some giant multinucleated cells; and round the peripheral portion lymphocytes, polymorphs, and plasma cells. Acid-fast bacilli were found within the large mononuclear cells. Shortly after the removal of the nodules the remaining lesions commenced to decrease in size; they ultimately disappeared. Similar results were obtained with two other sinicus and four rhesus monkeys. The incubation period varied from about five to eight weeks. The nodules reached in some instances the size of a small plum; they disappeared as a rule in from six to ten weeks. Clinically and histologically they closely resembled human lepromata. Acid-fast bacilli were uniformly found in films, but only occasionally in sections. Reincubation of two of the animals gave rise to the disease again, in each case with a shortened incubation period—nineteen and twenty-two days respectively. Passage experiments were unsuccessful, and in no case was the disease transmitted to guinea-pigs. The author concludes that the disease reproduced in the monkeys was a localized form of leprosy.

274. Effect of Carbon Dioxide on the Growth of the Tubercle Bacillus.

THE gaseous requirements of the tubercle bacillus are of importance in connexion with its ability to grow in the body. G. E. ROCKWELL and J. H. HIGHERBERGER (*Journ. Infect. Dis.*, January, 1926, p. 92) have carried out a number of experiments to determine the part that is played by carbon dioxide in the growth of the tubercle bacillus and the saprophytic acid-fast bacilli. Novy recently came to the conclusion that this gas was of no importance, and explained the results that have pointed to the contrary as being technically fallacious. One of the main errors that is likely to confuse the investigator is the action of dehydration on the medium. To control this the authors have made careful measurements of the loss of water throughout their experiments. The technique used was to incubate the culture tubes over water, sulphuric acid, or alkali, and to calculate the amount of growth that ensued. Briefly, they found that the best growth occurred over sulphuric acid, the next best over water; in the tubes incubated over alkali there was very little growth—never more than a few discrete colonies. The inhibitive action of the alkali was not due to dehydration, because this was not nearly so marked as in the tubes incubated over acid. It appeared to be due to the absorption by the alkali of the carbon dioxide in the atmosphere over the tube. When the alkali was saturated with carbon dioxide—that is, when the tube was incubated over sodium bicarbonate—profuse growth occurred. The authors therefore conclude that carbon dioxide is a vital factor in the growth of the tubercle bacillus.

275. The Wassermann Reaction in Congenital Syphilis.

F. BRUNETTI (*La Clinica Pediatrica*, November, 1925, p. 685) states that the founding hospital at Rome was one of the first to use the Wassermann reaction in the diagnosis and prognosis of congenital syphilis. In 1910, or three years after discovery of the reaction, the director, Professor Flaminio, was one of the first to show that the reaction in the newborn was often negative, even when the mother was syphilitic, and that the reaction in the child was very rarely positive before the tenth day of life, especially in cases in which syphilitic manifestations were absent. From 1921 to the first half of 1925 the Wassermann test was performed 2,846 times at the hospital, and there were 2,000 Sachs-Georgi and 440 Meinicke reactions. The patients were divided into the following three groups: (1) Mothers and children with active syphilitic manifestations. In this group the Wassermann reaction was always positive both in the mother and the child. (2) Mothers and children in whom the evidence of syphilis was doubtful. In these cases the reaction was positive in 70 per cent. of the children and 80 per cent. of the mothers. (3) Mothers and children in whom there was not the slightest evidence of syphilis. In this group the reaction was positive in 8 per cent. of the children and in 15 per cent. of the mothers. The Sachs-Georgi reaction gave less conclusive results than the Wassermann reaction, being positive in only 76 per cent. of the mothers, and in 62 per cent. of the children belonging to the first group, and the percentage of positive Meinicke reactions was still less. The occasional lack of correspondence between the Wassermann reaction in the child and that in the mother and the possibility of detecting syphilis in the child from examination of the mother's blood alone render it necessary that the Wassermann test should be performed on the largest number of mothers possible as well as on all the children.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

276. Cardiac Infarction.

H. A. CHRISTIAN (*Amer. Heart Journ.*, December, 1925, p. 129) considers cardiac infarction (coronary thrombosis) a condition easily recognizable by simple clinical methods. Since the pain in such cases may be referred to the abdomen, with fulminating and alarming symptoms simulating some lesion therein, the importance of correct diagnosis is obvious, lest, as not infrequently happens, an unnecessary laparotomy be performed. The differentiation of the condition from angina pectoris is essential, seeing that cervical sympathectomy might be advised in the latter case but is contraindicated in cardiac infarction. A history of varying degrees of precordial or epigastric distress without any evidence of cardiac insufficiency is suggestive, and in most cases the occurrence of the infarction is marked by pain which predominates over other symptoms. A few patients are without pain, but become collapsed and dyspnoeic with a feeling of impending death. The pain, which is always deep-seated, is generally felt behind the upper portion of the sternum, or it may be entirely below the diaphragm. The frequent history of attacks of "indigestion" without any definite cause suggests that such attacks may have been occasioned by slight vascular myocardial disturbances. Dyspnoea out of all proportion to any demonstrable pulmonary or cardiac lesion is a striking characteristic, and the most constant physical sign is a weak cardiac action with a poor arrhythmic pulse. Crackling râles at the bases of the lungs are nearly always present. The blood pressure is lowered after an attack and there is slight fever. Treatment consists in morphine for the relief of pain and absolute rest for as long as the blood pressure remains lowered, with avoidance of nitroglycerin. Christian prefers the intravenous or intramuscular administration of caffeine to digitals, and for grave circulatory failure 1/4 c.cm. of 1 in 1,000 epinephrin solution intravenously or intracardially.

277. Convalescents' Serum as a Protection against Varicella.

A. G. MITCHELL and S. F. RAVENEL (*Arch. of Ped.*, November, 1925, p. 709) injected intramuscularly 68 patients who had not previously suffered from varicella with 2 to 10 c.cm. of convalescents' serum within from one to seven days after exposure to the disease: 4 developed typical varicella in from seventeen to twenty-one days after exposure, and 64 showed no signs of the disease during a period of thirty days' observation after exposure. The ages of the patients ranged from 1 month to 27 years, and the percentage of those exposed who developed varicella was 4.4. After exclusion of 13 patients who were over 15 years of age and 11 who were under 6, the incidence of those developing the disease in the remaining 44 was 6.8 per cent. Twelve children were re-exposed to varicella twenty-one days after the injection of serum, six were re-exposed thirty-two days and three forty days after injection. One of the children re-exposed on the twenty-first day developed varicella, but the rest escaped. The authors' conclusions are as follows: (1) Varicella convalescents' serum has sufficient protective power against the disease to warrant its collection and employment in prophylaxis in hospital wards in the case of children whose nutritional state or general health is poor. (2) In view of the uncertainty of dosage it is probable that more than 4 c.cm. should be injected intramuscularly. (3) The serum should be given, when possible, within three days after exposure to varicella. (4) The serum is apparently protective for as long as eleven months after collection. (5) The temporary immunity conferred by varicella convalescents' serum possibly lasts as long as fifty days.

278. The Cardiac Symptoms of Aerophagia.

G. T. FLORA (*Thèse de Paris*, 1925, No. 514), who records numerous illustrative cases, states that the cardiac symptoms which may be caused by aerophagia are tender spots in the left submammary and precordial regions, extrasystoles, palpitation and tachycardia, faints, anginal attacks, and acute asphyxia. Angina pectoris associated with aerophagia is usually of mixed origin, the angina being due to a cardio-arterial affection and the asphyxia to the distension of the stomach and colon is the syndrome denominated "acute asphyxia," which is characterized by four

cardinal symptoms—namely, very intense respiratory disturbance causing orthopnoea, cyanosis, small rapid pulse; and disappearance of all the symptoms under the influence of oesophageal catheterization. As regards the pathogenesis, any severe vaso-sympathetic shock, like that caused by gaseous distension of the stomach and colon, is capable of affecting the neighbouring regions, which accounts for the cardiac symptoms of aerophagia. The prognosis is generally favourable, but an anginal attack caused by an impulse arising from the vagus may in rare cases give rise to sudden death. The prognosis of acute asphyxia is very grave unless it is relieved by oesophageal catheterization. The treatment consists in combating aerophagia by regimens and appropriate drugs, and the hyporexcitability of the vagus by belladonna, which often has a good effect.

279. Musculo-spiral Paralysis after Serum Treatment.

A. CARRAN (*Arch. Lat. Amer. de Ped.*, October, 1925, p. 1158) states that in 1911 Thoen published a case of partial neuritis of the brachial plexus with atrophy and paralysis of the muscles of the shoulder following injection of antitetanic serum. Subsequently Lhermitte drew attention to this sequel of serum treatment, and in 1924 about twenty-four cases were published, mainly in the *Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*. Carran now reports the case of a boy, aged 13, who, after receiving 20 c.cm. of antitetanic serum for a wound in the right foot, developed left musculo-spiral paralysis, which was still present six months after the onset. The paralysis could justifiably be attributed to the serum, as it appeared at the same time as the other serum phenomena. In two-thirds of the cases on record the cause of the paralysis was antitetanic serum, the next most frequent causes being diphtheria antitoxin and antistreptococcal and antipneumococcal serums. In most of the cases small doses have been employed for a prophylactic or curative purpose in subjects who have not been injected before, so that there could be no question of anaphylaxis. The subcutaneous route has been used in almost all the cases, so that the sequel is not more frequent after intraspinal or intravenous injection. Almost all the cases have occurred in adults, children being rarely affected. The clinical picture varies from a slight paresis to a complete paralysis. The commonest forms are neuritis localized to a single nerve, the left musculo-spiral being most frequently involved, though cases have been reported in which the vagus, recurrent laryngeal, and optic nerves have been affected; plexitis and radiculitis, especially of the brachial plexus, frequently in a dissociated form such as the Erb-Duchenne type; more or less generalized polyneuropathy in the form of hemiparesis or hemiplegia, with or without amyotrophy or sensory changes; and finally myelitis, which in one case assumed the form of Landry's ascending paralysis, with death of the patient from involvement of the bulbar centre. Some authorities regard the condition as due to oedema and infiltration of the nerve trunks, while others attribute it to fixation of the toxin in the nerves. Prophylaxis should consist in adopting the method advocated by Besredka and others of injection of sodium carbonate and daily ingestion of large doses of sodium citrate or calcium chloride before the appearance of serum sickness. Auto-haemotherapy has been recommended by A. Haedo, Zerbiuo, and others.

280. Intravesical Pressure.

F. VICENTINI (*Arch. Ital. di Urol.*, November, 1925, p. 93), who records twenty-eight illustrative cases, states that when the bladder is at rest the intravesical pressure is related to the muscular tonus of the organ. The curve of a perfectly normal evacuation of the bladder should be absolutely regular, but in practice it is affected by various individual or general factors which may lead to misinterpretation. In pregnancy the intravesical pressure is higher than normal, the highest values being found in primigravidae. Affections in the neighbourhood of the bladder may or may not affect the intravesical pressure according to their nature. In vesical affections the pressure may be greatly or only slightly above the normal, but it is always proportionate to the gravity and duration of the lesions. The characters which distinguish an abnormal from a normal curve of evacuation are the higher degree of pressure and a fall of pressure disproportionate to the quantity of fluid evacuated. Changes in pressure and in the curve of evacuation are also in some cases to hypertrophy of the vesical musculature and in others to hypersensitiveness of the bladder wall, which responds to stimuli in an abnormal manner.

Surgery.

281. The Serum Prophylaxis of Measles.

R. DEBRÉ, H. BONNET, and C. DEGAM (*Rev. d'Hygiène*, January, 1926, p. 24) describe the results they have obtained from the prophylactic injection of immune serum in patients or normal children exposed to measles. In March, 1925, a special laboratory was established in France for the collection of serum from convalescent and recovered cases of measles. From March 1st to November 18th 2,897 c.cm. of serum was collected, mostly from adults; this was equivalent to 555 doses. The serum has been used chiefly for controlling epidemics of measles that have broken out in children's hospitals, but part has been devoted to the protection of normal children in families in which a case of measles has developed. With the results the authors are entirely satisfied. Of children inoculated prophylactically 83.5 per cent. have been completely protected and 12.5 per cent. have had only a mild attack; not a single fatal case has occurred. Numerous instances are cited in which the serum appears to have been the means of rapidly controlling an epidemic, and many instances in which serum-injected children have escaped, while the control non-injected children have developed measles. Although no strictly comparable data are provided, the authors state categorically that during the time mentioned 875 children have been protected from measles.

282. Pleurisy in Scarlet Fever.

H. BERNARD (*Thèse de Paris*, 1925, No. 506), who records four illustrative cases, comes to the following conclusions: (1) Scarlatinal pleurisy is rare. (2) It is often purulent, but frequently remains sero-fibrinous. (3) It is almost always secondary to pulmonary lesions, which are frequently very slight and require looking for, but often escape detection. (4) The streptococcus and pneumococcus are the organisms most frequently found in the effusion. The presence of the tubercle bacillus is more frequently indicated by the cytological formula than by its actual discovery in the effusion. As soon as the effusion occurs, therefore, thoracentesis should be performed in order to determine the cytological formula and bacteriological nature of the effusion. (5) There is no antagonism between tuberculosis and scarlet fever. The two affections may exist concurrently, and the superinfection of one does not necessarily imply aggravation of the other. But in the tuberculous subject who is debilitated scarlet fever may assume a malignant character. Much more frequently scarlet fever rouses into activity a dormant or latent tuberculous focus. (6) The prognosis of scarlatinal pleurisy is generally favourable apart from tuberculous pleurisy and empyema which has received inadequate surgical treatment. (7) The treatment of scarlatinal pleurisy is the same as that of any other pleurisy.

283. Meningococcal Ependymitis.

VIALARD and DARLEGUY (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, January 14th, 1926, p. 14), who record four illustrative cases in soldiers, state that ependymitis is always present in meningococcal cerebro-spinal meningitis, at least in those forms beginning with mainly encephalitic signs, such as delirium, mental confusion, and coma. They do not think trephining is always necessary in the adult, followed by intraventricular injection of serum, as Lewkowicz suggests, since they have seen such patients recover after early and massive doses of serum given intraspinally. If, however, after energetic treatment by the intraspinal route has been continued for two or three days, and the physical and psychical symptoms do not subside, while the signs of cerebral blockage become definite, it is imperative to bring the serum into direct contact with the ependymal walls themselves, and if necessary into the region of the base of the brain by trephining followed by puncture. The procedure is simple and should be adopted without delay when there is any doubt as to the possibility of pyrocephaly developing.

284. Relapsing Fever.

A. Z. PÁRAMO (*La Medicina Ibero*, January 9th, 1926, p. 29), who records five illustrative cases with their temperature charts, states that relapsing fever occurs in the province of Toledo, the transmitting agent in most cases being an acarus of the family of Ixodidae, a parasite of the pig. In some cases relapsing fever may be transmitted by lice which have been infected by persons suffering from the disease. Páramo thinks it probable that relapsing fever is a disease of the pig, and that the Ixodidae mentioned is the intermediate parasite between the animal and man. The incubation period is between five and seven days, and the prodromal period from one to twenty-four hours. Headache and pains in the legs are constant during the febrile period. Splenic infarction is rare. After the fever has subsided the temperature remains below 98.8°F. for two or three days. Recovery is spontaneous.

514 B

285. Resection of Long Bones for Osteomyelitis.

G. I. BAUMAN and H. E. CAMPBELL (*Surg., Gynecol. and Obstet.*, January, 1926, p. 114) describe sixteen cases of subperiosteal resection of the diaphyses of long bones for chronic osteomyelitis. The patients selected for operation had had discharging sinuses from four months to four years. In all twenty-one resections were performed, five patients having two each. Out of nine femora which were resected, in only one case, a man aged 40, did regeneration fail to occur; in this case, however, the union was becoming firmer after a year and a good functional result appeared probable. Of six tibias three united perfectly, two have failed to unite, and one fractured at the end of two years with poor union, but later became firm under immobilization treatment. One ulna out of two resected failed to unite. Two clavicles, one fibula, and one humerus have regenerated perfectly. The authors suggest that the good blood supply to the femur is responsible for the excellent results, while the defective supply to the tibia and the bones of the forearm explains the failures in these regions. The calcium metabolism was, however, not investigated. They resect as much of the diaphysis as has become diseased, and the periosteal edges are stitched together over perforated rubber drainage tubes which are allowed to project from the wound. Through these tubes the cavity was irrigated with Dakin's solution for two to five weeks, depending upon the duration and character of the discharge. The patients were kept in bed with extension for eight to ten weeks and then allowed to walk with crutches and a cast or brace until the sixth month; partial weight-bearing with the cast or brace was then permitted until the eighth or tenth month. The authors do not recommend resection of the tibia except when nothing less radical will remove the infected bone, but they state that in properly selected cases subcutaneous resection of the long bones in cases of chronic osteomyelitis, together with subsequent bone grafting if necessary, offers the best chance of cure.

286. Tuberculosis of the Sacro-Iliac Joint.

M. N. SMITH-PETERSEN and W. A. ROGERS (*Journ. Amer. Med. Assoc.*, January 2nd, 1926, p. 26) report the results of arthrodesis in thirteen cases of sacro-iliac tuberculosis during the last seven years, and conclude that a more optimistic attitude is now justifiable with regard to this disease. In diagnosis they emphasize the following points. Pain radiating over the posterior aspect of the thigh and leg was present in ten of the cases, and tenderness over the inferior sacro-iliac ligaments and sacro-sciatic notch was invariably present. In no case was sensitiveness found at the lumbosacral junction, and the authors regard this absence of pain as a positive indication of sacro-iliac tuberculosis. In two cases in which the entire gluteal region and the lower abdominal quadrant were sensitive to touch the patients had psoas and gluteal abscesses. In the majority of cases there was an increased range of movement in the sitting position as compared with the standing, due to the elimination of leverage on the joint by the hamstring muscles. In only one-third of the cases was pain elicited by compression of the iliac crests. In the early stages of the disease rectal examination brought to light an increased density along the joint line and in the soft tissues at its inferior margin; in the later stages there was also erosion of the joint line and atrophy of the ilium and sacrum. In all cases x-ray examination showed that there was destruction of the joint surfaces and adjacent bone; an increased density was present in more than half the cases. Four deaths occurred in a series of thirteen patients. In one case there was a pre-existing extensive abscess which became secondarily infected after the patient had left hospital against advice. In the second case Pott's disease supervened, followed by tuberculous meningitis. The other patients died from tuberculous peritonitis more than a year after the operation; in no case was death attributable directly to the operation. The remaining nine patients returned to their previous occupations, and had been at work for an average of seven months; three of them had been at work for more than six years without local recurrence or the appearance of secondary foci. Post-operative fusion occurred in all the cases, with cessation of pain.

287. Cysts of the Urachus.

M. PATEL and R. LABRY (*Gynecol. et Obstet.*, 1925, xii, No. 6, p. 449) state that large closed cysts of the urachus are extremely rare; more commonly the whole of the urachus is canalized, giving an umbilico-vesical fistula; or the canal is closed at the umbilical end but at the other communicates with the bladder, forming a variety of vesical diverticulum. Cysts which originally were closed not uncommonly acquire,

as a result of accumulation of their contents, secondary communications with the exterior or the bladder. As a rule the fluid within closed cysts contains a considerable amount of effused blood, but in a personal case here recorded the liquid was non-albuminous and limpid, with a specific gravity of 1007. Acute traumatic rupture has not been recorded. The cystic swelling is strictly mesial and gives rise to a swelling closely resembling the pregnant uterus. These features, together with its adherence to the umbilicus, may in the case of moderate sized cysts render possible a pre-operative diagnosis, but usually the swelling is taken for an ovarian cyst or an encysted effusion in connexion with peritoneal tuberculosis. Although the cyst is entirely extraperitoneal it is best at operation to open the peritoneal cavity, when a portion of the parietal peritoneum can be excised with the cyst. Dissection of the cyst from the bladder is often difficult.

288. Treatment of Varicose Ulcer.

J. MEYER and R. WEILL-SPIRE (*Journ. de Med. et de Chir. Prat.*, January 25th, 1926, p. 49) state that in dealing with varicose ulcers excision of veins or of the ulcer itself is giving place to treatment by injections so as to produce venous sclerosis. After the ulcer has become clean and non-oedematous, and the inguinal glands are no longer swollen, an injection of 50 cc. of sodium citrate in 1 c.c.m. of distilled water is made into the varicosity, the needle being entered perpendicularly to the surface. Immediately on withdrawal a pad of cotton-wool is applied, and kept firmly in position by pressure for twenty minutes. It is important that there should be no escape of fluid, and the first injection may be more dilute, higher concentrations being used later according to the patient's reaction. A start should be made with veins in healthy tissue an inch or two above the ulcer. Other substances recommended include sodium salicylate 20 to 40 cc. in 1 c.c.m. of distilled water, quinine 10 to 20 cc., and urethane 5 to 10 cc. The amount injected should always be 1 c.c.m. This treatment is said to be applicable to about two-thirds of all cases of varicose ulcers. Insulin has been applied to the base of the ulcer, even in the absence of permanent glycosuria, in view of the fact that hyperglycaemia is not uncommon with varicose ulcer.

289. Gastro-Jejuno-colic Fistulas.

R. APPELMANS (*Rev. de Chir.*, 1925, No. 10, p. 757), having had two cases of this condition under his care, records their histories and has traced eighty-five similar cases in the literature. An interesting feature of these cases was that they all occurred in men. These fistulas followed both an anterior and a posterior gastro-jejunostomy. They are generally found on the anterior aspect of the jejunum, and usually follow operations for duodenal ulcer, very rarely operations for cancer. The ulcer often makes its appearance one or two years after the gastro-enterostomy. In the two cases described the fistula occurred sixteen and nineteen months respectively after the first operation. The symptoms are those of peptic ulcer—pain, vomiting, and often haematemesis. When the fistula becomes established diarrhoea is the most common symptom. It is often very profuse, and the faeces contain recently ingested food. There is often eructation of foul gas, which clinches the diagnosis. Radiography will clearly demonstrate the fistula; bismuth appears in the colon a few minutes after the test meal has been taken. The prognosis is bad; the surgical operation is difficult and dangerous, but without it death is certain to ensue in a short time. Preventive treatment aims at the avoidance of fresh ulcer formation; unabsorbable sutures should not be used, and care should be taken at the first operation not to cause traumatism and occlusion of the pylorus. Curative treatment includes the closure of the fistula and re-establishment of the continuity of the bowel. If the first ulcer is still active, gastro-enterostomy must be repeated. It may be best to excise the old gastro-enterostomy, the fistula, the colon, and the jejunum after the new channel has been formed. In both recorded cases the recovery was complete.

290. Non-venereal Prostatitis.

T. BAKER (*Journ. Amer. Med. Assoc.*, November 21st, 1925, p. 1606) holds that prostatitis due to non-venereal causes is commoner than is generally realized, amounting to 15 to 20 per cent. of all cases. The importance of recognizing a non-venereal cause is obvious in the interests of the patient; sociological and economic considerations are involved, and correct diagnosis is necessary for treatment. The author remarks that many cases are due to focal infections or arise as sequels of acute infections. Further investigation is necessary, but it appears already that these non-venereal cases are often more resistant to treatment and prone to relapse than gonococcal infections.

Therapeutics.

291. Mercurochrome-220 in Chronic Septic Endocarditis.

A. W. FALCONER (*South African Med. Record*, January 9th, 1926, p. 14) discusses the intravenous treatment of chronic septic endocarditis with mercurochrome-220. Other observers have reported successful results in the treatment of septicæmias due to various causes by intravenous injections of mercurochrome, and cures have been claimed in erysipelas, streptococcal pneumonia, septicæmia caused by staphylococci and *B. coli*, pyelonephritis, puerperal sepsis, subacute endocarditis, and gonorrhoeal infections. Notes of three cases of subacute malignant endocarditis are given, in two of which 25 to 35 c.c.m. of a 1 per cent. solution of mercurochrome were administered intravenously on several occasions. A definite temporary improvement resulted, as shown by diminution in the size of the spleen, disappearance of Osler's nodules, and a general improvement in the appearance and feelings of the patients, but in neither case was a fatal issue averted or life materially prolonged. Although the injections produced considerable reactions with severe intestinal irritation and high fever, the temperature generally settled down when the reactions were over. The third patient refused further injections after the first, from which no improvement was noted.

292. Application of Cold in Dermatology.

P. LORTAT-JACOB and P. LEGRAIN (*Presse Méd.*, January 30th, 1926, p. 131) say that the application of cold has a wide field of application in skin diseases. They use a cryocantery which can be recharged directly from a carbon dioxide container; regulation of dosage is easily obtained by a pressure screw and interchangeable nozzles. Each application lasts from ten to thirty seconds. The principal indications are angioneurotic oedema, lupus erythematosus, keloid, and small baso-cellular epitheliomata; to these must be added various affections of the mucous surfaces, such as leucoplasic patches on the tongue and cheek. Repeated applications at five-day intervals are required for their disappearance. Cervicitis necessitates much longer application and a special form of instrument; moreover, since the treatment tends to sclerosis and is not disinfectant, the cervicitis must not be a virulent type. Treatment by cold (cryotherapy) is valuable in that it is easy of application and leaves no scar. The pain is much less than that caused by "carbonic snow," and the authors state that they have not known any patients abandon treatment for this reason.

293. Treatment of Hay Fever.

E. W. PHILLIPS (*Journ. Amer. Med. Assoc.*, January 16th, 1926, p. 182) has obtained very good results from treating twenty-nine patients suffering from hay fever with daily intradermal injections of pollen extract. After determining the degree of sensitization and the size of the initial dose, the subsequent increase in dose was adjusted to the tolerance of each patient, the aim being to produce a local reaction about the size of the patient's palm which subsides within twenty-four hours. In some cases the dose could be doubled on each treatment, while others only tolerated a 50 per cent. increase. Care was taken to select a fresh site for each injection in order to avoid desensitized areas and to ensure a brisk local response. Intradermal injections were found painful if more than 0.25 c.c.m. was introduced into one wheel, and accordingly stronger dilutions of the pollen extract had to be prepared. Complete relief occurred quickly in each case; six patients were made comfortable by the first dose, others improved in less than three days, and the longest refractory period was seven days, with six doses. Phillips states that such injections are safe provided that the reaction from the preceding dose has begun to subside, and the ratio of increase is calculated carefully. He gives the warning that this form of treatment should only be employed by those who are familiar with the particular extract concerned.

294. The Use of Pimpernel in Intestinal Affections.

H. LECLERC (*Bull. Soc. de Thé.*, December 9th, 1925, p. 278) states that recognition of the astringent properties of the pimpernel (*Poterium sanguisorba*) can be traced back to the time of Atilia. Its chemical composition has not been investigated since the end of the seventeenth century, when the Royal Academy of Sciences discovered that it contained "much acid, much volatile salt, much oil, and earth." It is well known, however, that the reactions produced in its decoction in the presence of iron salts indicate the presence of tannin in large amounts, to which must be attributed its powerful antidiarrhoeic action. Leclerc has recently employed an infusion of the plant for infants suffering from entero-colitis. In most of the cases he noted a marked reduction of the hypersecretion from the intestinal mucous

membrane and rapid disappearance of streaks of blood from the stools. An equally satisfactory result can be obtained by using a tincture of the plant. In addition to its astringent effect the plimpnel possesses very marked carminative properties when taken a few minutes before meals.

295. Sodium Bicarbonate in Polycythaemia.

SCHUERMANS (*Le Scalpel*, January 23rd, 1926, p. 76) has had favourable results after giving sodium bicarbonate in two cases of Vaquez's disease—polycythaemia vera—and in two cases of secondary polycythaemia. He suggests that polycythaemia is affected by the acid base equilibrium of the blood, but admits that his treatment of these cases has been empirical. To three of his patients he gave 10 grains thrice daily and to the fourth 5 grains. In every case the red blood corpuscles diminished by about 25 per cent. during administration, though the haemoglobin and the white blood cells were relatively unaffected. Coincidentally with the diminution of the red blood corpuscles there was noticed an improvement in the patients' general condition, especially relief of pain in the long bones. When the administration of sodium bicarbonate was interrupted the erythrocytes rapidly returned to their former numbers.

296. Stovarsol in Chronic Respiratory Disease.

V. KOHEN (*Bull. Soc. de Thér.*, December, 1925, p. 287) has found that stovarsol (acetyl-ammon-hydroxy-phenyl-arsonic acid) has a favourable action when given by mouth to subjects of chronic bronchitis, tracheo-bronchial adenopathy, bronchial and pulmonary sclerosis, emphysema, inactive pulmonary tuberculosis, or chronic rhinitis, in an average dose of 0.50 gram given for periods of ten to fifteen days at a time, interrupted by intervals of equal duration. The cough, expectoration, and dyspnoea diminish and even disappear, the permeability of the nostrils becomes re-established, and the general condition is greatly improved. The only contraindication to the use of stovarsol is hepatic and renal insufficiency, shown by an eruption with or without fever. The drug can be given to children in smaller doses without any harm. Kohen does not suggest that most of the chronic affections of the respiratory tract are of a syphilitic nature, but maintains that pentavalent arsenic in this form frees the respiratory and intestinal tracts of waste matter and has a favourable action on their functions.

297. Tannic Acid as an Intestinal Astringent.

J. W. C. GUNN (*South African Med. Record*, January 9th, 1926, p. 11) discusses the behaviour of tannic acid in the intestine in the treatment of diarrhoea. He states that to be of any value in those cases due to inflammation after the passage of an irritant it would be necessary for tannic acid to precipitate protein all along the intestinal tract. Experiments indicate, however, that precipitation of proteins occurs mainly in the stomach and duodenum, and that as the acid passes along the intestines the less acid the contents become and the less favourable is the reaction for precipitation. After long trial of tannic acid in the treatment of moderately severe cases of dysentery and diarrhoea no difference in progress was noted between those patients receiving it and others treated as controls, while in the very severe types tannic acid had no effect at all. From his own observations as well as from the experience of other investigators Gunn concludes that treatment with tannic acid in mild cases of diarrhoea is unnecessary, while in severe cases it is useless.

Disease in Childhood.

298. The Effect of Early Treatment of Congenital Syphilis in Children.

G. GARDEL (*Thèse de Paris*, 1925, No. 520) states that of 80 children with more or less definite signs of congenital syphilis who had received early treatment and been kept under observation for several years 72, or 90 per cent., survived and 8 succumbed. Death in 5 of the 8 fatal cases was due to an intercurrent infection. Syphilis by itself was rarely the cause of death, which is not surprising in view of the fact that there were few severe cases with grave visceral lesions. Among all the manifestations of congenital syphilis eruptions entailed the gravest prognosis (6 out of 20 cases were fatal), as they were an indication of septicaemia. The earlier they appeared after birth the more serious they were likely to be. Eruptive cases constituted 80 per cent. of the deaths. In fatal cases death almost always occurred in the first year, especially in the first six months (in 7 out of 8 cases). The child's future depends mainly on the conditions of hygiene and the environment in which it is brought

up. None of the cases observed by Gardel were admitted to hospital and almost all (70 per cent.) had been fed at the mother's breast, or at least had had a mixed diet (13 per cent.). Of the 72 survivors who had undergone more or less regular mercurial treatment 48, or 66.6 per cent., were absolutely normal at the time of the last examination, and 24, or 33.3 per cent., showed stigmata of congenital syphilis. Sequelae were relatively rare and generally mild. In view of the fact that every severe case of congenital syphilis with profound visceral lesions or considerable mental impairment has never had the slightest treatment, it is concluded that apart from cases with early cerebral lesions every case which is recognized and treated early escapes severe late sequelae.

299. Nutritional Keratomalacia.

A. B. SCHWARTZ (*Journ. Amer. Med. Assoc.*, December 26th, 1925, p. 2025) reports a case of keratomalacia occurring in an infant and following deprivation for three weeks of the fat-soluble vitamin A. Breast-fed until 10 months of age, the baby later developed a "toxic dyspnoea" with stupor and intractable constipation; this was treated by a diet of oatmeal water and a proprietary infant food for three weeks. The infant was then admitted to hospital, the outstanding symptoms being stupor, irritability on being disturbed, loss of weight, pallor, doughy skin, dry inflamed mouth, cracked lips, fever, and the characteristic corneal ulceration. The liver was unusually large and firm; there were symptoms of meningeal disturbance and a transient strabismus. The cerebro-spinal fluid showed only slight diminution in the sugar content with no pleocytosis or increase in globulin. The infant assumed the frog-like attitude occasionally seen in scurvy, but which might have been due to the gluteal injections of cod-liver oil which were being given daily. In addition to this lactic acid milk and orange juice were given by the mouth; quartz lamp radiation was also employed. The child made a slow but complete recovery except for loss of vision in the right eye, in which there had been extensive ulceration of the cornea.

300. Hypertelorism.

E. A. COCKAYNE (*Brit. Journ. Child. Dis.*, October-December, 1925, p. 265) refers to the previous cases reported by D. M. Greig and D. C. Muir (see *Epitome*, September 19th, 1925, para. 223), and reports two cases which came under his own observation in a female child aged 7 months and a boy aged 6 years. From consideration of the six cases now on record Cockayne concludes that hypertelorism is congenital but not hereditary. He points out that there is nothing in any of the family histories to support Greig's contention that it is due to an hereditary want of balance in development occurring in a family marked by Nature for extinction. It is probable that the multiple abnormalities present are caused by a deficient oxygenation of other tissues which occurred at the same time as that of the chondrocranium.

301. Anaesthesia in Young Children.

P. ERLACHER (*Wien. klin. Woch.*, January 21st, 1926, p. 98) has performed major operations on infants under anaesthesia produced by rectal injections of hedonal in 10 cases and combined hedonal and local anaesthesia in 54 cases. The conditions treated thus included inguinal hernia, appendicitis, umbilical hernia, removal of angioma, and hydrocele. The method was also used for orthopaedic operations and blood transfusions. In two cases of congenital dislocation of the hip the combined anaesthetic effect was found to be inadequate. The patients ranged in age from 3 months to 4½ years. The dose of hedonal was 0.5 gram for an infant of 3 months, 0.75 gram up to 9 months, 1 gram up to 1 year, and 1.5 grams for over 1 year. The weight and physical condition of the child were also taken into account, and generally an amount of 0.15 to 0.2 gram per kilo of body weight was found sufficient. The bowel was washed out by a simple enema two hours before the operation. The hedonal was dissolved in 30 c.c. of rice water and introduced into the rectum, and the buttocks were then strapped together to prevent its being evacuated. It was found that in ten to fifteen minutes the child sank into a natural sleep, and after half to three-quarters of an hour the necessary degree of insensibility was reached. During this time the child should be protected from all external stimuli—light, shaking, noise. If the sleep was not sufficiently deep local anaesthesia was used. Immediately after the commencement of the operation the bowel was washed out to prevent unnecessary duration of the narcosis. The infant was usually awake after three hours, taking food well and not vomiting, which fact the author considers of great importance in infants. In one case the administration of hedonal was followed by collapse, which was treated by strychnine, a supposed specific antidote for hedonal poisoning.

Obstetrics and Gynaecology.

302.

Endometrioma.

S. B. HERD (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter No., 1925, p. 649) states the conclusions derived from a microscopical study of twenty-five cases in which endometrial tissue was present in abnormal pelvic situations, giving rise to the tumours which were formerly described as adenoma or adenomyoma, but have recently been called endometrioma. In their advanced stages as "chocolate" or haemorrhagic cysts with tarry contents, or in other formations—in the uterus, ovaries, ligaments of the uterus, recto-vaginal septum, or elsewhere—these tumours have been held to take origin (1) by direct extension from the uterine endometrium, (2) from serous (peritoneal) epithelium, (3) from Wolffian relics, (4) from germinal ovarian epithelium, (5) by implantation of endometrial fragments which have passed from the uterine cavity through the Fallopian tubes to the pelvis, whence they penetrate the ovary or other organ from without. The last-named view, elaborated by Sampson, is confirmed by many recent workers, and finds support in microscopical demonstration of retrograde menstruation in the human subject, and in the development of small "adenomatous" tumours after experimental implantation of endometrial fragments in the pelvis of the rabbit. That the adenomatous tissue is endometrium is proved by its showing menstrual reaction corresponding with the phase of the uterine endometrium, as well as its atrophy at the menopause and decidua reaction in pregnancy. Herd has found microscopical evidence of endometrioma originating in several ways. In the uterus he considers the tumour is nearly always due to direct extension from the endometrium, which seems to be endowed in certain cases with peculiarly invasive faculties. In the ovary, the endometrial tissue, he finds, gains access by (1) extension from the endometrium along the ovarian ligament, (2) implantation of fragments after retrograde passage through the Fallopian tubes, (3) conversion of the tubal epithelium in the abdominal ostium into endometrium, which then invades the ovary, (4) alteration of the capsular epithelium, (5) developmental errors—such as inclusion of part of the Müllerian duct in the ovary. Elsewhere in the pelvis endometriomata are due to extension of endometrium, developmental errors, implantation through the Fallopian tube, or extension from (or rupture of) an endometriomatous tarry cyst. Clinically neither physical signs nor symptoms are characteristic, but the patient is most frequently aged from 30 to 50 and has intra-menstrual dysmenorrhoea. Sterility is very common, and attacks of acute pain are often associated with the ovarian tumour; the presence of a fixed backward uterine displacement, with or without fixed adnexal swellings and tenderness, is suggestive.

303. Treatment of Fibromyomata of the Uterus.

FRANCES A. FORD (*Surg., Gynecol. and Obstet.*, February, 1926, p. 245) has made a comparative study of representative groups of patients treated in the Mayo Clinic for fibromyomata of the uterus, either by operation or by radiotherapy, surgical treatment being employed in 250 cases, while 344 received radiation treatment. The author points out that a small submucous fibromyoma responds usually to a small dose of radium, whereas a large tumour or a pedunculated tumour should receive a combination of radium and x rays or x rays alone. A relatively high percentage of the cases treated by radiotherapy required further treatment, either repeated radiation in 18 per cent., or operation in 13.7 per cent., as compared with 4 per cent. of the surgical group who received a second treatment. This is attributed to injudicious selection of cases or to inadequate dosage. Hard fibromyomata containing extensive calcium deposits cannot be reduced satisfactorily by radiation, and an incarcerated pelvic tumour should be removed surgically because of the inability to exclude adnexal disease. A radiogram may occasionally assist diagnosis by demonstrating calcium deposits within the tumour. The need of extreme care in excluding malignant disease was shown by the fact that in six of the patients treated by radiotherapy a well established malignant process appeared within one year of the treatment. Malignant disease also appeared later in other patients, and the question is raised whether a focus of relatively devitalized tissue, with an altered blood supply, may favour malignant change. The author pleads for careful recording of the history of the subsequent life of all patients treated with radium or x rays, so that more information may be obtained in this respect.

304. L. MARTINDALE (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter No., 1925, p. 690) reports a series of 252 cases of fibromyoma of the uterus treated either by surgical operation or intensive x-ray therapy. Of these cases 111 received x-ray treatment and 141 were treated by hyster-

ectomy or myomectomy. The Freiburg technique of x-ray therapy was employed in the first 51 cases, and the remaining 60 cases were treated by a modification of the Erlangen technique, which allows precision of dosage. Martindale points out that it is dangerous to use intensive x-ray therapy for any case except those in which it is fairly certain that there is no complication and that the diagnosis is clear. X-ray therapy is the ideal treatment in the case of a fibroid uterus well under the size of a six months' pregnancy, the growths being interstitial rather than subperitoneal, and the chief or only symptom being profuse menorrhagia. It is also justifiable in the presence of grave heart disease, when surgical treatment is impossible; the improvement in the general health of such patients is remarkable. In all cases of doubtful diagnosis the possibility of carcinoma of the body of the uterus must be eliminated by dilating the cervix and curetting if necessary. In other doubtful cases, and especially in young women, an exploratory laparotomy, followed by hysterectomy or myomectomy, is the correct treatment. The advantages of x-ray treatment include the elimination of nervous shock, of the inconvenience of an anaesthetic, and of the long convalescence and nursing home expenses. The author adds that the climacteric symptoms have been considerably less troublesome in patients treated by x rays than in those treated by operation. The danger of a severe x-ray burn occurring renders it essential that the treatment should be administered carefully and accurately calibrated installations be employed.

305. Molar Pregnancy and Hysterectomy.

LÉVY-SOLAL and R. DUPONT (*Gynecol. et Obstet.*, January, 1926, p. 46) describe the case of a primipara, aged 18, who was admitted to hospital suffering from intractable vomiting; she was approximately two months pregnant. Twelve days later symptoms suggesting acute appendicitis occurred, and four days afterwards laparotomy was performed. One ovary was as large as an apple and contained a typical leucine cyst; the appendix was long and bent. Vomiting persisted, and the next day a mole was expelled, but this did not arrest the vomiting. The patient grew weaker and was slightly jaundiced. Histological examination of the mole showed signs of malignancy, and total hysterectomy was performed thirty days after admission. Vomiting ceased immediately, and the patient was discharged well a month later. In the mole there were signs of early malignant changes around some of the villi, and at the fundus of the uterus two small yellowish masses were present which showed early invasion of the uterine wall by large mononuclear and polynuclear cells, grouped irregularly between the muscular fibres. The authors observe that the great majority of cases of chorion-epithelioma occur after a molar pregnancy, and they advocate a very careful histological examination of the mole. If cells suggesting malignancy are discovered they urge that total hysterectomy should be performed without delay. They comment also on the absence of records of the histological examination of moles in the voluminous literature dealing with the incidence of chorion-epithelioma following the expulsion of a mole.

305. Treatment of Hyperemesis Gravidarum.

V. J. HARDING and H. B. VAN WYCK (*Amer. Journ. Obstet. and Gynecol.*, January, 1926, p. 1) consider that the successful treatment of hyperemesis gravidarum depends upon the use of fluids, and they describe a routine procedure which has given excellent results during the last four years. This consists in the intravenous injection of 1,000 c.c.m. of 1 per cent. saline solution containing 5 per cent. glucose every day until diuresis is obtained, as evidenced by the twenty-four hour output of urine reaching 1,000 c.c.m., with a specific gravity of 1010 or less. During treatment the patient is isolated and rectal enemata of 200 c.c.m. of 10 per cent. glucose in normal saline solution are given three times a day, with the addition of 30 to 60 grains of sodium bromide in each enema for the first day or two. No solids are given by the mouth, but the patient is encouraged, even if vomiting freely, to drink any liquid she likes, except tea, coffee, milk, or cocoa. The treatment is not continued for more than six days if there is no clinical improvement, but usually this is so marked within three or four days that the patient is able to take food, the average for fourteen cases being 4.1 days from the commencement of treatment to the cessation of vomiting and the taking of food. Briefly, the treatment consists in rest in bed with isolation and the forcing of fluids by all routes, the use of glucose being secondary in importance to the use of fluids. Glucose solutions injected intravenously give rise to no untoward results if proper care as regards sterilization, temperature, and slow rate of administration is taken. While the vomiting of pregnancy is usually not characterized by acidosis, there is always a ketonuria arising partly from the accompanying starvation, but this is not a causative factor of the condition.

Pathology.

307. Diagnostic Value of the Cerebro-spinal Fluid Sugar Content.

W. P. STOWE (*Journ. Lab. and Clin. Med.*, January, 1926, p. 307) has estimated the sugar content of the cerebro-spinal fluid in 122 cases of nervous disease of different types. The technique adopted was the method of Folin and Wu, essentially the same as that employed for blood sugar. Cell counts were made in a Fuchs-Rosenthal chamber. Ten normal fluids gave a range of sugar from 60 to 90 mg. per 100 c.cm., the average value being 83 mg.; this is considerably higher than the amounts that have been considered normal by French workers. In neuro-syphilis fifteen cases gave values of 60 to 91 mg., thus showing no departure from the normal. Of twenty cases of encephalitis lethargica examined only two showed departures from the normal value, in each case in excess. Twenty-one cases of proved tuberculous meningitis had a sugar content of 10 to 50 mg.; fourteen cases of purulent meningitis had values of 0 to 25 mg. These results show that in neuro-syphilis, lethargic encephalitis, and other neurological conditions the deviation of the sugar value from the normal is so slight as to be devoid of diagnostic significance. In tuberculous meningitis the sugar is well below normal, but not so low as in the cases of purulent meningitis, in which it is frequently absent. This reduction or disappearance of sugar in infective meningitis is a valuable aid in differentiation from cases in which the spinal fluid is purulent without being actually infected—as after intraspinal therapy, in brain tumours, and sympathetic meningitis. In these, even though pus cells are often abundant, the sugar content remains normal.

308. The Path of the Rabies Virus in the Nervous System.

E. W. GOODPASTURE (*Amer. Journ. Path.*, November, 1925, p. 547), following his earlier work on herpes, inoculated the virus of rabies into the right masseter muscle of rabbits. Negri bodies were always demonstrable in the right motor nucleus of the fifth cranial nerve, in the left nucleus, and widely in the central nervous system. The most severe lesions were always found in the pons, medulla, and cervical cord, and they were apparently more extensive on the right side. Lesions in the sensory division of the fifth cranial nerve and in the cells of the corresponding Gasserian ganglion suggest an axis-cylinder transmission of the virus. Goodpasture found that the action of the virus upon the cells of the fifth motor nuclei was relatively slow and mild as compared with its effect upon the nerve cells of the Gasserian ganglion. Negri bodies appeared in the fifth motor nuclei, but it was rare to find actual necrosis, though degenerative changes might be marked. In the Gasserian ganglion, however, most of the cells died without the appearance of Negri bodies. This was in striking contrast to the action of the virus of herpes simplex, which rapidly causes necrosis of the ganglion cells first attacked—namely, those of the right fifth motor nucleus following an inoculation into the right masseter muscle. The cells of the brain are apparently more strongly resistant to the virus of rabies than those of the Gasserian ganglion, and the author suggests that this very resistance might be responsible for the development of Negri bodies in greater numbers. The impression he has gained is that the various structural changes observed in ganglion cells, including the appearance of Negri bodies, are the result of the action of the virus upon the cell and the reaction of the cell to the resulting injury. A focal degeneration of neuro-fibrillar material occurs which melts and coagulates or coheres about one or more of the structures which result from mitochondrial degeneration of axis cylinders and nerve cells. He believes that neither the virus itself nor a characteristic structural change which may be regarded as a constant accompaniment of the virus has yet been demonstrated. The hypothesis is advanced that the degenerative changes observed in axis cylinders are the result of the passage of the virus along these processes, and indicate its manner of extension from one focus to another.

309. The Metabolism in Marasmic Infants.

F. F. TISDALL, T. G. H. DRAKE, and A. BROWN (*Amer. Journ. Dis. Child.*, December, 1925, p. 829), as the result of experimental work, report that there is no evidence that the marasmic infant is less able to digest and absorb carbohydrates than the normal infant, providing there is no diarrhoea present. The heat output per kilogram of active metabolic tissue is approximately normal in the marasmic infant. The only abnormality they have been able to find in the carbohydrate metabolism in marasmus is that the average fasting blood sugar content is about 10 per cent. lower than that of the normal child; from this they infer

that the glycogen store of the marasmic infant is below normal, and they conclude that there is probably an increased heat loss in these infants. For this reason, and also to promote the building up of a store of glycogen and fat, they recommend that the feeding should be calculated upon the basis of 70 to 100 calories per lb. of body weight per day, as compared with the 45 calories required by the normal infant. In another article (*ibid.*, p. 837) they state that in infants with diarrhoea, infection, or acute intestinal intoxication there is derangement of the carbohydrate metabolism which is not primarily associated with defective production of insulin.

310. Bacteriology of Goitre.

A. CANTERO (*Surg., Gynecol. and Obstet.*, January, 1926, p. 61) has investigated the bacteriology of chronic colloid or adenomatous goitres. He made cultures of the thyroid tissue in 50 goitres under aseptic conditions immediately after removal of the gland by the surgeon. A large surface of the gland was seared by a hot blade, punctured with a sterile pipette, and some fluid removed. About 1 c.cm. of the tissue was also removed through the seared surface with sterile instruments. The excised tissue was passed rapidly through a flame, washed three times with normal saline solution, and emulsified in a sterile air chamber with normal saline solution and sand. The pipetted fluid and the emulsion were inoculated on various media. In only three cases was there failure to obtain a growth. Organisms of the streptococcal group were isolated in 31 out of the 50 cases, staphylococci in 7, pneumococci in 5, *B. welchii* in 2, and a diphtheroid, *B. pyocyaneus*, and *Micrococcus tetragenus* in one case each. Cantero suggests that organisms of the streptococcal group may be an important factor in the pathogenesis of goitre, especially since enlargement of the thyroid gland and true thyroiditis are often associated with localized streptococcal infections. He refers to the previous work of Rosenow in 1914, who recovered non-haemolytic streptococci from 25 out of 32 cases of goitre in man and from 8 out of 12 cases of goitre in dogs. Cultures of these organisms when injected repeatedly into dogs gave rise to loss of weight, diarrhoea, and thyroid enlargement, while in one case softening and pulsation of the thyroid developed together with marked tachycardia and tremor.

311. Splenomegaly of the Gaucher and Niemann Types.

W. BLOOM (*Amer. Journ. Path.*, November, 1925, p. 595) contributes a study of two cases of the unusual symptom complex associated with large cell splenomegaly described by Gaucher in 1882, and three cases of a condition frequently confounded with Gaucher's disease, and first described by Niemann in 1914. The two cases of the Gaucher type were a Jewish boy, aged 6, and a Jewish woman, aged 42; in both cases the spleen was removed. The clinical signs are marked chronicity, leucopenia, mild secondary anaemia, slight tendency towards bleeding, a peculiar brown-yellow pigmentation of the skin, splenomegaly and cirrhosis of the liver without ascites. Peculiar large pale cells occur in the liver, spleen, lymph nodes, and bone marrow. Numerous observers state that these cells are reticulum cells and possibly certain endothelial cells which have stored large amounts of a substance closely allied to cerebrin. The Gaucher cells with certain stains, especially with Mallory's aniline blue connective tissue stain, show a distinct longitudinal striation of the cytoplasm. They frequently give a positive iron reaction with the Turnbull blue method. There is no typical lipid staining. Both patients improved after splenectomy, and there was no evidence of progression of the disease. The three cases of the Niemann type reported were in Jewish infants, aged 16 months, 14 months, and 7 months respectively. Niemann's disease is characterized clinically by its appearance in infancy, under 2 years, with impairment of growth, by anaemia, leucocytosis, and by a large spleen and liver; there is no evidence of diabetes or lipaemia during life or at necropsy. These cases are also characterized by the presence of large, pale, lipid-containing cells, apparently derived from the reticulo-endothelial system, in the pulp of the spleen and lymph nodes, in the thymus, mucosa of the intestine, and medulla of the adrenals, and by the presence of lipid material in the clasmatocytes of the connective tissue, in the Kupffer cells, and in large cells lying free within the alveoli of the lungs. In sharp contrast to the Gaucher cells, the large pale cells in these cases stain positively for the complex lipids; they do not contain iron and are markedly vacuolated after treatment with absolute alcohol. Splenectomy was performed in one case; some improvement was noted for two months, when the child began to fail and died later. The author suggests the term "lipoid histiocytosis" for cases of the Niemann type, as tending to convey the idea of a process involving the storing of lipid material by the histiocytes throughout the body.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

312. Epigastric Distress.

A. MCPHEDRAN (*Canadian Med. Assoc. Journ.*, February, 1926, p. 121) discusses in detail the etiology and treatment of gastric discomfort and pain, with or without acidity. He finds that gastric distress is more common in the anxious and energetic type of patient, the usual cause being spasm of the stomach excited by air imprisoned by spasm of the oesophagus and pylorus. The author does not think that high gastric acidity is the primary cause, and attributes the discomfort to irritability of the gastric nerves, or rather to their centres in the spinal cord. The production of acidity is due to vagal stimulation, and the acidity frequently excites the spinal centres and induces gastric spasm. This can be promptly relieved by such antacids as sodium bicarbonate and magnesia. Some cases are due to chronic focal disease within the abdomen, especially of the gall bladder, appendix, stomach, and duodenum, which increases the irritability of the spinal and pneumogastric centres; a searching examination should therefore always be made of these organs, and x rays assist in doubtful cases. Other causes may be cystitis, or disease of the ear, teeth, or tonsils, the pain being referred to the stomach through the vagal and spinal centres. Cardiac symptoms, such as irregularity of beat and premature ventricular systoles, may occur, and increased salivary secretion is frequent. Stress is laid on dealing with functional causes in obtaining permanent cure. W. Verdon has suggested that oesophageal gastric spasm may sometimes be the exciting cause of angina pectoris; the present author agrees with this, and believes also that angina pectoris may be the cause of the latter condition. Treatment includes the administration of 15 grains of sodium bicarbonate, or more, in half a pint of water, one hour before each meal, to lessen acidity and flush out the stomach contents. A mild laxative is usually required, and attention should be paid to the diet. Strontium bromide and tincture of belladonna have also been found useful.

313. Dieting in Diabetes.

W. D. SANSUM, N. R. BLATHERWICK, and RUTH BOWDEN (*Journ. Amer. Med. Assoc.*, January 16th, 1926, p. 178) have been increasing the amounts of carbohydrate in the diet of diabetic patients, and have obtained good results by giving white bread, potatoes, milk, and fruit, only excluding sugar as a rule. Whereas their former diet contained, in addition to adequate protein, as much as 2 to 2.5 grams of fat to each gram of carbohydrate, the new diet contained 2 or more grams of carbohydrate to each gram of fat. The consequent increase in insulin was not found to add appreciably to the cost of treatment, since the expense of the diet was reduced. Striking improvement in the physical and mental activity of the patients was observed, and there was no trace of the acetone type of acidosis. The patients lost their craving for forbidden foods, and a somewhat lower caloric intake was apparently adequate. Such a diet has been used in the treatment of more than 150 patients, and at no time did any patient pass sugar in the urine, or signs of hypoglycaemia appear. In the milder cases improvement was noted in a few weeks after a change in diet, but in those who had been on the old diet for many years the change occurred more gradually over a period of three to four months.

314. Chronic Ulcerative Colitis.

J. A. BARGEN and A. H. LOGAN (*Arch. Intern. Med.*, December 15th, 1925, p. 818) have isolated in 88 per cent. of a series of cases of chronic ulcerative colitis a Gram-positive lancet-shaped diplococcus, growing in pairs or fours and occasionally with a capsule. It resembles Fränkel's pneumococcus morphologically, but is not bile-soluble and it does not ferment insulin, though it ferments dextrose, lactose, saccharose, maltose, raffinose, salicin, and acidified milk. The diagnostic serums of the pneumococcal types I, II, and III failed to agglutinate a number of typical strains of this organism. On blood agar the diplococcus is haemolytic (alpha) and six strains have shown cross-agglutination. The organism has been obtained in pure culture from the early lesions of ulcerative colitis, from the depths of chronic ulcers, and from distant foci elsewhere in the body. When injected intravenously into rabbits and dogs lesions were produced, especially in the dog, where the necrosis was more chronic in nature and resembled the morbid appearances found in human cases. The authors consider that the finding of this diplococcus in

distant foci and the production of acute lesions in the colon account for the repeated exacerbations of the disease and the pathological picture of layer upon layer of chronic inflammatory tissue displacing the mucosa of the colon. They suggest that the treatment of chronic colitis with necrosis should consist of (1) removal of distant foci of infection, (2) the use of vaccines or other methods of immunization against the disease, (3) local applications and irrigations, (4) the empiric use of iodine in the form of the tincture, which was found valuable by them, (5) the administration of a substance like kaolin by the mouth, (6) a non-irritating but general diet.

315. The Past History in Late Congenital Syphilis.

Y. CHATENET (*Thèse de Paris*, 1925, No. 492) investigated the past history of 75 children, aged from 2 to 15 years, who had been brought to the out-patient department at the Hôpital Trousseau, Paris, for late manifestations of hereditary syphilis. In only 12 was there no history of symptoms suggestive of syphilis in early infancy. In the remaining 63, or in 84 per cent., there was a suggestive history, such as frequent abortions and premature confinements, a high infantile mortality in the same family, hydramnios and placental lesions, melæna neonatorum, convulsions, delayed physical and mental growth, early rickets and craniotabes, convergent strabismus, hypertrophy of the thymus, irreducible unilateral hydrocele, icterus, and Sisto's sign. There was hardly ever a history of an eruption or of obvious signs of congenital syphilis, but the disease assumed the form of ordinary morbid states, such as nervous or digestive troubles, and it was only the association of several of the probable signs enumerated above that indicated the presence of syphilis. Chatenet comes to the conclusion that the discovery of such probable signs in an infant is a bar to sneaking by a hired wet-nurse and is an indication for immediate and prolonged treatment of the child without taking any notice of a negative Wassermann reaction.

Surgery.

316. Partial Resection of the Upper Jaw in Malignant Disease of the Nasal Fossa and Sinuses.

S. CITELLI (*Arch. Ital. di Otol., Rinol. e Laringol.*, December, 1925, p. 795) describes a method of resection of the supero-internal portion of the upper jaw in which the essential step is the removal of the ascending process and the neighbouring supero-internal region of the body of the maxilla, as far out as the infraorbital foramen. Portions of the nasal and ethmoid bones are resected to meet the requirements of the case. The incision begins at the supero-internal angle of the orbit and follows the margin of the nose till it ends below the nostril of the same side. A second incision passes horizontally outwards from this at the lower border of the orbit. The bone is then cut through along a line from the lower border of the pyriform fossa to the infraorbital foramen and the whole of the ascending process removed. The aperture can be easily extended by removing the anterior surface of the maxilla or the floor of the frontal sinns, and it gives very liberal access to the nasal passages. This method of approach is used chiefly in tumours of the nasal fossae and the accessory sinuses. Malignant tumours are not often brought to notice in their early stages and are difficult of diagnosis. By the time they are usually seen they have a wide area of attachment and a very liberal supply of blood and lymphatic vessels. It is then often found that a tumour presenting in the nasal fossa has invaded various of the sinuses, chiefly the frontal and sphenoidal, and may have penetrated the orbit or the naso-pharynx. The ethmoid is much less often involved secondarily than primarily, tumour formation usually starting in it and extending into the sinuses. Opacity to transillumination or to x rays in the accessory sinuses does not always indicate malignant extension, but is often a sign of purulent sinusitis only. Citelli's method is applicable to malignant tumours arising in the nasal fossae, accessory sinuses, or in the naso-pharynx. Tumours limited to the anterior portion of the septum or the floor of the nasal fossa can be treated by a much less radical operation. For tumour of the alveolar margin of the maxilla only the lower part of the maxilla is removed and any extension of disease can then be followed up. Except when dealing with a generalized osteosarcoma of the upper maxilla the author does not employ the classical operation of excision of the

bone, but performs the operation described. Moore, Liébault, and Canuyt have described a somewhat similar operation in which a vertical cut is made in the nasal bone, close to the septum; a horizontal cut is made outwards from the anterior naris in the anterior surface of the maxilla; this latter is joined to the orbital margin by a vertical cut immediately internal to the infraorbital foramen. The cut in the nasal bone is joined to the orbit by a horizontal incision and the large surface of bone thus freed is separated from its attachment to the floor of the orbit and removed.

317. Traumatic Adhesion of the Alar Ligaments to the Femur.

N. GRZYWA (*Zentralbl. f. Chir.*, January 23rd, 1926, p. 198) states that this pathological condition of the knee-joint has not been described hitherto. He reports the case of a soldier who injured his right knee, was confined to bed for a week, and afterwards treated on ordinary lines. He returned to duty, and eighteen months later on a long march he was seized with severe pain in the joint which prevented complete extension or flexion. There was no history of venereal disease. The joint was inflated with oxygen, and a skiagram showed no abnormality other than a distinct shadow, broader than normal, of the alar ligament, which entered the intercondylar fossa. The knee condition remained unchanged, and a month later Grzywa opened the joint, by Payr's method, under local anaesthesia. The alar ligament, greatly thickened, formed a dense band, adherent to the upper part of the intercondylar fossa, and covering the crucial ligaments with a red membrane resembling pannus. The band was resected and the subjacent structures were found to be normal. Complete recovery followed.

318. Pre-operative Treatment in Exophthalmic Goitre.

R. S. DINSMORE (*Surg., Gynecol. and Obstet.*, February, 1926, p. 177) discusses the methods which may be adopted for protection of the patient suffering from hyperthyroidism upon whom operation is to be performed. He points out that the conditions contributing to the risk are marked loss of weight within a short period of time, instability of the nervous system, myocardial changes, dehydration, and impending acidosis. The first and second are treated by absolute rest in bed and the administration of sedatives. The cardiac condition with the possibility of auricular fibrillation is countered by giving 30 minims of the tincture of digitalis every four hours for twenty-four hours. The dehydration and impending acidosis, with the attendant diarrhoea and vomiting, are treated by the subcutaneous administration of normal saline solution to which novocain has been added. In the treatment of the delirium which sometimes develops in the course of acute hyperthyroidism Dinsmore has had good results from the transfusion of whole blood. He considers that the best time to perform an operation is on the twelfth day after the commencement of the administration of Lugol's solution for the first time, since in uncomplicated cases the maximum improvement is noted on the eighth day of this treatment, and it is extremely difficult to produce the same condition with successive courses of treatment. Reactions have followed operations undertaken during the period of maximum benefit. For the treatment of post-operative tetany he recommends one or two intramuscular injections of 1 c.cm. of a parathyroid extract prepared by Collip's method.

319. Subperiosteal Fractures with Persistent Displacement of Fragments.

E. MÜLLER (*Zentralbl. f. Chir.*, January 30th, 1926, p. 258) describes twelve cases of subperiosteal fracture of the radius and ulna in children and a similar fracture in a man aged 38. The children's ages ranged from 2 to 15 years. In all these cases skiagrams taken after treatment of the fractures by plaster bandages showed persistent displacement of the fragments. On cutting down to the periosteum at the site of the fractures it was invariably found that the periosteum was intact, and that there was no extravasation of blood in the overlying soft tissues. On incising the periosteum Müller found fluid blood and clots which had apparently prevented reposition of the fragments, since after removal of the clots replacement of the bony fragments was easy. The author also describes the case of a boy aged 8 who sustained a fracture of the left humerus in the middle third of the shaft, with angular displacement. Reduction was effected under an anaesthetic, but a subsequent skiagram showed that the angular displacement had been converted into one of the usual longitudinal type. Müller made an incision over the site of the injury and found a subperiosteal fracture of the humerus. He recommends incision of the periosteum and evacuation of the blood and clots in all cases in which a skiagram shows persistent bony displacement after the application of splints or plaster bandages.

Therapeutics.

320.

Insulin in Surgery.

F. N. G. STARR and A. G. FLETCHER (*Surg., Gynecol. and Obstet.*, February, 1926, p. 194) draw attention to the various ways in which insulin administration is of especial value in surgery and obstetrics. By giving insulin any diet may be prescribed to strengthen a debilitated patient—a point to be remembered in preparing for operation subjects of chronic cardio-vascular disease. Excess of carbohydrate may be given under these conditions, with some apparent protective action on the liver during the course of the anaesthetic and operation. The authors recommend that 20 to 40 grams of glucose or other carbohydrate and 15 units of insulin should be administered three or four hours before the operation. Post-operative treatment should aim at anticipating metabolic disturbances so far as possible, and therefore small doses of insulin, such as 10 units three times a day, may be given as a routine as soon as food is taken. The dose should be based upon the determination of urinary sugar, and, when possible, upon the blood sugar. In major operations some degree of hyperglycaemia is unavoidable, but insulin should be increased in an attempt to control the rising blood sugar level. Ketosis may develop rapidly after an operation, and steps must be taken to re-establish adequate utilization of carbohydrates when there is hyperglycaemia and glycosuria. Increased doses of insulin may suffice for this purpose, but otherwise additional carbohydrates must be supplied. Post-operative nausea and vomiting may occur, aggravated by the ketone intoxication, and marked dehydration may set in. It may be necessary, therefore, to administer the glucose and fluid intravenously, giving 500 c.cm. of a 5 per cent. solution as often as required. In the event of infection or severe toxæmia, the insulin value may be much lowered and the patient require 50 units or more four times a day. Under such conditions the insulin administration must be pushed until it is effective in lowering the blood sugar level. Although insulin has been advocated in the pernicious vomiting of pregnancy the authors doubt its value, since it now appears that the ketonuria is the result of dehydration.

321.

Ultra-violet Rays in Asthma.

P. DUHEM (*Paris Méd.*, February 20th, 1926, p. 190) reports the treatment of 33 cases of infantile asthma with ultra-violet rays during the last year and a half. Complete cure resulted in 17 cases which had previously appeared to be hopeless, 6 were markedly improved, 4 were definitely benefited, in 4 cases no change was produced, and in 2 cases the treatment had to be terminated prematurely owing to return of the symptoms. Duham considers that the treatment should not be prolonged or intensive, and that intervals without treatment should be interspersed. He starts with an exposure of two minutes, the quartz lamp being placed at a distance of 60 cm., and increases the subsequent exposures by two minutes up to a final total of six minutes. The lamp is brought nearer by 5 cm. at each exposure, until a distance of 45 cm. is reached. Duham draws attention to the production of ozone by the quartz lamp with irritant effects on the bronchi and the lungs. He therefore emphasizes the need of caution in treating asthma in this way.

322. Stovarsol and Tréparsol in Congenital Syphilis.

R. DUPÉRIÉ, FAYREAU, and CAUTORNÉ (*Gaz. Hebdom. des Sci. Méd. de Bordeaux*, January 31st, 1926, p. 67) report four cases of congenital syphilis treated orally with stovarsol and tréparsol in the form of their soluble alkaline salts. Their toxicity is said to be weak. An infant, aged 2 months, was given stovarsol in daily doses of 0.12 g. four days a week to a total of 6.6 grams. The treatment was well borne and a marked improvement in the weight followed. All mucocutaneous lesions disappeared, but enlargement of the spleen and liver persisted until mercurial inunction was also employed. There was some craniotabes and rickets—the child was artificially fed—which were treated with ultra-violet radiation. Ten months after treatment the Wassermann reaction of the blood was negative, but four months later it was weakly positive. An infant, aged 3 months, was given daily doses of 0.05 g. of tréparsol four days a week, followed by three days of rest, with mercurial inunction. The drug was well tolerated. After two months of treatment all mucocutaneous lesions had disappeared and also a serohaemorrhagic coryza; the weight increased by nearly 1½ lb. in less than a month. The spleen and liver remained large, but three months later the liver was found to have diminished considerably. The treatment was interrupted for a month and then resumed, till in ten months the infant had had about 6 grams of tréparsol. The general condition then was very good and the Wassermann reaction of the blood was negative. Similar results were obtained in the other two

cases, the initial daily doses of tréparsol having been 0.025 and 0.05 cg., and the principle of four successive days' treatment a week with three days' rest being observed. When about 3 grams had been administered there was remission of treatment for a month; then it was resumed till a total of 3.5 to 4 grams had been taken. Symptoms of intolerance were observed in one case—vomiting, colic, and diarrhoea. The dose was lessened during these attacks. Marked general improvement and apparent cure are reported in both cases.

223. The Treatment of Latent Congenital Syphilis.

WHEN an infant presents only signs of presumptive or probable syphilis, without any evidence of active disease, M. LUST (*Le Scalpel*, January 30th, 1926, p. 112) states that mercurial function gives excellent results and is all that is necessary. He recommends that the periods of treatment be spaced so as to allow of breaks of twelve days to two months. The mother, however, is apt to interrupt the treatment on the first signs of improvement, as inunction takes time and is messy. He then falls back on the neutral mercury lactate in a solution of 1 in 1,000, the dose being spread over three feeds daily. He quotes Marfan's dosage—namely, up to 3 months, 12 drops per kilogram of body weight; from 3 months to 3 years, 10 drops per kilogram of body weight. It is given fifteen, ten, and seven days a month respectively during the first, second, and third years. It should be interrupted when there is diarrhoea, but if diarrhoea recurs each time the drug is administered recourse should be had to inunctions of mercury.

324. Local Vaccine Treatment of Chancre.

J. HABABOU-SALA (*Thèse de Paris*, 1925, No. 508), who records seven illustrative cases, employs a specific anti-Dnergy vaccine filtrate for the local treatment of chancre. Filtration is necessary, as the presence of micro-organisms would cause an intense local reaction. If the bubo has not been opened, as much pus as possible is evacuated by puncture, and then the vaccine filtrate is injected. Cotton-wool or gauze soaked with the filtrate is then applied as a dressing. Open buboes are treated in a similar way. The soft chancre itself is first cleaned with sterile water and then dressed with cotton-wool or gauze soaked in the vaccine filtrate. The dressing is renewed every day, and no other treatment is employed. The vaccine filtrate acts with remarkable rapidity. Within the first twenty-four hours the pain disappears, the pus becomes serous, and by the fourth day the bubo may be regarded as healed.

Laryngology and Otology.

325. Trigeminal Lesions in Mastoiditis.

H. ALOIN (*Rev. de Laryngol., d'Otol. et de Rhinol.*, December 31st, 1925, p. 805) describes certain cases of mastoiditis which are followed by crises which on superficial examination may be mistaken for meningeal symptoms. He mentions two cases, in girls aged 7 and 8 respectively, who suffered from acute otitis media for which paracentesis had been performed; in neither case did this prove sufficient and cortical mastoid operations were performed. In one girl a second and much more extensive operation was required before the inflammatory processes were sufficiently dealt with. In both cases the operations were followed, at some little interval, by crises of great pain, which was referred to the distribution of the inferior maxillary nerve and was associated with a functional inability to open the mouth. These attacks were very severe and continued at the rate of two or more a day for a period of several weeks. The wound showed very little tendency to heal for some time and then repair was very slow. The skin of the scalp was very unhealthy, and in one case a "bedsore" formed over the occipital protuberance. The period between the attacks was entirely free from pain or discomfort, but complete recovery from the attacks had not been attained after more than a year, though they were now slight and infrequent. The author considers that the explanation of these phenomena lies in the fact that the petrous bone is affected by an osteomyelitis which is comparable to that in the long bones. The two petrous bones are affected successively but to an equal extent. All the structures around the apex of the petrous bone are affected and there may be some transient meningeal symptoms. Various cranial nerves may be affected, but the most common is the trigeminal, and of its branches the inferior is more often involved than the others. This may be due to the very close proximity of this division of the nerve to the bone, and it also explains the fact that the motor division is affected equally with the sensory, causing the inability to open the mouth. The anterior portion of the petrous bone is much more cancellous than the posterior, and is affected

to a much greater extent than the posterior. The author has traced the progress of tuberculous disease from the middle ear by an osteomyelitis of the petrous bone to the meninges, and he thinks that, when there is evidence of petrous involvement, the possibility of infection by the tubercle bacillus must not be lost sight of. Treatment should consist of a very early and vigorous excitation of the diseased bone, and, given this, there is a fairly good prognosis. The author remarks that the surgeon must guard against being persuaded into further extensive operations at the time when the crises of pain are causing great anxiety.

326. Leptomeningitis due to Nasal Furuncle.

A. LOGAN TURNER and F. ESMOND REYNOLDS (*Journ. of Laryngol. and Otol.*, February, 1926, p. 73) describe the case of a male patient in a mental hospital who developed a boil on the right nostril which burst forty-eight hours later with much purulent discharge. The condition improved, but three days after the onset the patient complained of headache and the following day he vomited. By the fifth day the eyeballs were prominent and vision was dimmed; there was very marked conjunctival chemosis, and the eyeballs became immobile. On the sixth day the temperature, which had been 102°, rose to 106°; the patient was unconscious and died that day. At the necropsy a diffuse leptomeningitis was found and the cavernous sinuses were filled with septic blood clots. A large block of the base of the skull and the orbits was removed and serial sections were cut. It was found that practically all the veins of both orbits were filled with septic clot; the walls of the veins had necrosed, and pus had formed around them. The authors describe at length the anatomical arrangement of the venous channels of the area. They consider that thrombosis started in a venule close to the furuncle and extended into the superior ophthalmic veins, whence an embolus was detached which passed on to the cavernous sinus. Here a septic thrombus formed and spread in a retrograde direction to the veins of both orbits, both sides of the dura mater, the middle meningeal vessels, and the sphenoparietal veins. There was no involvement, either primary or secondary, of the accessory sinuses of the nose. The particular danger associated with furuncles of the face appears to be due, in the first place, to the fact that there is a very intimate association between the skin and the muscles of the face, causing almost incessant movements of the skin and a great tendency to separate off fragments of the septic clot. Secondly, the wide communication of the ophthalmic vessels with those of the intracranial region favours the disposition of the septic clot. In the case described the diploë of the bone was severely infected, its vessels being thrombosed and surrounded by pus. The optic nerve showed purulent infiltration of the subarachnoid space and the pia membrane of that nerve.

327. The Effect of Electric Shocks on the Auditory Apparatus.

U. CALAMIDA (*Arch. Ital. di Otol., Rinol. e Laringol.*, December, 1925, p. 805) records three cases in which he was able to examine the ears of patients who had been struck by lightning or powerful electric charges. In the first a sentry was struck by lightning; the right ear was not injured, but the left ear showed a small perforation of the drum with infection and thickening. Weber's and Rinne's tests indicated a middle-ear deafness, and examination of the posterior labyrinth showed no change. The second case was that of an electrician who was struck by a spark from a current of about 2,000 volts in the region of the right ear. There was some excoriation of the pinna and the drumhead was slightly reddened. Tests of hearing showed a marked internal ear deafness, tuning-forks and the Edelmann-Galton whistle being unheard. Tests of the posterior labyrinth showed a decreased excitability of the semicircular canals but a normal reaction of the otoliths. There was oscillation of the head towards the right; the nervous system showed signs of involvement—namely, uncertainty of movements and thoughts. The third case was also an electrician, who was struck by a current of 13,000 volts. He suffered from a severe bilateral deafness which was shown to be due to lesion of the apparatus of transmission and not of perception. The labyrinth was normal to rotation but hypoeccitable to caloric tests, and the otolith function was normal. Ten years after the accident this patient had markedly retracted but mobile drumheads and still very severe deafness. In these cases it is comparatively rare for the middle ear to be affected to the exclusion of the internal ear, and of the labyrinth it is usually the anterior or cochlear portion that is damaged, and the posterior escapes. This portion is, however, affected in some cases, and there is occasionally a central lesion which gives rise to symptoms such as inco-ordination and oscillation of the head, as described in the second case. It is thought that previous catarrhal changes in the middle ear predispose this part of the organ to injury.

Obstetrics and Gynaecology.

328. Forceps Delivery in Persistent Occipito-posterior Presentations.

H. C. WILLIAMSON (*Amer. Journ. Obstet. and Gynecol.*, January, 1926, p. 37) describes a method of terminating labour in a persistent occipito-posterior presentation: he combines manual rotation of the head to a transverse position with forceps application, the posterior blade in the hollow of the sacrum and the anterior blade under the symphysis. The blades thus face the occiput, so that a second application is unnecessary. In a right presentation the left hand is used to rotate and hold the head, the right hand being similarly employed in a left presentation. The hand is cupped so that the fingers are posterior to the head, with the occiput lying in the palm. Firm pressure may be made with the other hand upon the fundus, thus forcing rotation; by this manoeuvre flexion is secured and the head retained in the pelvis. In a right occipito-posterior position the right blade of the forceps is applied posteriorly, and should be introduced first without withdrawing the hand which has been passed into the uterus. The blade is passed in the mid-line and the handle depressed to avoid the promontory. The hand may now be withdrawn, since the first blade will hold the head in a transverse position; the second blade is then introduced along the side of the pelvis and rotated into position, its placing being facilitated by depressing the handle. Since the right blade was introduced first it will be necessary to cross the handles before they can be locked. In a left occipito-posterior presentation the left blade is introduced first, and the technique is similar to that described for the right occipito-posterior presentation, except that the handles do not have to be crossed. In many cases when the forceps is locked the head instantly rotates to the anterior position, but in cases in which this does not occur only slight rotation is necessary. Rotation must be completed before traction is made, so as to avoid damage to the soft tissues. Williamson reports 100 mid and high forceps cases treated successfully by this procedure.

329. Dangers of Pubiotomy.

NIEDERMAYER (*Zentralbl. f. Gynäk.*, January 23rd, 1926, p. 221) records two cases of pubiotomy in multiparae which were followed respectively by urinary fistula and by a large hernia in the labium majus at the site of rupture of a traumatic vesical fistula. Among other dangers of the operation are bleeding from the cavernous tissue or bone, infection of a haematoma, and injuries of the soft parts leading to prolapse; the formation of a psondarthrosis and difficulty in walking have also been not very rare sequelae. Although believing that pubiotomy is probably preferable to symphysiotomy, Niedermayer is inclined with increasing experience to limit still further the therapeutic scope of operations on the bony pelvis. He thinks that these are to be regarded as an alternative to perforation rather than to Caesarean section, and are absolutely contraindicated where (1) the true conjugate is less than 7 cm., (2) infection or fever is present or the liquor amnii has drained away, or (3) the foetus is dead. He adds that it is also inadvisable to perform pubiotomy in primiparae, or when the conjugate, although exceeding 7 cm., is less than 8 cm.

330. Retroposition of the Uterus.

J. F. MCGRATH (*Surg., Gynecol. and Obstet.*, February, 1926, p. 241) discusses the incidence, symptomatology, prevention, and treatment of retroposition of the uterus. He believes that retroposition *per se* does not produce symptoms and therefore does not require treatment, but where symptoms are present these are a result of associated lesions, and treatment is then called for. McGrath considers that the displacement can be the cause of the associated lesions. He distinguishes (1) a congenital type, most frequently found in young girls and nulliparous women, and (2) an acquired type which, he says, is more common than the former. He states that little can be done to prevent the congenital lesion, but suggests that careful supervision of the hygiene of the young girl at the age of puberty, combined with the occasional use of gland therapy, may lessen the incidence. Treatment of this type unless the disability is severe is unnecessary, since marriage and pregnancy usually relieve the condition. Proper preventive post-partum treatment, rapid resolution of injuries, rest in a suitable position, and, if necessary, the use of a pessary, may do much to prevent acquired retroposition. Where the condition has been present for less than a year a suitable pessary may cure it. If it has been present for a longer period conservative treatment is hardly likely to cure, but an operation will probably be successful if a pessary relieves the symptoms. Of the various methods of surgical intervention he does not recommend ventrofixation, or the operations of Olshansen and Gilliam, since by these strangulation of the intestines is possible; he prefers a modified

Simpson-Montgomery technique; or, where this is not possible or suitable by reason of prolapse of both adnexa with marked varicose veins of both broad ligaments, he advises the Baily-Webster operation.

Pathology.

331. Vaccination against Anaerobic Infections.

M. WEINBERG and J. BAROTTE (*C. R. Soc. de Biologie*, February 12th, 1926, p. 312) have attempted to immunize guinea-pigs to some of the anaerobic organisms that are likely to gain access to wounds. The vaccines used were prepared by the addition of 0.3 to 0.5 per cent. formal to a twenty-four hours' glucose broth culture, incubating for a week or a fortnight to kill the organisms, centrifuging, and suspending the deposit in 50 per cent. glycerol. Immediately before use the vaccine was made up to its original bulk with saline. One set of twenty guinea-pigs received two doses of *B. welchii* at fourteen days' interval. Two to four weeks after the second injection they were tested for immunity by the inoculation of virulent bacilli. All of them withstood one lethal dose; the control animals died the same night. Another set of twenty guinea-pigs received two injections of *B. oedematis mallei* vaccine, and forty-six days later they were injected with living bacilli. The controls died during the night; the vaccinated animals either survived or did not die for two days. A third set of guinea-pigs received two injections of a vaccine consisting of equal numbers of these two organisms. Sixty-nine days later they were injected with a mixture of living organisms of both species. The control animals died or recovered slowly after showing serious lesions; the vaccinated animals all survived, though they developed a more or less marked tumefaction of the thigh. These experiments are admittedly not conclusive because many of the vaccinated animals appear to have died from intercurrent epidemic diseases, but they do show that a certain degree of immunity can be attained as the result of the injection of formalized vaccines. The authors suggest the addition to the vaccine of *B. oedematis*. A few experiments made on human volunteers show that the bivalent vaccine at least is well supported in doses of 5 to 10 c.cm.

332. Blood Calcium in Eclampsia.

S. M. FEINBERG and A. F. LASH (*Surg., Gynecol. and Obstet.*, February, 1926, p. 255) have made a pathological investigation of the calcium content of the blood in eclampsia to ascertain whether any etiological significance could be traced. Disturbance of the calcium metabolism has been described in infantile tetany; it is also known that during pregnancy osseous changes, such as softening of the bones and dental decay, may occur, which might be interpreted as evidence of interference with the calcium balance. The blood calcium figures of eleven cases of normal pregnancy were determined shortly before delivery, and twelve cases of pre-eclampsia and eclamptic toxæmias were examined. Although the calcium figures for eclampsia were slightly lower than those for normal pregnancy, the authors conclude that the difference is so slight as to be negligible. Moreover, in cases of anaemia, chronic nephritis, and cavernous sinus thrombosis, still lower figures were obtained. In none of the cases of eclampsia was there any evidence of a disturbed calcium metabolism as suggested by a history of delayed dentition, tetany, or rickets.

333. Inoculation of Herpes Febrilis.

P. REMLINGER and J. BAILLY (*C. R. Soc. de Biologie*, October 30th, 1925, p. 983) describe the various methods employed by them in inoculating the virus of herpes febrilis into rabbits. (1) Intraperitoneal inoculation. Two out of four animals so inoculated developed typical herpetic encephalitis. (2) Inoculation into the tongue muscles, a method which Remlinger had previously described as likely to be useful owing to the close proximity of the nerve centres and the richness of the tongue in nerves and lymphatics. Of two rabbits inoculated in this manner one remained unaffected and the other developed typical herpetic encephalitis. (3) Intratesticular inoculation. A rabbit so inoculated developed paraplegia followed by fatal ascending paralysis. Subdural inoculation of a testicular emulsion produced typical encephalitis in two other rabbits. (4) Inoculation of an emulsion of a herpetic brain into the marginal vein of the orbit caused sudden death of a rabbit ten days later, and passage produced typical encephalitis in four days. (5) Conjunctival instillations of a cerebral emulsion from a rabbit which had died of encephalitis reproduced the disease in another animal. (6) Intranasal inoculation after scarification of the mucous membrane caused progressive cachexia, and passage gave rise to typical encephalitis. (7) Nasal instillations without damage to the mucous membrane had no effect on one rabbit and caused the death of another with symptoms of encephalitis.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

334.

Protein Sensitivity.

I. M. ALLEN (*New Zealand Med. Journ.*, December, 1925, p. 285) reports a consecutive series of 65 patients suffering from such affections as asthma, urticaria, hay fever, eczema, and food idiosyncrasy; in each case some indication of protein sensitivity was detected. He states that this sensitivity is entirely responsible for hay fever and for the majority of cases of asthma, urticaria, eczema, and food idiosyncrasies. In 26 cases the sensitivity was manifest before the age of 5, and 22 patients first noticed their disability between the ages of 20 and 40. In no case was the sensitivity first observed after the age of 45. He distinguishes three types of asthma: (1) that preceded by hay fever—hay asthma; (2) that secondary to bronchitis; and (3) that due to food sensitivity. He considers hay fever, all respiratory infections, and severe respiratory infections in adults as being pre-asthmatic conditions, and stresses the need for early treatment in the pre-asthmatic stage or on the first appearance of asthmatic symptoms. He thinks that this pre-asthmatic condition should be regarded as seriously as the precancerous condition in view of the individual disablement and the economic loss. Treatment should therefore be energetic and include alleviation of symptoms, removal of the irritating substance, specific desensitization, group desensitization, and non-specific desensitization, undertaken in this order. Allen has also investigated cases of idiosyncrasy towards aspirin, and found that these patients were very sensitive to many different proteins; the symptoms in each case were rhinorrhoea, urticaria, and asthma.

335.

Prophylaxis against Tuberculosis.

F. CEVEY (*Journ. Trop. Med. and Hygiene*, February 15th, 1926, p. 53) urges the necessity of a more efficient prophylaxis against tuberculosis by seeking for its earliest signs without waiting until the infection has become a disease. He points out that this can only be attained by the systematic examination of school children. At the earliest sign of undernutrition and diminished resistance, as shown by clinical symptoms, x-rays, and von Pirquet's reaction, active immunization, followed by physical training, should be commenced. Periodical examination should follow so that treatment may be repeated if found necessary, and the spread of infection prevented by education and disinfection. By treating any accompanying tuberculous infection at the same time that the undernourishment is being corrected the gain to nutrition has been more than doubled in six classes of children under observation, and Cevey argues that a method which has been found capable in three or four months of providing for tubercle-infected children in cities a state of nutrition two and a half times greater than that found among children living in the country is deserving of attention.

336.

Glandular Fever.

F. MÜNDEL and J. FRANZ (*Monatsschr. f. Kinderheilk.*, February, 1926, p. 54) report an epidemic of eight cases of glandular fever which occurred in the whooping-cough department of the children's clinic at Frankfurt. The following features were common to all: (1) The patients were children aged from 2 to 3 years. (2) They were mainly children of a pasty lymphatic appearance and with active rickets. (3) A sudden onset of fever with a low degree of rhino-pharyngitis, regularly followed within twenty-four to forty-eight hours by swelling of the neck glands. (4) Absence of enlargement of the liver and spleen, which Pfeiffer regards as characteristic of glandular fever. (5) Normal blood picture. In spite of repeated examinations, there was no increase of eosinophils or relative lymphocytosis, to which Sammel attaches considerable diagnostic importance. The authors attribute the glandular enlargement to the child's lymphatic constitution and not to a bacterial infection.

337.

Diphtheria following Tonsillectomy.

A. ZINGHER (*Amer. Journ. Dis. Child.*, January, 1926, p. 72) points out that diphtheria as a complication following tonsillectomy may be overlooked until too late for effective antitoxin treatment. The post-operative slough closely resembles a diphtheritic pseudo-membrane, and consequently may lead to the danger of a superimposed secondary diphtheria being unrecognized. The necessity for routine bacteriological examination of the nose and throat before operations in these regions is emphasized, unless a previous negative

Schleik test has been obtained; carriers so discovered may be protected by a prophylactic dose of antitoxin. Zingher gives notes of four cases occurring in children, aged from 3 to 9, in which diphtheritic faucial lesions developed immediately after tonsillectomy. The serious nature of such a superimposed diphtheria lies in the early and rapid absorption of a fatal dose of toxin from an extensive raw surface, and the difficulty in recognizing the disease in the post-operative slough until much time has been lost and the opportunity for effective antitoxin treatment has passed. If cultures are positive a prophylactic dose of 1,500 units should be given unless the patient already shows a definite negative reaction with the Schleik test. Zingher recommends the active immunization of all young children with the new toxin-antitoxin mixture or with diphtheria toxoid.

338.

Measles and Poliomyelitis.

D. TRONCONI (*Riv. di Clin. Ped.*, January, 1926, p. 58), imitating the method of treatment of general paralysis and encephalitis by malarial virus, exposed two children, aged 4 and 2 years respectively, after a recent attack of acute poliomyelitis, to the infection of measles. The poliomyelitis had developed five days previously in one child, in whom it had caused flaccid paralysis of the right shoulder girdle, and a week previously in the other, in whom it had produced flaccid paralysis of the lower limbs. One child developed measles in seventeen days, and the other in twenty-three. On subsidence of the fever and disappearance of the rash spontaneous movements occurred in the paralysed limbs, being at first very limited, but subsequently more extensive and energetic, until in twenty days' time one child was able to raise his shoulder girdle, and the other to perform normal flexion and extension of the limbs, which had hitherto been as lifeless as those of a puppet. Tronconi suggests that the virus of poliomyelitis was modified by the action of the measles virus, and that the neurones which had been affected but not destroyed were thereby enabled to make an anatomical and functional recovery.

Surgery.

339. Resection of the Lumbo-sacral Sympathetic in Impending Gangrene of the Leg.

Y. OSAWA and G. USAMI (*Zentralbl. f. Chir.*, February 6th, 1926, p. 326) state that the success of Leriche's and Brüning's periarterial sympathectomy induced them to resect the lumbo-sacral sympathetic trunk in a case in which ligature of the popliteal artery for aneurysm was followed by serious symptoms of impending gangrene. A workman, aged 55, with a syphilitic history and strongly positive Wassermann reaction, noticed a pulsating swelling in the left popliteal space; he was given a short course of antisypilitic treatment. On admission to hospital six months later the swelling was found to be as large as a child's head and the overlying skin was necrotic. The internal organs were healthy, but the patient was anaemic. The left dorsalis pedis artery could not be felt. Four days later the aneurysmal sac was laid open, clots and necrotic tissue removed, and lateral suture of the artery was performed. After the operation there was distinct pulsation in the small arteries of the foot. Three days later serious secondary haemorrhage occurred and the artery was ligatured above the aneurysm. After the artery had been ligatured and an Esmarch's bandage removed there was very slight bleeding from the distal portion of the popliteal artery. Subsequently the leg became cold and pale, with diminished sensibility for more than three inches above the ankle. In the evening the skin of the limb became wrinkled and the whole foot was colder than the other. Next day the foot and calf were cyanosed and the temperature (between the toes) was two or three degrees lower than that on the right side. On the following day subumbilical laparotomy was performed under a general anaesthetic. The three lower lumbar sympathetic ganglia were exposed, the sympathetic trunk was freed from the common iliac vessels and resected together with the three upper sacral sympathetic ganglia; the posterior and anterior layers of the peritoneum were sutured and the abdomen was closed. After the operation the temperature of the left toes rose rapidly; in six hours they were two degrees above those of the right foot, and the left dorsalis pedis artery was pulsating. Cyanosis and pallor were replaced by slight reddening. Twelve hours later the posterior tibial artery was pulsating.

the wrinkled skin had become smooth, and sensation was normal; the necrotic area in the popliteal space showed a line of demarcation and free granulation. No bladder complication occurred, and the patient made a good recovery.

340. Diagnosis of Lateral Sinus Infection.

G. L. TOBEY (*Boston Med. and Surg. Journ.*, January 14th, 1926, p. 53) describes means of detecting lateral sinus thrombosis, and states that, when there is evident sepsis during the course of an aural infection, failure to localize the seat of infection is an indication for ligature of the jugular vein and exploration of the lateral sinus. When thrombosis with complete or incomplete obliteration of the sinus is present it may be demonstrated by observations on the pressure of the cerebro-spinal fluid. His method of conducting this test is as follows. With the patient in the lateral position a lumbar puncture is made and the fluid allowed to run into a glass manometer of 2 mm. bore. The initial pressure is noted, as also are the variations due to the pulse and respiration. Without disturbing the patient pressure is applied to the normal side of the neck between the larynx and the sterno-cleido-mastoid muscle until a strong carotid pulsation is felt. During the compression the height of the column in the manometer rises, to fall again when the pressure is released. This is repeated on the opposite side and then on both sides simultaneously. When lateral sinus thrombosis is present there is no rise, or only a slight rise, when the abnormal side is compressed, and pressure on both sides gives approximately the same reading as when the normal side only is pressed. Tobey has found this test of great value in cases of double mastoiditis with symptoms of lateral sinus thrombosis. He admits the possibility of two dangers: (1) sudden death, from the presence of subdural abscess or tumour, following the lumbar puncture; (2) the precipitation of acute meningitis due to the liberation of organisms from an area of localized infection or from the blood stream. The first may be almost excluded by not performing the test where there is a possibility of these conditions existing. The latter he considers hardly likely to occur, and in a series of eighty-four cases he has not had evidence of ill effects resulting from the use of this test.

341. Etiology of Surgical Tuberculosis.

H. KELLER (*Med. Journ. and Record*, February 3rd, 1926, p. 169), who reports a series of 46 cases of joint tuberculosis, states that tuberculous infection in childhood is responsible for the majority of tuberculosis in all ages; it is therefore important to trace the seat of the primary infection. Bone and joint tuberculosis generally arises from a primary focus elsewhere in the body, and this is most often found in the lymph nodes lying in the mediastinum. This statement, he says, is very well substantiated by x-ray photographs and post-mortem findings, and therefore an x-ray examination of the chest should always be made when there is tuberculous disease of the bones or joints. Moreover, treatment directed solely towards cure of the joint infection is only palliative, and attempts should be made to eradicate the primary focus. For this purpose radiation of the chest should be employed in those cases where enlarged lymph nodes are present in the mediastinum, as by this means the lymphoid cells are destroyed and replaced by fibrous tissue, thus simulating Nature's method of combating tuberculosis. Keller has examined the tonsils in forty children treated for joint tuberculosis, and found them infected in thirty-two cases. Therefore, he adds, the tonsils should always be removed when they are suspected, and further, small buried sclerosed tonsils are often a greater danger than those of normal size, since they may increase the facility for infection because of the wider openings of the crypts and atrophy of the lymphatic tissue.

342. Congenital Displacement of the Scapula.

R. D. SCHROCK (*Journ. of Bone and Joint Surgery*, January, 1926, p. 207) points out that at the ninth week of foetal life the scapula begins to descend from the neck to the thorax. Failure in descent may be due to maldevelopment in bone, cartilage, and muscle, or the movement may be interrupted by abnormal pressure in the uterus. There is still much doubt about the exact cause of this congenital deformity, and its treatment appears on the whole to have been discouraging in the past. In cases where a chondro-osseous bridge was present a simple resection was advised; if the muscles were shortened myotomies were performed. Schrock has obtained far more satisfactory results by a more radical procedure; this consists of radical subperiosteal transplantation of the scapula with osteotomy of the base of the acromion process. After exposure of the scapula the muscles are removed by subperiosteal elevation. Where a chondro-osseous bridge passes from the vertebrae to the upper border of the scapula this is removed freely. If the shoulder cannot then be

brought back, an osteotomy of the base of the acromion is performed; this gives an appreciable downward drop of the shoulder. The lower angle of the scapula is then anchored to the lowermost rib and the muscles are sutured in anatomical layers. This procedure was adopted in two cases with good results, and full details and photographs are given to explain the technique of the operation.

Therapeutics.

343. Prophylactic and Curative Value of Pertussis Vaccine.

HÉLÈNE M. BROUWER-FROMMANN (*Nederl. Tijdschr. v. Geneesk.*, January 9th, 1926, p. 142), owing to an outbreak of whooping-cough in a children's home, employed pertussis vaccine in 38 cases. The children, whose ages ranged from 2 months to 3 years, were given subcutaneous injections in doses from 750 million to 3,000 million bacilli. The results were as follows: (1) All the 38 children contracted the disease. (2) The epidemic ran a very mild course. The number of the paroxysms was not very great and the paroxysms themselves were not very violent in character. (3) Sudden cessation of the paroxysms after injection of the vaccine did not occur. (4) No complication developed and there was little loss of weight, but rather the reverse. (5) In patients aged from 18 months to 3 years the disease was over in four weeks' time; in children aged from 6 to 18 months it lasted somewhat longer; and in younger children still it lasted six weeks or more. The author's experience thus differs from that of Freeman, Luttinger, Marinucci, Galli, Auricchio, and von Bokay, who obtained good results from prophylactic injection of pertussis vaccine.

344. W. F. ENKLAAR (*Ibid.*, January 23rd, 1926, p. 349) treated a hundred cases of whooping-cough in children aged from 0 to 12 years with Bordet-Gengou vaccine, and obtained good results in all but four, in whom the disease was not affected by treatment. The first requirement of a pertussis vaccine is that it should be absolutely pure and contain virulent pertussis bacilli. As a general rule three injections are sufficient, the dosage on each occasion being 3,000 million bacilli. The patients usually showed little or no rise of temperature after injection, unlike what happens after injection of other vaccines, especially antipneumococcal, when a temperature of 104° is frequently observed. No bad effects were noted. The injections were given intramuscularly every other day. Improvement occurred sometimes after the first injection, often after the second, and after the third at latest, and consisted in the cough becoming loose and less frequent, so that the disease could be regarded as cured in nine to ten days. In infants the improvement was shown by disappearance of the almost pathognomonic facial pallor. Pulmonary complications were rarer and milder than usual, and suppurative otitis cleared up completely after paracutis. Lastly, the good effect of the vaccine treatment was shown by the mortality among the hundred cases being nil. Enklaar concludes that pertussis vaccine is a remedy of great value.

345. Insulin in Exophthalmic Goitre.

O. KLEIN (*Med. Klin.*, February 12th, 1926, p. 248) states that encouraging results have been reported from the treatment of exophthalmic goitre by insulin. The improvement was shown by gain in weight and the relief of tachycardia, mental disturbances, and tremor, as well as by a general improvement in the patients' condition. Klein has had three cases of similar improvement. He suggests that there are several forms of exophthalmic goitre and that insulin is useful only in the pancreaticogenous type, but fails in cases of thyroid origin and in those due to primary hypophyseal disease. He adds that confirmation of this view has been provided by other Austrian and German investigators.

346. Treatment of Parkinsonism by Stramonium.

E. JUSTER and R. HUERRE (*Bull. Soc. de Théor.*, January 13th, 1926, p. 11) have treated several cases of Parkinsonism, both of the post-encephalitic variety and paralysis agitans, by stramonium in pills or cachets in progressively increasing doses of 0.05 or 0.10 gram, which were given preferably during meals. They always tried to reach the maximum limit of tolerance, being guided by the following symptoms of intolerance: pain in the stomach, dryness of the mouth, and mydriasis sufficient to interfere with reading. The improvement was most marked in the rigidity, while accessory symptoms, such as salivation, sweating, insomnia, emotionalism, and anxiety, were much attenuated. On the other hand, the tremor was little affected. The action of stramonium on the rigidity was undoubtedly due to the

alkaloids contained in stramonium—namely, atropine and hyoscyamine. Treatment of Parkinsonism by stramonium is merely symptomatic, but in the absence of etiological therapy it is one of the most successful, least toxic, and simplest measures. In order to prevent habituation to the drug the authors administer it for periods of twenty days, followed by an interval of ten days, or alternate it with other drugs, such as arsenical compounds or derivatives of malonylurea or hemlock seeds:

347. Intravenous Injection of Camphor.

G. HOSEMAN (Zentralbl. f. Chir., February 13th, 1926, p. 394) states that he has used camphor injections in over a thousand cases during the last ten years and that the method has also been well tested by a number of leading surgeons. Schröder (Kiel) reports that he has recently abandoned the transfusion of large quantities of blood, as he considers that the intravenous injection of camphor is preferable. Hosemann's solution had the following formula: "Spiritus camphoratus" 3.5 parts, alcohol 2 parts, and sterile distilled water 4.5 parts. The results are said to be more certain than those produced by the injection of sodium chloride, and normal saline, or glucose solutions. This injection of camphor into the blood stream is stated to have remarkable results in cases of severe haemorrhage and of circulatory failure, whether due to shock or to septic absorption. A patient had had intestinal obstruction for several days; he was pulseless, with cold blue extremities, but after the above treatment he rallied sufficiently to enable laparotomy to be performed. In twelve cases of paralytic ileus, following suppurative appendicitis and peritonitis, the patients' lives were saved by injections of camphor-glucose solutions, and Heidenhain's ileal fistula. The patients rally immediately after the injection and experience a sensation of warmth and of returning strength.

Radiology.

348. Aplastic Anaemia due to X Rays.

J. LANKHOUT (Nederl. Tijdschr. v. Geneesk., December 19th, 1925, p. 2789), who records an illustrative case, states that it is generally known that x rays and radium may cause changes in the blood. Mottram and Clarko (1920) have shown that persons who employ radium for therapeutic purposes may present leucopenia at the end of a fortnight. Mottram (1920) has emphasized the importance of early blood examination in radiologists. Not only did he find in many cases a diminution of the red corpuscles and a high colour index, but he also observed three fatal cases, and Larkins recorded another. In all these cases the disease ran a rapid course, death occurring in a few months. Amundsen (1924) found that the blood in radiologists always differed from the normal. The total number of red corpuscles was often unusually low. The change in the blood picture, however, was most marked in the relation of the polymorphonuclears to the lymphocytes. The haemoglobin value was usually normal. The effect of radiological work on the blood becomes distinct after one or two months, and may be observed even in the servants attached to a radium institute. The new Coolidge tube is particularly dangerous owing to the remarkably penetrative power of its rays. Lankhout's case was that of a medical practitioner, aged 34, who was director of an x-ray institute, and had been working without any protection against deeply penetrating rays. When he was first seen by Lankhout he was moribund, but he gave a history of weakness, shortness of breath, and pallor of some months' duration. Examination of the blood gave the following results: Haemoglobin 13 per cent. (Sahl), colour index 1.3, red cells 610,000, leucocytes 900, 52 per cent. of which were polymorphonuclears and 48 per cent. mononuclears. The red cells showed anisocytosis, poikilocytosis, polychromatophilia, basophil stippling, and nucleated forms.

349. Radiological Diagnosis of Gastric Syphilis.

L. T. LEWALD (Radiology, February, 1926, p. 138) maintains that a radiological examination affords the best means of recognizing the existence of syphilis of the stomach, and reports cases with radiograms in illustration. He considers that the characteristic evidence so obtained is as follows. The stomach in syphilis may appear to be diminished in size, and there is always immediate evacuation of most of the stomach contents; compensatory dilatation of the oesophagus is often present. In other cases there may be a fairly symmetrical deformity involving the middle of the stomach and producing a dumbbell-like appearance. When this is found in a young patient or in an older one, without cachexia commensurate with a malignant involvement of the stomach of this extent, syphilis should always be suspected. Some

cases show a remarkably small and tubular stomach; this is far more difficult to distinguish from carcinoma. In another class the x-ray appearances resemble those of carcinoma, there being localized infiltrated areas of the stomach wall. When the syphilitic lesion is situated at the pylorus, producing stenosis and gastric retention, it is always more extensive than the lesion in simple ulcer and may be as marked as in gastric carcinoma. The warning is given that, though a positive Wassermann reaction does not necessarily prove the specific nature of a stomach lesion, yet, on the other hand, a negative Wassermann reaction does not exclude it. In doubtful cases antisyphilitic treatment under radiological supervision should always be employed in cases where there is any doubt as to the diagnosis, or where malignancy is believed to be present and so advanced as to render operation impracticable. A case is cited of syphilitic perforation causing death, no treatment being given, owing to an erroneous diagnosis of advanced malignancy.

350. X Rays in the Diagnosis of Intestinal Tuberculosis.

N. H. BLAKIE and A. T. LAIRD (Minnesota Med., February, 1926, p. 66) believe that with the aid of x rays it is possible to diagnose tuberculous ulceration of the colon near the caecum much earlier than formerly. They consider that every case of pulmonary tuberculosis should be examined with the aid of a harlin test meal or enema to demonstrate such evidence of tuberculosis as the too rapid passage of the meal through the inflamed areas (Stierlin's phenomenon). In tuberculous enteritis the harlin passes rapidly through the large bowel, evacuation often being completed within twenty-four hours; the caecum and lower colon appear to pass the meal along as soon as it is received. The usual haustral sacculations are lacking and the affected portions are only partially filled, presenting a ragged and irregular appearance. Occasionally the barium is delayed at the ileocaecal valve from spasm (ileal stasis), and these pictures of hypermotility, filling defects, and ileal stasis are regarded as characteristic of ulceration of the caecum and ascending colon.

351. X Rays in Carcinoma of the Breast.

B. J. LEE and N. E. TANNENBAUM (Journ. Amer. Med. Assoc., January 23rd, 1926, p. 250) record 363 cases of recurrent inoperable and metastatic carcinoma of the breast treated by radium and x rays. Of these, 158 were too far advanced to benefit by treatment, thus leaving 205 for whom treatment by irradiation offered a reasonable hope for some regression and control of the disease. Irradiation by low voltage was used in the majority of instances, treatment being repeated over the same areas if regression was insufficient or if the disease remained stationary. This form of therapy was employed for supraclavicular or axillary involvement and for diffuse cutaneous recurrences with striking disappearances of cutaneous nodules. For large, well circumscribed recurrences the radium pack or radium tray was used, while harlin tubes of emanation were employed in the smaller superficial recurrent nodules or in axillary nodes. Of the 205 favourable cases 34 (17 per cent.) patients are alive, and the authors are convinced that treatment by irradiation gives a definite prolongation of life with an amelioration of many symptoms and may control the disease for some years. As prophylactics against recurrence they advocate careful selection of patients for operation and pre-operative and post-operative cycles of x-ray treatment.

Obstetrics and Gynaecology.

352. Late Urinary Sequels of Gynaecological Operations.

G. ALBANO (Ann. di Ostet. e Ginecol., December 31st, 1925, p. 861) remarks that in addition to the retention of urine immediately following gynaecological operations, which yields promptly to treatment by urotropine, it is not uncommon to encounter urinary symptoms beginning from three weeks to three months subsequently. These late symptoms have been considered to indicate a bacterial invasion, and the condition has been termed by Grandjean post-operative cystitis; but in addition to cases in which there is clearly an element of infection others exist in which the disturbance is functional; these are often associated with the menopause. The symptoms, arranged in order of prevalence, are: diurnal frequency of micturition, cystalgic pain, pyuria, nocturnal frequency, dysuria, and haemorrhage at the end of micturition. Albano found that late urinary symptoms occurred after 18 per cent. of gynaecological operations, and were most frequent after operations on the uterus; careful inquiry showed that, as a general rule, the earliest symptoms were experienced within the first thirty days. Prognosis is favourable, and most cases speedily clear up spontaneously or after medical treatment.

353. Evolution of the Graafian Follicle and the Corpus Luteum.

W. SHAW (*Journ. Obstet. and Gynaec. of the British Empire*, Winter No., 1925, p. 679) points out that very little attention has been paid to the Graafian follicles which do not rupture and shed their ova. He describes the results of investigations of young and degenerated corpora lutea, and gives an account of the atretic processes in follicles which do not rupture. The ovaries were obtained from patients who were operated upon for various pelvic conditions. Although a minor degree of follicular ripening frequently occurs before puberty no ovum is shed, and no corpus luteum is produced. The majority of follicles formed before puberty undergo atresia, other primordial follicles maturing in their place. The process of ripening occurs before rupture of the follicle and ovulation ensue. The size of the follicle increases through the distension of the cavity with liquid, and the granulosa cells proliferate and hypertrophy, the most marked change being seen in the cells of the theca interna layer, which increase in bulk and number, assume a brown colour, and their protoplasm becomes granular. Shaw has obtained three specimens of very early corpora lutea, and gives a brief account of their development. He concludes that the large lutein cells are derived from the granulosa layer of the follicles; the paralutein cells develop from the theca interna layer. The corpus luteum becomes converted into a corpus albicans in about eight months. The following atretic structures are derived from the Graafian follicle: the corpus atreticum, the corpus canalicans, the corpus fibrosum, and the corpus testiforme.

354. Appendicitis and Pregnancy.

MAORTÚA and G. DUARTE (*Arch. de med., cir. y esp.*, February 20th, 1926, p. 337), who record a fatal case in a woman aged 27, illustrate the rarity of appendicitis in pregnancy by the fact that Reeb's case was the only instance of the kind among 5,000 pregnancies in the Strasbourg maternity. The gravity of appendicitis in pregnancy is shown by the following high case mortality reported by various observers: 50 per cent. among 486 cases (Schmid), 59 per cent. (Rosner), 50 per cent. (Heaton), and 53 per cent. (Abraham). In the present case, which the authors regard as an example of recurrent appendicitis, the exciting cause was probably a gastro-intestinal disturbance which occurred two nights before the attack. Operation was performed within twenty hours of the onset. A gangrenous appendix was found with turbid sero-purulent fluid in the peritoneal cavity. Removal of the appendix was followed by posterior colpotomy and drainage. Death from peritonitis occurred forty-eight hours after the operation.

Pathology.

355. Filter-passing Forms of Bacteria.

P. HAUDUROY (*C. R. Soc. de Biologie*, February 5th, 1926, p. 246) filtered some water containing bacteria through a Chamberland L3 candle that had been carefully tested. The filtrate was divided into two parts, one of which was left untouched, and the other added to peptone water; both parts were incubated at 37°C. After a week small white granules were visible in the culture, forming a slight deposit at the bottom of the tube. Microscopically they consisted of Gram-negative granules of irregular shape, and varying in size between the limits of visibility and the diameter of a staphylococcus. No change occurred in the culture on further incubation, even after several months. Subculture was attended by great difficulty, but after several attempts it proved successful. The description of the appearances on subculture is reserved for a future article, but apparently the growths obtained were of an unusual type. After several subcultures Hauduroy succeeded in demonstrating bodies that morphologically and biochemically were indistinguishable from normal bacteria. In particular he isolated one bacillus closely similar to, if not identical with, *B. typhosus*. In conclusion he affirms that in polluted waters there exist abnormal forms of bacteria which can be isolated by filtration. They pass through a stage in which they are invisible, followed by one in which they assume a granular form, and eventually reach a stage in which they develop into normal bacteria.

356. Mediastino-pulmonary Lymphosarcoma.

C. ROUBIER (*Rev. de méd.*, No. 7, 1925, p. 537), who records three illustrative cases, states that in the large group of intrathoracic cancers a special place must be reserved for a peculiar variety of new growths which originate in the mediastinal glands, and are characterized by a very early invasion of the lung and almost exclusively pulmonary symptoms. The proof of the mediastinal origin of such

tumours is supplied by their morbid anatomy, which reveals the existence of a diffuse cancerous mediastinitis invading one of the lungs by the hilum and penetrating the pulmonary substance along the peribronchial sheaths. Histological study of these growths shows that their structure, like that of malignant tumours of the mediastinum, is that of lymphosarcoma. Unlike cancers of the pulmonary hilum, in which signs of compression predominate, they do not give rise to any pressure symptoms. Mediastinal symptoms are completely absent, and the clinical picture is that of a chronic pulmonary affection, which may be mistaken for pleurisy or tuberculosis. Invasion of the lung may occur in several ways. The growth may attack an upper or lower lobe in which it remains localized (mediastino-lobar cancer), or it may extend along the fissure between the lobes (mediastino-fissural cancer). These lymphosarcomatous tumours are generally of large size and rapid growth, and often give rise to multiple metastases. Sometimes they undergo softening and form cavities full of a puriform fluid which may be mistaken for pulmonary abscesses. The course is rapid and death from progressive cachexia occurs in a few months. Association with pulmonary tuberculosis is not an exceptional occurrence.

357. Action of Mercury Vapour Arc Baths upon the Blood.

R. G. BANNERMAN (*Brit. Journ. of Radiol.*, February, 1926, p. 71) reports the result of an investigation of the effect on the blood of rather heavy single doses of light from the mercury vapour lamp, administered in cases of pseudo-coxalgia and certain orthopaedic deformities, as well as in surgical tuberculosis. In all cases irradiation was followed by a diminution of the number of red corpuscles, but in the absence of blood volume determinations it is not certain whether this is a real or an apparent change. The reduction occurred immediately and persisted for several days, to be succeeded in some cases by a rise above the original level. The total leucocyte count was sometimes, but not always, increased, but a rise in the polymorphonuclear cells occurred, and in many cases there was a reduction in the number of mononuclear cells. Monocytosis followed in some cases, but after a few days the normal number and distribution of the cells returned. Eosinophil cells were markedly diminished, both relatively and absolutely, after the exposure, but then returned to or exceeded the original number. The sedimentation rate increased soon after exposure to the lamp and remained at a high level for some days; it was then reduced to or below the original level. As a rule there was an increase in the ability of the defibrinated blood to destroy staphylococci for some hours after light treatment, but this fell to the original figure in twenty-four hours, and in some cases remained subnormal for some time. Bannerman thinks it significant that these results were not obtained in patients habituated to light treatment and already pigmented, but were associated rather with the stage of erythema, which is a sequel of such massive doses. He draws the conclusion that such excessive dosage is to be avoided.

358. Filterable Forms of Tubercle Bacilli in Apparently Normal Organs.

J. VALTIS (*C. R. Soc. de Biologie*, February 19th, 1926, p. 376), who has already shown that it is sometimes possible to pass a suspension of tuberculous material through a Chamberland filter without depriving it of its infectivity to animals, now reports that the filter-passing forms of the tubercle bacillus may be present in apparently normal organs. Three rabbits were injected intravenously with a bovine strain of tubercle bacillus; a fortnight later they were killed, and their spleens, which appeared quite normal, were ground up in a mortar with sterile sand, suspended in saline, and filtered through a Chamberland L2 candle. Two days later 15 c.cm. of this filtrate was injected subcutaneously into two guinea-pigs, and on the following day 10 c.cm. was injected, the filtrate having been kept on ice in the meantime. One of these animals died three and a half months later, and no local lesion or local adenitis was found, but the spleen was enlarged and showed haemorrhagic points and caseous lesions. The tracheo-bronchial glands were enlarged, and typical tubercles were found in the lungs. In all these lesions the tubercle bacillus was found microscopically. The second animal was killed two days later. No local lesion was present and the spleen appeared healthy, but there were two nodules in the omentum, and the tracheo-bronchial glands were enlarged. In both lesions Koch's bacillus was found. It would appear from these experiments that filterable forms of the tubercle bacillus may be present in the apparently healthy organs of tuberculous animals; that they are virulent, giving rise, on injection into guinea-pigs, to typical tuberculous lesions containing acid-fast bacilli; but that the type of disease they cause is different from that usually observed after subcutaneous inoculation of ordinary tubercle bacilli.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

359. Bronchial Asthma in Children and Young Adults.

A. H. ROWE (*Amer. Journ. Dis. Child.*, January, 1926, p. 51) records his experience of 110 cases of bronchial asthma in children and young adults treated for a minimum period of four months, 77 being under 10 and 33 between 10 and 20 years of age. He considers it to be the most serious of all respiratory disturbances due to allergy. Skin testing with proteins of the organic substances which may cause asthma should, he thinks, always be a routine procedure, and retesting may be necessary when a satisfactory result does not follow a course of treatment. The proteins used were those associated with food reactions—namely, wheat, corn, oats, rice, egg, milk, fish, nuts, meats, fruits, and vegetables—while the animal emanations concerned included those arising from feathers, horse, cat, rabbit, sheep, and silk. Vegetable substances employed were orris root, and two and spring and autumn pollens. One or more positive reactions were given by 95 per cent. of his patients, 71.7 per cent. reacting to proteins of animal emanations; 58.2 per cent. of these were due to feather proteins, and the use of food and pollen proteins gave rise to many cutaneous reactions. Multiple sensitization was the rule in nearly every instance, and treatment based upon the results of the tests was satisfactory in 91 per cent. of the cases. Rowe regards climatic change as unnecessary, and considers that surgery of the nose and throat is contra-indicated in asthmatic patients, except in so far as it may improve the general health.

360. Hyperthyroidism in Children.

R. S. DINSMORE (*Surg., Gynecol. and Obstet.*, February, 1926, p. 172) states that hyperthyroidism in children is more common than is generally supposed, and suggests that cases will be reported more frequently in the future. The etiology of this complaint is unknown, but in a small percentage of cases the onset appears to follow an acute infection. The commencement is acute, the symptoms being nervousness, followed by enlargement of the thyroid gland, with tachycardia and exophthalmos. Cases of acute hyperthyroidism are rare but may occur. Many of these children show no decrease in weight and their mentality is normal for their age. Dinsmore states that induced hyperthyroidism may follow the prophylactic use of iodine, but the symptoms usually disappear when the drug is discontinued. In the majority of the author's cases the disease was chronic, and in nearly all thyroidectomy was necessary. These children are apt to react seriously to operative procedures, and any operation should be planned so as to require a minimum amount of anaesthetic. Excellent results often follow ligation of the vessels. When other foci of infection are present these should not be removed until the patient has recovered from the thyroidectomy.

361. Measles and Tuberculosis.

W. BEISKEN (*Zeit. f. Kinderheilk.*, December 16th, 1925, p. 353) remarks that almost all writers maintain that measles and whooping-cough are the determining causes of tuberculous meningitis in latent or manifest tuberculosis. On the other hand, Noeggerath and Eickstein at the Freiburg children's clinic found that measles and whooping-cough did not cause any general activation of tuberculosis, and their observations were confirmed by S. Meyer and Burghard from examination of 1,064 cases of whooping-cough. In 162 cases of tuberculous meningitis treated in the children's clinic of the Medical Academy at Düsseldorf from 1908 to 1924 Beisken found that 64 had a history of no previous disease, especially measles, and only 56 had actually had measles. This figure, moreover, was considerably reduced by the fact that it included children whose attacks of measles had occurred as long as twelve years before the onset of tuberculous meningitis. Only 40 children had had measles within a period of three years before the meningitis, and it was only during this period that measles could have had any causal influence. Moreover, the curve of observation remained at approximately the same level and bore no relation to the measles mortality, which was subject to considerable fluctuations. There was therefore no justification for regarding tuberculous meningitis as being caused by measles. Attention was also paid to the relation between tuberculous invasion of other organs and a previous attack of measles. In 18 cases of tuberculosis the pulmonary lesions were well marked, in 16 moderate, and in 128 slight. It was

a remarkable fact that in cases with only slight pulmonary lesions the number of measles cases was particularly high (42), whereas only 7 of the severe and 7 of the moderate cases had had a previous attack of measles.

362. Trophic Ulceration following Lethargic Encephalitis.

E. HOFFMANN (*Deut. med. Woch.*, February 5th, 1926, p. 238) states that Büchler (*Klin. Woch.*, No. 31, 1925) has recently described vasomotor trophic symptoms following lethargic encephalitis. In addition to a case of symmetrical gangrene of the hands, Büchler mentions a similar case of Wiclig and one of Biering of gangrene of the leg. Ulceration of the bladder and skin has been reported by Adler, who attributes it to trophic changes. Hoffmann now reports a case of trophic ulceration in a man aged 27, the subject of Parkinsonism, who had had lethargic encephalitis four and a half years previously, and now presented ulceration of the left nasal cavity, hard palate, and buccal mucosa. Tuberculosis, sporotrichosis, syphilis, and diphtheria could be excluded by the appropriate tests. Lumbar puncture showed nothing peculiar in the cerebro-spinal fluid, and therapeutic tests with potassium iodide, salvarsan, and bismuth, as well as animal inoculation, had a negative result. Histological examination showed non-characteristic vascular changes. In the absence of any tendency for the lesions to heal, a diagnosis was made of trophic ulceration favoured by salivation. So far as Hoffmann is aware, no similar cases are on record.

333. The Incidence of Syphilitic Aortitis.

C. BRUNNS (*Med. Klin.*, February 19th, 1926, p. 279) states that although salvarsan has reduced the occurrence of secondary and tertiary lesions of the skin, mucous membranes, and bones, yet late nervous involvement and aortitis appear to be getting more common. There is evidence in the literature that aortitis develops in about 25 per cent. of all cases of syphilis. Brunn now reports the following figures, derived from 200 patients coming from all classes of society, and mostly in men, the cardiac diagnosis being facilitated by the use of x-rays. Aortitis appeared in 23 per cent. of the hospital patients between eight and thirty years after infection, and in 38 per cent. there were grounds for suspicion that the lesion existed. In the case of private patients there was definite aortitis in 27 per cent., and probable in 31 per cent. Brunn, therefore, recommends that dermatologists and others who are likely to encounter syphilis in its later stages should make a special examination for aortic lesions, since treatment is far more effective when early. Prolonged or repeated courses of antisyphilitic treatment may avert the serious cardiac complication.

Surgery.

Subphrenic Abscess.

A. O. WHIPPLE (*Amer. Journ. Surg.*, January, 1926, p. 1) considers subphrenic abscess the most important variety of intra-abdominal abscesses on account of its nature and sequelae, and also because of the difficulty caused by its occurrence as a post-operative complication. When developing as a complication of such severe conditions as a perforating ulcer or appendix, or in gangrenous cholecystitis, the subphrenic abscess does not appear until late in the course of the illness, when sepsis or tumour has greatly enfeebled the patient. It is insidious in onset and course and difficult to distinguish from such thoracic conditions as pulmonary or pleural infections. The irregular drainage from the original focus of disease may distract the surgeon's attention and cause him to overlook for some time the new infection. The mortality of cases in which drainage is provided is 30 per cent. and for undrained cases 80 per cent. A subphrenic abscess may arise from the direct spread of bacterial infection, or from fluid escaping from a leaking or perforated viscus; it may also be due to a distant pyogenic focus. In 1,000 collected cases the foci were: stomach 25 per cent., appendix 21 per cent., biliary tract 16 per cent., and duodenum 5 per cent. Whipple now records 32 cases, the primary foci being as follows: biliary tract 8, stomach 4, duodenum 3, appendix 5, pelvic organs 3, hepatic abscess 2, perforated intestine 2, empyema 2, kidney 2, pneumococcal peritonitis 1, and two undetermined, but associated with tuberculous foci. The colic bacillus was isolated in 13 cases,

streptococci in 9, staphylococci in 5, *B. welchii* in 4, pneumococci in 2, *B. pyocaneus* in 2, tubercle bacilli in 1, and in 7 the etiology was undetermined. With such a variety of organisms concerned it follows that the abscess contents are very variable, but in most cases they are very foul, and contain gas—an important factor in diagnosis. Three clinical types are described. The first is characterized by an abrupt onset, and usually a previous history of some chronic lesion such as ulcer, cholecystitis, salpingitis, or lung abscess. In the second group the abscess develops insidiously, the patient having some obscure lesion, such as carcinoma of the posterior wall of the stomach, or there is a gradual invasion from some thoracic lesion. Such patients are very weak and show no changes in temperature, pulse, weight, or strength. The abscess may not be found until an autopsy. The third group contains the post-operative cases, and the abscess may be due to errors of drainage or technique; in many cases the patient has been very ill with peritonitis, cholangitis, or liver abscess. The author condemns the use of an exploratory needle, unless it can be left in position and immediate operation be performed. A high white cell count is usual and x rays give the greatest help. A bubble of gas is important; it appears whether the patient is in the sitting or lateral position, and there will be the changing level of the fluid. Where upper abdominal drainage has been employed the patient should be turned over on the face two or three times a day for the first week after operation to empty the sub-hepatic space, and the drain should be left long enough for a track to be established. Whipple thinks that the tenth rib in the mid-axillary line gives the best approach, and that either intercostal incision or removal of a segment of rib will supply good exposure and drainage, provided the incision is long enough. Electrically lighted retractors assist in the determination of the site and size of the abscess.

365. Post-operative Parotitis.

T. C. PEIGHTAL (*Amer. Journ. Obstet. and Gynecol.*, January, 1926, p. 88) calls attention to acute pyogenic parotitis as a post-operative complication and gives notes of nine cases. Two were of the mild form, probably due to some temporary duct obstruction rather than to a diffuse glandular inflammation, and they subsided rapidly. In five moderately severe cases the infection involved the whole gland but did not give rise to suppuration or abscess formation, and the characteristic massive induration subsided slowly without incision. In two cases of a severe type suppuration occurred and incision was necessary. The *Staphylococcus aureus* is the most common cause and pneumonia the most frequent complication. Cold applications, mouth washes, and mastication usually suffice by way of treatment in the early stages, and in the milder cases, but incision is indicated in the severer cases even before fluctuation is noted, because gangrene may develop rapidly owing to the tough capsule with which the parotid is surrounded. For prevention Peightal urges the systematic examination of the teeth and mouth and the treatment of oral sepsis before operation, and immediate post-operative care of the mouth in emergency operations.

385. The Surgical Treatment of Gall Stones.

K. H. DIGBY (*Annals of Surgery*, January, 1926, p. 47) maintains strongly that whenever a reasonably probable diagnosis of gall stones can be made an operation should be undertaken immediately. He condemns the not infrequent practice of waiting for the attack to subside before operative procedures are commenced. His reasons are as follows. During an attack of gall-stone colic the stone may pass into the common bile duct and give rise to obstructive jaundice from which a biliary type of hepatic cirrhosis may develop. With stones in the gall bladder there is a 2 per cent. surgical mortality, but when they have entered the common bile and common hepatic ducts the mortality rises to 10 per cent. Again, impaction may occur at the ampulla in such a way that the gall bladder forces bile into the pancreatic duct; thus a true biliary colic may be insidiously transformed into an acute haemorrhagic pancreatitis with its high mortality of 75 per cent. or more. The obstruction of the cystic duct may, moreover, lead to such distension that the walls of the gall bladder become devitalized with the sequel of gangrene or perforation. Digby advocates a very free exposure of the biliary tract, using an angled incision such as that of Perthes. The bile duct should be opened just above the duodenum in every case and the main ducts very carefully explored both from within and without. He adds that in most cases it is advisable to remove the gall bladder and cystic duct, the main ducts being protected from accidental injury by a metal T-shaped tube. He recommends that the stem of this tube should be three inches long, the cross piece extending for half an inch on one side and one and a half inches on the other. The long end is passed into the common hepatic duct and the short end into the bile duct, so that the tube is

self-retaining. Various sizes of tube, ranging by sixteenths of an inch from 1/8 to 3/4 inch, are sterilized in advance and the appropriate size used. This mechanism permits the safe removal of the gall bladder from the fundus towards the ducts and moderate traction may be employed with impunity.

Therapeutics.

357. Treatment of Hyperchlorhydria by Sodium Bromide.

F. F. MARTINEZ (*Arch. de med., cir. y esp.*, February 13th, 1926, p. 293) states that Loven was the first to describe the importance of the solar plexus in the production of numerous symptoms in dyspepsia, and to treat this condition by sodium bromide, which has an important action on various painful symptoms, whether these are due to ordinary dyspepsia or to ulcer or cancer. Loven has shown that the drug acts not only on the gastric nerves, but also on the glandular secretion. Martinez, who records twenty-four personal cases of hyperchlorhydria, gastric and duodenal ulcer, and cicatricial pyloric stenosis, has found that sodium bromide checks exaggeration of the motor and secretory functions of the stomach. Improvement is shown within the first few days of its administration by a permanent disappearance of the clinical symptoms, such as pain, vomiting, dyspepsia, sensation of pharyngeal constriction, salivation, and so on. Other symptoms, such as headache, vertigo, and constipation, are also relieved at the same time. The phosphaturia diminishes, the amount of urea in the urine increases, and the proportion of phosphoric acid to urea approaches the normal. There is a simultaneous fall in the quantity of uric acid and chlorides in the urine. The dose of sodium bromide in adults is 2 to 3 grams a day, but it is harmless in doses of 6 to 7 grams, even when continued for some time.

368. Toxic Effects of "Bismuth-Diasporal."

O. FISCHER (*Dermatol. Woch.*, February 20th, 1926, p. 268) describes a case of severe bismuth poisoning after a course of intravenous injections of bismuth-diasporal, a preparation which has been extensively advertised as having a low degree of toxicity. A man, aged 26, who had a subacute polyarthritis, a specific sore throat, and indolent enlarged submaxillary glands, was found to have spirochaetes in the pharyngeal mucus and a strongly positive Wassermann reaction. He had contracted syphilis in 1919, and subsequently received various kinds of antisyphilitic treatment. In 1922 he had syphilitic ulceration of both feet which was cured by a course of mercuric and salvarsan. Bismuth-diasporal treatment began with four injections of 50 mg. each in the course of ten days. In the following week, two injections, each of 100 mg., were given, all without toxic symptoms, but after the sixth injection the patient had pain in the lower teeth and a "bismuth liao" around the lower incisors. The sore throat had disappeared after the second injection. As the polyarthritis became worse, the patient received ordinary anti-rheumatic treatment, and the seventh injection was postponed for five days; but immediately after this the patient complained of pain at the site of the injection and the whole arm became stiff, apparently owing to phlebitis. The patient had severe attacks of abdominal pain and diarrhoea, followed by blood-stained, mucous stools. He had also a severe haematuria, and other signs of acute nephritis, such as albuminuria and epithelial casts. The abdomen was very rigid, especially in the left flank. Proctoscopic examination was painful and revealed an extensive ulceration of the mucosa. The enteritis and nephritis improved, and four weeks later the patient was discharged.

369. Cod-liver Oil Spray in Laryngeal and Tracheal Tuberculosis.

LEROUX-ROBERT (*La vie méd.*, February 5th, 1926, p. 189) states that for the last ten years he has used inhalations and sprays of cod-liver oil in the treatment of tuberculosis of the larynx and upper respiratory tract. In cases where the larynx alone is affected the supraglottic method is employed. The practitioner draws out the patient's tongue and passes the syringe as far down as possible in close contact with the posterior wall of the epiglottis, a few drops of oil being injected at each inspiration until 3 to 5 c.cm. in all have been given at each sitting. When both the larynx and upper respiratory tract have to be treated one of two methods may be employed. (1) Tracheal injection: The injection is made with the aid of a laryngoscopic mirror, 10 c.cm. being introduced between the vocal cords. Novocain anaesthesia may be required in patients with a very irritable larynx. The only contraindication to tracheal injection is bacemoptysis. (2) Leroux-Robert's method of spraying and inhalation: There is no contraindication to this method, which can be

practised by the patient himself several times a day. A nasal spray is converted into a laryngeal spray by the addition of a glass tube with a curved extremity, which is inserted behind the base of the tongue. When the bulb is squeezed the patient makes an inspiratory movement and thus allows the oil to penetrate into the larynx and upper respiratory tract. Treatment by cod-liver oil is specially indicated in the medical forms of laryngeal tuberculosis. The best results are obtained in the early stage of erythema and coagulation, but very marked results are also observed in the stage of extensive infiltration of the vocal cords. Lastly, the pain due to small ulcers may be relieved by this method. The effects differ according to the patient and his environment. In hospital involvement of the larynx is usually secondary to severe pulmonary tuberculosis, while in private practice laryngitis is often observed at the onset of the disease, so that it may be regarded as primary. In conclusion, Leroux-Robert states that, apart from cases of tuberculous earlities and surgical laryngeal tuberculosis, more than a third of 200 hospital patients were relieved, improved, or even cured by this treatment. In private practice the results were much more encouraging, good effects being obtained in more than half the cases.

370. The Value of Artificial Heliotherapy.

G. VIANA (*Raggi Ultravioletti*, December 21st, 1925, p. 354) publishes brief records of six cases of pulmonary affections, showing the great benefit which followed treatment by radiation from a Kromayer quartz lamp. For the last fifteen years the author has treated over a thousand cases of various types of disease by violet rays: 211 pulmonary, 117 sciatica, 139 varicose ulcers, 227 arthritis, and 231 cutaneous diseases. The chief effects noted were slight rise of temperature, euphoria and perspiration, improved blood pressure, increase in the number of red corpuscles, haemoglobin increased from 50 to 72 per cent, diminution in number of leucocytes, and improved general condition. In the six cases recorded either tuberculosis or a positive tuberculous skin reaction was present. It is not suggested that treatment by violet rays is a universal panacea, nor should it replace regular modes of treatment, but as a supplementary aid the author, after his experience, finds it of undoubted value.

371. Calcium Lactate in Migraine.

C. E. RIGGS (*Minnesota Med.*, February, 1926, p. 87) advocates the use of calcium lactate as a preventive in migraine. Notes of six cases are given in which attacks of migraine were aborted by administering 30 grains of calcium lactate at the first warning of the onset. It is not claimed that the drug will cure an attack when once established, but in the majority of cases it prevents their occurrence, and in some instances renders them much milder and less frequent. Riggs suggests that the tablets should always be kept in readiness, and that they should be fresh since age renders them inert.

Anaesthetics.

372. Combined Nitrous Oxide and Local Anaesthesia.

P. K. GILMAN (*Amer. Journ. Surg.*, January, 1926, p. 21) states that the combination of nitrous oxide and novocain in abdominal surgery, together with the avoidance of abrupt surgical manipulations, enables the operation to be performed with a very slight degree of anaesthesia, complete relaxation of the abdominal wall being obtained. Preliminary treatment includes an enema and a liberal diet; an injection of morphine and atropine is given half an hour before the anaesthesia begins. With the patient anaesthetized by a mixture of nitrous oxide and oxygen the final skin preparation is performed, after which the entire abdominal wall on the side of the proposed incision, or of both sides in the case of a mid-line opening, is blocked with novocain from the level of the sixth intercostal space to the anterior superior spine of the ilium below. Before opening the peritoneum the entire length to be incised is infiltrated with novocain. The utmost gentleness must be used in opening and elevating the incised abdominal wall; pressure and traction on the tissues should be as light as possible, sponging and clamping performed with the greatest care, and care must be taken in closing the abdomen. Shock and Gilman states that it is by no means unusual for the patient to leave the operating table with an unaltered blood pressure. Post-operative nausea and vomiting are rare, and at the most only slight; intestinal paresis seldom occurs. As compared with ether narcosis, this combined form of anaesthesia enables the patient to take fluids earlier after the operation and to recover strength more rapidly; it causes much less general post-operative distress. Gilman maintains also that the relaxation obtained is equal to that produced by deep ether anaesthesia.

373. Spinal Anaesthesia in Urology.

M. DEVROYE (*Le Scalpel*, February 20th, 1926, p. 177) discusses the difficult problem of anaesthesia in urological operations. Chloroform is particularly dangerous in the case of renal operations, or of enlarged prostate in the elderly in whom the kidneys already show some changes or are impaired by the chronic urinary retention. Ether, though less toxic than chloroform, is difficult to use without incurring the risk of operative shock. Devroye, therefore, recommends the more frequent use of spinal anaesthesia according to the method of Hannecart, from which very satisfactory results have been obtained. Novocain has been recommended by many for operations on the prostate, but Devroye prefers scurocaine powder (a French modification) administered in a 1 per cent. solution in sterile distilled water. The adult dose of such a solution is given as 175 to 200 c.cm., and a preliminary injection of 1 to 2 cg. of morphine is advised. The spinal anaesthetic should be introduced slowly, especially after the first 100 c.cm. has entered; more rapid injection incurs the risk of convulsive attacks, which, though never serious and very transitory, are nevertheless better avoided. Anaesthesia is said to be obtained in about twenty to thirty minutes, nearly always accompanied or preceded by somnolence, but with a full pulse. In some cases consciousness is retained with loss of sensation. The tendency to sleep may persist for some time after the operation, but there is no operative reaction, such as vomiting or dyspepsia. Devroye has used this method in twenty-one cases, and reports that Hannecart has tried it on 200 occasions without ill results. The chief objection is the length of time before anaesthesia is complete.

374. Ether in Lung Operations.

M. LIDWILL (*Med. Journ. of Australia*, December 19th, 1925, p. 693) advocates ether administration in operations on the lungs as the safest and best anaesthetic. He considers that the so-called "ether pneumonia" is not a direct result of the anaesthetic, and in no way contraindicates its use. In his opinion most of the post-operative "pneumonias" are not true pneumonias, but are either infarcts due to emboli or thrombosis or collapse of the lung; he believes that when a true pneumonia occurs it is chiefly due to inhalation of foreign matter or to chill from exposure during the operation. His practice is to anaesthetize by the open method until the jaws are completely relaxed, when a Belfast linen catheter can be passed into the trachea and intratracheal anaesthesia commenced. After a few minutes the anaesthesia may be reduced and the patient kept in a state of light anaesthesia throughout the operation and placed in any position desired by the surgeon. When the pleura is reached co-operation between the anaesthetist and the surgeon is most important, since the former has complete control of the inflation of the lung; care must be taken that the vapour is not pumped in at too great a pressure, 25 mm. of mercury generally sufficing. He adds that if it is desired to stitch the parietal and visceral layers of the pleura together these can be brought into apposition by inflating the lungs by placing the head over the mouth and compressing the nose until the stitching is completed, when removal of the hands will allow the lungs to deflate. Such inflation is necessary when opening a hydatid cyst or when searching for a bronchiectatic cavity, and since 25 mm. of mercury only equals the pressure in the lungs in blowing out a candle or in blowing air through a tube immersed in six inches of water no evil results need be expected from its use.

Obstetrics and Gynaecology.

375. Treatment of Sterility in Women.

H. CAUFMAN (*Paris Méd.*, February 6th, 1926, p. 135) discusses the effect of small doses of x rays in treating sterility in women, and reports in detail the case of a patient, aged 27, who had suffered from metrorrhagia since the age of 19, and was sterile owing to functional ovarian disturbance. The uterus was small, but there was no evidence of disease or abnormality in any of the pelvic organs. Treatment of the ovaries and spleen by x rays resulted in the cure of the metrorrhagia, and two normal menstrual periods followed. The patient then became pregnant and gave birth to a healthy child. Caufman mentions three explanations of this restoration of lost reproductive power as the result of x rays—namely, stimulation of the ovarian tissue; the cure of some slight ovarian lesion; and destruction of impaired follicles, thus leaving the way open for the development of more robust follicles. He does not favour particularly any of these theories. He has also cured amenorrhoea in a woman by administering x rays for pruritus vulvae, and has had cases of pregnancy following the treatment of fibroids by x rays.

376. Compression of Aorta in Post-partum Haemorrhage.

O. NEUMANN (*Zentralbl. f. Gynäk.*, February 20th, 1926, p. 469) reports favourable results obtained in severe cases of bleeding after labour by application of a clamp designed to compress the abdominal aorta. This consists of a pad placed over the lower part of the spine and joined by an adjustable rigid support to a smaller padded clamp which is applied to the abdomen and is regulated by a screw so as to give the requisite amount of pressure. It has been found effective in controlling haemorrhage, and its use has in general been found free from the dangers attending the application of Momburg's abdominal ligature; nevertheless, it has occasionally been found to injure the viscera. A case of ileus is recorded which followed fifteen minutes' application of the compressing clamp, and allusion is made to a fatal case, mentioned by Schultzeiss, in which the only morbid finding was a haematoma in the root of the mesentery extending to the solar plexus. The author believes that a carefully applied aortic clamp is a valuable instrument for the general practitioner.

377. Corpus Luteum Necrosis in Hyperemesis Gravidarum.

D. BRANNAN and M. COHEN (*Surg., Gynecol. and Obstet.*, February, 1926, p. 228) report two fatal cases of hyperemesis gravidarum occurring in the third month of pregnancy; necrotic changes were found in the corpus luteum. In one case, a primipara, the illness lasted forty-four days, and on post-mortem examination the only gross change found was marked pulmonary oedema. Microscopically there was shown to be considerable coagulative necrosis of the corpus luteum, fatty changes in the liver, and a parenchymatous degeneration of the kidneys. In the other case, a multipara, the disease had lasted only about sixteen days. The macroscopic post-mortem examination showed oedema of the lungs and an adenomatous goitre. Microscopically there was a massive necrosis of the corpus luteum with extensive liquefaction of the luteal cells; there were fatty changes in the hepatic central cells with here and there one or more necrotic cells, and the kidneys showed parenchymatous degeneration. The authors state that the changes occurring in the corpus luteum resulted from the underlying toxæmia, and do not suggest that the necrosis and resulting deficiency in the secretion of the corpus luteum are the cause of hyperemesis gravidarum.

Pathology.

378. The Pathogenesis of Polypi of the Septum.

F. MANGABEIRA-ALBERNAZ of Brazil (*Arch. Internat. de Laryngol., Otol. et Rhinol.*, February, 1926, p. 139) reports three cases of nasal polypi in persons who had suffered from leishmaniasis. In all his cases leishmaniasis had been successfully and rapidly cured by intravenous injections of tartar emetic, leaving the characteristic cicatrices of the disease. From one to two years later the patients presented themselves at the author's clinic suffering from polypi of the septum, and he found that in one case two polypi had formed on the site of former ulcerations due to leishmaniasis. He attributes this occurrence to the fact that the previous lesions were cured by very short courses of tartar emetic, but that the disease remained latent and as a result of later activity gave rise to the polypi. He is of the opinion that if the patients had submitted to a longer course of injections this recurrence would not have taken place. Mangabeira-Albernaz draws attention to the close resemblance between leishmaniasis of the mucosal surfaces and rhinoscleroma. This has also been pointed out by Moraes of Bahia (Argentina); the work of Alvarez of San Salvador shows the two diseases to be intimately connected in that country, while Kubelik (Poland) and Symmers (Prague) have treated rhinoscleroma by injections of tartar emetic with great success.

379. The Prevention of Rickets by Irradiated Cholesterol.

R. FABRE and H. SIMONNET (*C. R. Soc. de Biologie*, February 26th, 1926, p. 455) confirm the results of American workers on the activation of cholesterol by ultra-violet rays, but find that the time necessary for the activation is less than has been supposed. The rats with which these experiments were made were fed on cornflour, butter-fat, egg albumen, calcium carbonate, and sodium chloride. The diagnosis of rickets rested on the macroscopic demonstration of the costo-chondral rosary, the histological and the radiographic examination of the bones and joints, and in some instances on McCollum's line test. The cholesterol, in a 2 per cent. solution in petroleum

ether, was exposed to a mercury vapour lamp running at 115 volts and 3.5 amperes for periods of 15, 45, and 60 minutes. The distance of the solution from the lamp was 30 cm. After irradiation the cholesterol was suspended as a 2 per cent. solution in olive oil, and the ether driven off in a vacuum. Of this solution three drops, corresponding to 1.5 mg. of cholesterol, were given daily to each of the experimental rats; the control animals received non-irradiated cholesterol. After twenty-five days the animals were killed. The controls and the rats that had received the 60-minute irradiated cholesterol showed typical signs of rickets. The animals receiving the cholesterol that had been irradiated for only 15 minutes were absolutely free from rickets, while those receiving the 45-minute irradiated cholesterol showed doubtful signs of rickets. Thus the optimum results were obtained with cholesterol which had been irradiated for 15 minutes. Irradiation in an alcoholic solution was less satisfactory. The observation was made that the irradiated cholesterol was more permeable to light of short wave-length than was the non-irradiated cholesterol.

380. The Effect of Sodium Salts on Blood Pressure.

L. AMBARD and R. CAHN (*Bull. et Mém. Soc. Méd. de Paris*, January 28th, 1926, p. 77) point out that though a salt-free diet is one of the few ways of reducing blood pressure that has stood the test of time, experimental work does not substantiate this. One of the experiments which led them to this conclusion is described in detail. The patient was a nephritic of the azotæmic type, with urine containing about 1 per cent. of albumin. The sodium chloride in his diet was reduced first to 3 and then to 2 grams a day. The blood pressure was measured daily and the amount of sodium chloride excreted each day was calculated. After fourteen days of this regime the blood pressure was unaltered—195/125. Less urine was being excreted daily, and the total amount of chloride lost was 18 grams in excess of that ingested. A normal dietary was then given containing about 15 grams of salt a day. The blood pressure rose in a week to 230/145 and the experiment was then stopped. Another point which the authors mention is that the blood pressure taken morning and evening showed no difference in reading during the salt-free period, but that during the latter part of the experiment the evening reading (after the ingestion of a large meal containing salt) was higher.

381. M. RENAUD (*ibid.*, p. 102), in studying the action of sodium citrate on the blood and on the cardio-vascular system, has found that large doses given daily by the mouth raise the blood pressure. The tests were made on patients with arterio-sclerosis whose pressure was already high, and in every case it rose still higher. It fell again in two or three days after the salt had been stopped. In view of the effect that this salt has on haemorrhages when given intravenously the author suggests that it may have a specific action on the vasomotor centre and that its action when given by the mouth is due to accumulation of the salt. He thinks that in all cases where it is used the dosage should be controlled by the regular use of the sphygmomanometer.

382. Tubercle Bacilli in the Faeces.

C. VERDINA (*Giornale di Batteriologia e Immunologia*, January, 1926, p. 34) has examined the faeces of 40 patients suffering from pulmonary tuberculosis: 50 grams of faeces were ground up in a mortar with saline till a homogeneous suspension was obtained. This was filtered through sterile gauze, mixed with an equal volume of 10 per cent. sulphuric acid, shaken repeatedly for an hour, and centrifuged for fifteen minutes at 3,000 revolutions a minute. The supernatant fluid was decanted, neutralized with sodium hydrate, and the sediment thus obtained was examined microscopically, injected into a guinea-pig, and planted on Petroff's medium. All positive cultures were tested for virulence by injection into guinea-pigs. Of 20 patients whose sputum was found to contain tubercle bacilli on microscopical examination the bacilli were found microscopically in the faeces in 15, by cultural examination in 13, and by guinea-pig injection in 14. It was observed that the injection into guinea-pigs of the pure cultures obtained gave rise nearly always to a disease of low virulence, characterized by small foci limited to the lungs, liver, and glands. Of 20 patients in whose sputum no tubercle bacilli could be demonstrated microscopically bacilli were found in the faeces microscopically in 4, by culture in 3, and by guinea-pig injection in 3. It appears, then, that tubercle bacilli may sometimes be found in the faeces when they are absent from the sputum. This, the author thinks, occurs in those cases in which the pulmonary lesion is closed, but in which tubercle bacilli are occasionally circulating in the blood; excretion occurs by the biliary tract into the intestine.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

383.

"Pleural Epilepsy."

E. LEURET and J. CAUSSIMON (*Journ. de Méd. de Bordeaux*, February 25th, 1926, p. 143) describe under the above title certain rare muscular spasms occurring in the course of the production of an artificial pneumothorax. They report four cases personally observed and refer to nine reported by others. The symptoms come on suddenly and do not seem to have any direct relation to the amount of pain. The first thing noticeable is a change of colour and kind of sardonic grin. Usually the symptoms appear after the puncture and not during insufflation. Consciousness may be completely or only partially lost, vasomotor blotches may appear, convulsions are often present but tonic spasm is more common, the reflexes may remain unchanged, and the pulse is sometimes unaltered. Prognosis in the majority of cases is favourable, the attack passing off in three or four hours. In more severe types coma sets in almost at once and death follows. Any attack lasting more than six hours is likely to end fatally. However alarming and serious these attacks are they are fortunately very rarely met with, and then more often in women, but not necessarily neuropathics. The authors do not believe the attacks to be due to gaseous emboli, more especially because they often start before any air has been introduced. In one case it was only at the thirty-fifth insufflation that an attack supervened; it proved fatal. The fourth intercostal space in the axillary line, especially on the right side, appears to be a dangerous area, as more attacks followed puncture in that region than in others. In nearly every case the pleura has been unhealthy, and in the authors' view the cause of the attacks is reflex action from an abnormally sensitive pleura; where the pleura is healthy no trouble has arisen.

384.

Cardiac Extra-systoles in Childhood.

M. H. BASS (*Journ. Amer. Med. Assoc.*, February 6th, 1926, p. 387) points out that extra-systoles—premature and abnormal cardiac contractions—start at some abnormal site in the auricles or ventricles. The extra beat, coming before the heart muscle has had time to recover from the previous contraction, is usually smaller and weaker than the regular beats, and is followed by a compensatory pause, so that the irregularity is easily diagnosed by palpation of the pulse and the apex beat. Extra-systole in childhood may be toxic, idiopathic, or emotional in origin. The toxic variety is due to infectious toxins associated with such conditions as rheumatism, tonsillitis, and diphtheria, or to drug toxins, such as digitalis, and the salicylates. This variety lasts usually for only a short time. The idiopathic type of extra-systole starts without apparent cause and continues for some years. The nervous or emotional type includes cases in which premature beats follow a great mental shock or emotion. The author gives clinical illustrations of the three types, and concludes that extra-systoles are not of very serious import in childhood; the involvement of the heart muscle, though sometimes acute, is not necessarily grave. Medicinal treatment is seldom required. For extra-systoles occurring in acute diseases such as rheumatism or diphtheria, the specific treatment for the infection is alone necessary, but the child should be kept at rest for a prolonged period subsequently. Quinine, quinidine, and digitalis have been shown to diminish the number of extra-systoles, and in some cases to bring about their disappearance, but such a result appears to have been only temporary, and in the author's cases drugs were found to be of no use.

385.

Black Tongue.

J. MONTPELLIER and A. CATANEI (*Ann. de Derm. et de Syph.*, February, 1926, p. 78) report two cases of black tongue, in one of which, despite treatment, the condition had lasted for six months. The troublesome symptoms were slight pharyngeal pain on deglutition, a sense of fullness in the mouth, and salivation. The dorsum of the tongue was evenly furred from two-thirds of an inch to an inch deep, the fur being blackish in the middle and behind. From the fur were removed numerous grains like cooked sage, which at the middle of the tongue were attached by long filiform processes. No swelling of the glands occurred. From the fur were isolated streptococci and the fungus *Mucor*, which resembled in its reactions Castellani's *M. paratropicalis*, isolated from human sputum.

386. Artificial Pneumothorax in Children.

P. F. ARMAND-DELILLE (*Med. Journ. and Record*, January 20th, 1926, p. 113) believes that in every case of unilateral pulmonary tuberculosis in children, with bacilli in the sputum, artificial pneumothorax should be performed. There is no other curative method at the present time that will cause the disappearance of tubercle bacilli in a few weeks with a real improvement in the general health, cessation of fever, increase in weight, and ability to indulge in sports with moderate care. He has performed this operation in 100 cases and has never had a serious accident; in young children a little subcutaneous emphysema was observed if the child cried between or immediately after the injections, but this always disappeared rapidly. Of these cases up to the present he has had only three deaths—two from purulent pleurisy and one from tuberculous meningitis. In performing the operation for the first time the child is previously given scopolamine and morphine, while novocain is used locally; for babies he considers it best to use chloroform because in crying the pressure in the chest is increased. At the first puncture 50 c.cm. of oxygen and then 200 to 300 c.cm. of nitrogen are injected; in the subsequent punctures from 200 to 500 c.cm. are injected, depending on the resorption. In children these refills must be repeated every other week. Armand-Delille has applied this treatment to children as young as 17 months with success.

387. Diabetes Insipidus of Syphilitic Origin.

L. BABONNEIX and J. LHERMITTE (*Ann. de Méd.*, December, 1925, p. 471), who record an illustrative case, state that it has long been recognized that syphilis is one of the most important causes of diabetes insipidus. Whether the condition is due to gummata at the base of the brain, opto-puncular meningitis, or complicated tabes, syphilis should always be sought for in cases of diabetes insipidus in which the etiology is uncertain or obscure. The present case was that of a woman, aged 42, picked up unconscious in the street, in whom the presence of syphilis was associated with a new growth, as was shown by the autopsy. The hypophysis appeared normal to the naked eye, but on histological examination the infundibulum was found to be the site of an infective process which was undoubtedly of syphilitic nature.

Surgery.

398. Arterial Pressure after Cervical Sympathectomy.

R. LERICHE and R. FONTAINE (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, January, 1926, p. 21) have divided the lower cervical rami communicantes running to the stellate and intermediate ganglia (when the latter is present) of the cervical sympathetic in fifteen cases during the past year, and have studied the subsequent changes in arterial tension. They state that excision of the cervical sympathetic results in a transient production of a paralytic type of circulation through the arteries involved. Careful observations before and after operation show that the variations of arterial tension are quite temporary, and also that after unilateral ablation of the cervical sympathetic or of its communicating branches such variations occur on both sides of the body. The authors cite the case of a woman, aged 26, who suffered from Raynaud's disease in both arms and legs; after unilateral brachial and femoral sympathectomy all symptoms disappeared. This indicates that the vessels have sensory centripetal fibres running among the centrifugal vasomotor fibres. In 1917 Leriche and Heitz applied Pachon's oscillographs to both forearms prior to performing unilateral peribrachial sympathectomy; both instruments registered the same oscillatory changes. Numerous experiments have shown that if one arm be plunged in cold water the arterial tension in both arms falls; this suggests that there is only one vasomotor centre in the medulla. The authors point out that each organ which is innervated by the sympathetic possesses ascending (centripetal) fibres which carry information to the vasomotor centre concerning the state of the organ; this is analogous to the muscular sense in the skeletal system. Ordinarily we are unconscious of the activities of our organs; but if sensory fibres are exposed to abnormally strong stimulation painful sensations are produced, varying with the organ in question. Strong excitation of the intestinal sensory fibres causes colic or, in the case of the intracardiac sensory fibres, an attack of angina pectoris.

The sensory vascular fibres regulate vascular tone, and their abnormal stimulation furnishes an explanation of the pain endured by most patients who suffer from any arterial constriction.

389. Metastatic Infections of the Prostate with Staphylococci.

L. STROMINGER (*Presse Méd.*, February 20th, 1926, p. 226), from an analysis of the literature, finds that metastatic infections of the prostate may occur in influenza, pyaemia, parotitis, streptococcal angina, pneumonia, typhoid fever, furunculosis, and other diseases. He himself has found them in furunculosis and in anthrax. Reports are given of four fatal cases. The first occurred in a man, aged 65, with a large anthrax pustule on the neck. Some weeks after its incision he was seized with shivering, perineal pain, fever, and frequency of micturition. A prostatic abscess was opened, staphylococci found in the pus, and an autogenous vaccine was given, but the man died a fortnight later. The second case was similar, also following anthrax of the neck; death occurred a month after the opening of the prostatic abscess. The third case was that of a young man with an anthrax-like furuncle of the zygomatic region. Some days after the wound had healed he developed a rigor, high fever, multiple abscesses of the skin, and retention of urine. Surgical treatment was refused, but the prostatic abscess burst after perineal massage, and death followed shortly afterwards. In the fourth case, a man, aged 26, with an anthrax pustule of the neck, pain and haematuria developed five days after the pustule had healed. The prostatic abscess was opened and an autogenous staphylococcal vaccine was given. All went well for a time when, after fever and sudden collapse, he died. At the autopsy the coeliac axis was found to be perforated. Close to it was a metastatic abscess which had destroyed its base. As regards the treatment of these staphylococcal infections the author is in favour of autogenous vaccines—particularly of the local applications devised by Besredka.

390. The Blood Picture in the Diagnosis of Appendicitis.

G. VOLK (*Deut. Zeit. f. Chir.*, January, 1926, p. 367), who reports numerous illustrative cases, states that in acute appendicitis the most exact and reliable information is furnished by the blood picture. If the displacement to the left (modified Arnet's formula) does not exceed 15 per cent., leucocytes with rod-shaped nuclei primitive forms are absent, and the number of leucocytes is below 15,000, an expectant policy may be adopted. But if the displacement exceeds 15 per cent. and primitive forms appear there is danger in delay, as the second stage has been reached and abscess formation or gangrene of the appendix has taken place. Advanced lesions of the second stage caused by highly virulent organisms are sometimes not distinguishable haematologically from local or diffuse peritonitis. This, however, is of no practical significance, as immediate operation is required in both cases. An appendicular abscess when completely encapsulated causes only very slight changes in the blood picture. Volk comes to the conclusion that the blood picture is of considerable diagnostic and prognostic value to the surgeon.

391. Bone Dystrophy in Carcinoma of the Breast.

S. LABORDE, H. JOUVEAU-DUBREUIL, and ALICE ROQUES (*Bull. l'Étude du Cancer*, December, 1925, p. 485) record an unusual case of a woman operated on for carcinoma of the breast where the skeleton was affected with multiple and diffuse lesions not typical of metastases. One year after radical removal of the breast the patient suffered from pain in the limbs and the lumbar region. This condition became worse and the pain was very severe. The reflexes were exaggerated and the condition suggested the presence of metastasis in the spinal column, though there was no localized tenderness of the vertebrae. Radiograms showed no definite metastases, but certain diffuse lesions of the lumbar vertebrae, the sacrum, iliac bones, femora, and certain other bones. They appeared as transparent zones resembling vacuoles and suggesting decalcification of the bones. This condition has also been noted in cases of carcinoma of the prostate where the bones have been diffusely affected, as in Paget's disease. These appearances have been regarded as pathognomonic of cancer of the prostate, and a diagnosis has been made on the radiographic appearances. The authors add that the nature of this affection of the skeleton is altogether obscure and is met with in malignant disease of the breast and prostate; in both these diseases metastasis in the bones is not uncommon. It appears that certain types of cancer are able to produce a dystrophy of the bones from some disorder of the calcium metabolism.

392. Gangrene of Scalp due to Hydrogen Peroxide.

K. VON BERDE (*Dermatol. Woch.*, February 20th, 1926, p. 257) reports a case of gangrene of the scalp in a woman, aged 26, who had had her hair bleached by a 30 per cent. solution of hydrogen peroxide. No other chemical was used. Fifteen minutes after the application the hair was partially dried by means of an electrical apparatus, without previous washing. The patient put a tightly fitting felt hat on to her damp hair and arrived home suffering from great pain in the head. She had had a patch of dry scaly eczema on her chin as large as a child's hand for a year previously. Her hair was of a pale golden colour except over a pear-shaped area extending from just behind the vertex to the occipital margin of the scalp; laterally this area reached forwards to both mastoid regions. It was covered by a dirty grey necrotic mass, representing the entire thickness of the scalp down to the aponeurosis, which was visible in places where the necrotic mass had broken down. A probe could be passed for 2 to 3 cm. under the edges of the dead tissues and pus exuded on pressure. The author treated the patient for over two months after the separation of the necrotic tissues, and finally a smooth bare scar measuring 9 by 10 cm. remained. He considers that there were several accessory factors in the production of this condition: the unusual strength of the hydrogen peroxide solution; the chronic eczema of the patient's face and chin; the failure to wash and dry the hair; and finally, the fact that while her hair was still damp with the peroxide solution the patient put on a closely fitting felt hat which interfered with the circulation.

Therapeutics.

393. Treatment of Senile Pruritus by Sodium Silicate.

SCHAEFFER, A. SARTORY, and P. PELISSIER (*Progrès méd.*, February 28th, 1926, p. 289), who have several times previously drawn attention to the improvement obtained in arterio-sclerosis by intravenous injection of silicates, and especially sodium silicate, state that F. Luthier of Vienna, inspired by their work, has employed sodium silicate in senile pruritus. In view of the chemical analysis of K. Schultz, who found 51 mg. of silicic acid in 1,000 grams of skin in young persons and only 38 mg. in elderly subjects, Luthier concluded that the elasticity and vitality of the skin were due to the presence of silicic acid in sufficient quantities. He had therefore given patients suffering from senile pruritus an intravenous injection of sodium silicate every two or three days, each injection representing 0.01 to 0.02 cg. of pure sodium silicate, and found that after the first injection the pruritus became less and completely disappeared after the sixth injection. The present authors' experience of nine cases of senile pruritus in arterio-sclerotic subjects aged from 59 to 73 fully confirms that of Luthier. Intravenous injections were given every two or three days, each consisting of two ampoules of 2 or 4 c.cm. of a solution containing 0.005 mg. of sodium silicate per c.cm. The results were as follows. In four cases the itching ceased after the second injection, and completely disappeared after the seventh or eighth. In three cases ten to twelve injections were necessary to produce a complete cure. In the remaining two cases the improvement was very marked, but the pruritus was still present after the twelfth injection. As a local sedative a sponge or lint was applied soaked in a solution containing equal parts of sodium silicate and chloral hydrate. The authors attribute the action of the silicate on the pruritus first to the improvement in the organic exchanges in the tissues, causing a diminution of toxins in the circulating blood, and secondly to an improved flow of blood increasing the vitality of the tissues.

394. Oxygen Treatment in Pneumonia.

A. L. BARACH (*Arch. Intern. Med.*, February 15th, 1926, p. 186) discusses the methods and results of oxygen treatment in pneumonia. He points out that to be of therapeutic value oxygen should form from 30 to 60 per cent. of the inspired air, and that the optimum concentration is usually about 40 per cent., the maximum safe concentration being 70 per cent. Trial of various methods showed that administration with the tube and funnel only gave approximately 24 per cent. of oxygen in the inspired air, and was therefore clinically useless; the nasal catheter method varied in effectiveness, but under special conditions with a flow of 2 litres of oxygen a minute the percentage was raised to about 50. With the rebreathing apparatus and a specially constructed glass nose-piece 1 litre of oxygen a minute gave a percentage of 40; the effectiveness of this method was confirmed by observations upon the arterial blood. A glass mouthpiece was used at times when mouth-breathing was present. In the majority of cases treated the portable oxygen tent was used, and it

secured an oxygen-rich atmosphere capable of regulation to the precise concentration desired. The clinical signs of improvement following inhalation of from 40 to 60 per cent. oxygen were: clearing of cyanosis, relief of dyspnoea, diminution of delirium and restlessness, the promotion of sleep, and a slowing of the respiratory and pulse rates. Barach considers that oxygen treatment is not directly curative, but that it maintains the strength of the patient; in six cases it appeared to prolong life until the immunizing process had become established.

395. Deodorants in Cancer.

L. FREUND (*Med. Klin.*, January 29th, 1926, p. 170) discusses the value of the various antiseptics and escharotics used for the removal of the offensive smell produced by cancerous ulcers. Charcoal and other absorbents are not continuous in their action, but during their active period they have an oxidizing as well as a deodorizing action which is of benefit. The fact, however, that they must be applied dry prevents them gaining access to cavities which are often the most foul. The action of douches of hydrogen peroxide or permanganate solution is very fleeting, and, though effective, must be repeated every four hours. Freund thinks that escharotics are the drugs of choice, and he recommends a liquid preparation containing phenol and naphthol. After douching with borie acid or peroxide solution it is applied on a tampon, which must be secured in position and need only be changed two or three times a day.

396. Diathermy in Acute Gonorrhoeal Epididymitis.

M. E. GREENBERGER and S. LUBASH (*Urol. and Cut. Rev.*, February, 1926, p. 88), who report thirteen illustrative cases, maintain that owing to its sedative effects diathermy is the treatment *par excellence* for acute gonorrhoeal epididymitis. Any diathermy machine capable of producing a high frequency current of from 500 to 1,500 milliamperes at an even flow can be employed. The patient is placed in a recumbent position with the small electrode adapted to the affected testicle, while the large electrode is placed over the internal abdominal ring. Green soap lather is applied to both skin and electrodes. The d'Arsonval current should be slowly advanced to the extent of slight discomfort, and then immediately reduced, the point of tolerance varying with the individual. The average length of time devoted to treatment in hospital practice is twenty-five minutes, and in private practice about an hour.

Radiology.

397. Radiological Treatment of Operable Carcinoma of the Breast.

J. H. D. WEBSTER, J. P. THIÉRENS, and F. G. NICHOLAS (*Brit. Journ. Radiol.*, February, 1926, p. 59) give notes of fifteen cases of operable carcinoma of the breast treated by radium and x rays. While not advocating radiation in preference to operation in such operable cases, they point out that, since radiation has sometimes caused the disappearance of inoperable growths, it is important that radiologists should study the problems of treatment of operable breast cancers with a view to determining the best methods of radium and x-ray therapy to be adopted. From their experience the authors consider that the possibility of radiation treatment should be more freely offered to patients than is at present the case, and that they should not be told that there is no alternative to operation. Eight of the cases now recorded were treated by x rays, two by combined radium insertion and x rays, and five by radium surface applications. Of the fifteen patients, one died from bronchopneumonia not connected with the carcinomatous condition and another from the disease two years after treatment had been discontinued. In one there was an abdominal metastasis, but as recently as two months ago ten of the patients were reported as being well with little or no sign of disease. A comparison of the relative value in this field of radium and deep x rays shows no notable difference. Though the periods of observation are too short for conclusions as to technique and results, the authors think that they warrant radiation being offered to operable patients, to those who refuse operation, and to those patients for whom operation is inadvisable on account of age or some intercurrent affection.

398. Lipiodol in Skiagraphy and Treatment.

M. R. CASTEX, H. CARELLI, and H. GONZALEZ (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 18th, 1926, p. 217) refer to the great advances in the skiagraphy of internal organs and structures since the introduction of lipiodol. They have been very successful in studies of the respiratory tract, the nervous system, subphrenic abscess (suppurating hydatid

cyst), and pericarditis with effusion. They find that lipiodol gives perfect contrasts in the skiagrams; it is quite harmless, even in large doses, and the technique is simple. It has been reported also that it has a definite therapeutic value when injected into a purulent pericarditis or an empyema. The authors give details of the case of a man, aged 24, who had a large pericardial effusion in which tubercle bacilli were found. Lipiodol was injected many times at intervals of from five to fifteen days, and skiagrams were taken in various positions. Although lipiodol was well tolerated, it did not retard the progress of the disease in this particular case.

399. M. R. CASTEX, N. ROMANO, and H. GONZALEZ (*ibid.*, p. 222) describe a case of a suppurating hydatid cyst of liver in a man aged 45. The patient suffered from violent burning pains in the stomach and right hypochondrium, vomiting, and recurrent obstructive jaundice. An exploratory puncture yielded very offensive pus and gas, the latter under such tension that it forced back the piston and filled the exploring syringe. A skiagram showed a cavity below the right half of the diaphragm partially filled with fluid, which changed its position with the patient's movements. Lipiodol was injected into this cavity, and by reason of its greater density it gravitated to the lower part of the cyst, producing a deeper shadow than that of the pus, and thus indicating the lower limit of the cyst.

400. A. LEMAIRE (*ibid.*, February 11th, 1926, p. 166) reports the case of a phthisical patient who developed tuberculous pericarditis in March, 1925. On puncture pus was found, which on injection infected a guinea-pig. Two injections of lipiodol were made intrapericardially with an interval of a fortnight between them. The cardiac symptoms improved and the pericardial effusion diminished so that no further paracentesis was necessary. In June, 1925, some cerebral symptoms developed (paralysis of the sixth nerve and slight right-sided hemiparesis). The pericardial condition remained quiescent until October, when a few cubic centimetres of pus were withdrawn from the pericardial sac and 5 c.cm. of lipiodol were then injected. The cerebral symptoms increased and the patient died on October 30th. At the autopsy tuberculous masses were found in the brain; the pericardium was slightly adherent and contained 50 c.cm. of creamy purulent fluid, the pericardium was notably thickened. The cause of death was cerebral tuberculosis. Lemaire considers that if the lipiodol did not cure the pericarditis it certainly delayed its progress.

401. X-Ray Treatment of Glandular Tuberculosis.

P. AMUNDSEN (*Norsk. Mag. f. Lægevid.*, February, 1926, p. 119) made a careful examination of 150 persons who had undergone x-ray treatment for glandular tuberculosis in the Röntgen Institute at Oslo between the years 1915 and 1922 inclusive. The examination was made from two to nine years after termination of the treatment. The cases were divided into three groups. In the first group, which consisted of 32 patients with simple glandular enlargement, 26 (81 per cent.) were cured. In the second group, which comprised 65 patients with glandular enlargement associated with peradenitis, 32 (49 per cent.) were cured. In the third group, which consisted of 53 cases of suppurative adenitis with fistulae, 41 (77.4 per cent.) were cured. The proportion of recoveries in all three groups was thus 66 per cent. Recurrence was noted in 4 per cent., and skin changes, such as atrophy and telangiectases, were observed in 10 per cent. Amundsen is opposed to early x-ray therapy being continued for several years, as such treatment is likely to give rise to cutaneous lesions. Each series of irradiations should be distributed over a period of several days, and there should be an interval of from five to six weeks between the different series.

Obstetrics and Gynaecology.

402. Torsion of the Myomatous Uterus.

ACCORDING to E. HITZANIDIS (*Gynéc. et Obstét.*, 1926, xiii, 2, p. 103) axial torsion of the myomatous uterus has been recorded in 85 cases; it is almost always from left to right, and the twist is most commonly through less than 180 degrees but may be as much as 360 degrees. The term "torsion of the uterus" is usually a misnomer, for it is in reality the upper portion of the tumour-bearing organ which rotates around a softened and lengthened supravaginal cervix. The tumour is usually large and heavy, but, as in a case recorded by the author, its weight may not exceed 1,250 grams. It seems to be about equally common to encounter a uterus of which the torsion is secondary to that of a pediculated myoma and primary torsion of a uterus containing an interstitial myoma. Acute torsion is characterized clinically by

very sudden and violent pain, accompanied by pallor and collapse, with a pulse frequency of 130 to 160 and repeated vomiting; there is, however, little or no rise of temperature. Owing to the strong muscular resistance physical examination is difficult, but exploration of the fornices may serve to exclude haematocoele from ruptured ectopic gestation. Slow torsion with no acute symptoms is not uncommon, and in a case recorded by the author the patient first sought advice on account of supposed progonia. In certain cases the torsion produces a haematometra and crises of pain occur at monthly intervals. Suppression of the menses in a young person and the impossibility of passing the uterine sound are important diagnostic signs; the hardness of the tumour may distinguish it from a twisted ovarian cyst, but the rotated myoma may be softened owing to oedema. The mortality is given as 63 per cent. in cases not operated on, and 8 per cent. after operation.

403. Treatment of Puerperal Fever.

A. ABELHEIM (*South African Med. Record*, February 13th, 1926, p. 50) considers that local treatment of early puerperal infection is apt to be harmful and that general infection cannot be prevented by local treatment after infection of the tissues or blood has occurred. Four days after confinement a wall of leucocytes protects all wounds in the genital canal, and careless examination, douching, or curetting may damage such a protection and allow streptococci to penetrate and set up a general infection. He deprecates uterine douching, since it will not wash away what is not loose or destroy organisms in the uterine tissues, and it often causes damage to the protective wall of leucocytes, thereby propagating infection; he also regards curetting as dangerous. He does not consider that there is danger of severe infection arising from the retention of a piece of placenta, and advocates such general lines of treatment as quinine, ergot, and drainage while awaiting spontaneous expulsion. Only in severe haemorrhage is he in favour of plugging the vagina or uterus daily until the temperature has been normal for a week, or until it is possible to remove the piece easily with forceps. Abelheim concludes that the best treatment is to interfere as little as possible, and he regards puerperal fever as affording a comparatively favourable prognosis if local treatment is avoided. As a prophylactic measure he advocates the injection of 50 c.cm. of antistreptococcus serum in all instrumental deliveries or those in which there has been any local manipulation.

404. Mural Salpingitis.

C. DANIEL (*Gynéc. et Obstét.*, 1926, xiii, 2, p. 81) states that the interstitial part of the Fallopian tube is normally 7 or 8 mm. long; it is lined by epithelium consisting of a single layer of ciliated columnar cells surrounded by a connective tissue stroma which is poor in cells. Inflammatory conditions extend to this region both downwards from the free portions of the Fallopian tubes and upwards from the uterus, so that pathological changes recognizable both by the naked eye and the microscope are present in the interstitial tube in 70 per cent. of cases of uterine and adnexal disease. In cases of simple salpingitis inflammatory lesions are recognizable in 95 per cent. of cases; the lumen of the interstitial tube is only very exceptionally obliterated, but a pressure of 200 to 250 mm. of mercury (compared with 60 to 100 mm. normally) is required to inject it from the uterus. In salpingitis the intrauterine opening of the tube is not as a rule discernible by the naked eye. In adnexal tuberculosis the interstitial tube always shows gross alterations, which according to microscopic examination appear to be the result of tuberculous lesions in only one-half of cases. In cases of large uterine myoma the interstitial canal can no longer be traced, microscopically or macroscopically. In cases of ovarian tumour and of cancer of the cervix the interstitial part of the tube is unaltered even in the presence of lesions of the extramural tube.

Pathology.

405. Preparation of Malarial Blood for Treatment of General Paralysis.

O. KAUDERS (*Biochim. e Terapia sperimentale*, January, 1926, p. 33) recommends the following methods for the conservation and transmission of blood taken from malarial patients that is to be used for the treatment of patients suffering from general paralysis. With aseptic precautions 5 c.cm. of the blood is removed from a vein in the arm during or just after the decline of a febrile paroxysm and collected in a sterile test tube containing 0.5 per cent. sodium citrate solution. The tube is covered with a rubber cap rendered airtight with paraffin; it is important that the fluid in the tube should not come into contact with the cap. Another 10 to 15 c.cm. of blood is withdrawn into a small sterile flask containing glass

beads, which are then shaken thoroughly. The defibrinated blood is then poured on to the surface of a blood agar slope, taking care not to allow it to pass above the upper limit of the medium. The tube is capped and paraffined as before. A third amount of 2 c.cm. of blood is taken into a tube containing 10 c.cm. of melted gelatin at a temperature not above 30°C. The mixture is well shaken till the blood is evenly distributed; the gelatin is then allowed to set, either at room temperature or in the ice-chest, capping and paraffining as before. The infectivity of blood so preserved lasts for two days certainly, sometimes for three days, and occasionally for four days; the blood can be transported for long distances without mishap. For infecting the patient it is desirable to inject the three specimens of blood. The citrated blood is injected subcutaneously; the blood in the blood agar tube is decanted into a sterile vessel and injected; the blood in the gelatin tube is likewise injected subcutaneously after the mixture has been melted in a bath at 28°C.

406. Basal Metabolism in Artificial Pneumothorax.

N. SANTANGELO (*Il Morgagni*, February 21st, 1926, p. 225), using Zuntz-Geppert's apparatus with an open circuit, has measured the respiratory exchange and the basal metabolism of patients suffering from pulmonary tuberculosis on whom an artificial pneumothorax had been performed. In the cases that were doing well the basal metabolism was found to be about 15 per cent. below normal; in the cases that were doing badly, or in which there was still slight fever or dyspnoea, it was normal or increased. In one case in which a fresh focus of tubercle had appeared, accompanied by fever, cough, and loss of weight, the basal metabolism was increased 15 per cent. above normal. Measurements were made in one patient just before and a quarter of an hour after the induction of artificial pneumothorax; the second figure was 5 per cent. below the first; the absolute measurements were 35 per cent. and 30 per cent. above normal. It is evident that in favourable cases the basal metabolism becomes subnormal. Parisot and Hermann found that the effect of performing artificial pneumothorax on healthy rabbits was to double the respiratory activity, to prevent further growth in young animals, and to lead to a loss of weight in adult animals; this was clearly due to an increase in oxidation. But in human tuberculous patients the reverse is found. The respiratory activity is diminished and the weight increases; oxidation is diminished. The author believes that this difference is explained by the suppression in human patients of the tuberculous focus and the shutting off thus from the circulation of the toxic substances that formerly stimulated katabolism. He concludes that the diminution in basal metabolism in pneumothorax patients is due far more to this factor than to the mechanical decrease of respiratory surface.

407. The Antirachitic Value of Fresh Spinach.

HARRIETTE CHICK and MARGARET H. ROSCOE (*Biochem. Journ.*, 1926, vol. xx, No. 1, p. 137) have investigated the antirachitic value of fresh spinach leaves. Young rats, about 3 weeks old, were placed upon diets devoid of fat-soluble vitamins, but containing adequate contents of calcium and phosphorus salts. Some of these animals received a daily ration of spinach; others received the basal diet without spinach. The increase in weight during the next six weeks was taken as an indication of the amount of vitamin A in the spinach, and the degree of calcification of the bones at the end of this time provided a measure of the calcium-depositing power or vitamin D content of the spinach. The spinach was grown in the open at different times of the year—winter, spring, midsummer, and autumn—to test the effect of the sun's rays on the antirachitic content. The results showed that fresh spinach leaves contain a large quantity of vitamin A, but that, with the exception of spinach grown in midsummer, they contain no detectable vitamin D; the midsummer spinach contained a small but appreciable quantity. On the other hand, spinach that was irradiated for thirty minutes at a distance of 36 cm. from a quartz mercury vapour lamp just prior to consumption was found to be powerfully antirachitic. The authors suggest that in spinach grown in the open the vitamin D may be removed or destroyed shortly after formation, whereas in spinach that has been cut before ultra-violet irradiation no such change can occur. MARGARET A. BOAS (*ibid.*, p. 153) also contributes an article on the antirachitic value of fresh spinach, with particular reference to its effect on the retention of calcium and phosphorus by young rats. The conclusions reached are similar to those of Chick and Roscoe. Fresh spinach was found to contain ample vitamin A but a negligible quantity of vitamin D. Cod-liver oil, on the other hand, contained both the A and the D vitamins. Both cod-liver oil and spinach increased the amount of phosphorus excreted in the urine at the expense of that excreted in the faeces; but it is pointed out that the ability to do this is no measure of the antirachitic power.

Medicine.

408. Spasmophilia.

G. MOURIQUAND and P. BERTOYE (*Journ. de Méd. de Lyon*, February 20th, 1926, p. 85) define spasmophilia as an increased excitability of the peripheral nervous system causing tonic or, less frequently, clonic convulsions of the muscles and associated with a deficiency of calcium in the system. Of its physical signs, that of Chvostek is very important, though difficult to elicit from infants. Contraction of the muscles supplied by the facial nerve follows percussion of the mid-point of a line joining the zygomatic process and the corresponding angle of the mouth. In infants Lust's sign is useful; percussion a little below the middle of the calf results in the foot jerking upwards and outwards. The clinical picture is that of a tonic or clonic spasm, latent or manifest and occurs often and may be caused by spasmophilia or by rickets, had hygiene from want of sunshine, and heliotherapy and dietary measures are the most essential points in treatment; the authors recommend large doses of calcium chlorid combined with cod-liver oil and phosphorus to reduce the spasms. Ultra-violet rays have also been found valuable.

409. W. STOELTZNER (*Med. Klin.*, March 5th, 1926, p. 357), in discussing the etiology of spasmophilia, does not think that epilepsy is to be considered a sequel of this disease, but that mental weakness, showing itself in stammering, tics, and bed-wetting, may follow. Prophylaxis, being the avoidance of rickets, is best secured by breast-feeding. Treatment in doubtful cases consists in reducing the cow's milk in the diet by about one-half; in definite cases cow's milk should be eliminated entirely for at least a fortnight. The child must, however, not be fed only on carbohydrates during this time, but substitutes for the albumin, fats, and minerals must be given in the form of eggs, finely shredded meat, broth, rusks, butter, vegetables, and fruit. This treatment will as a rule clear up the symptoms at once, but it must be remembered that even one drink of milk may bring them on again. In all cases cod-liver oil should be given, with or without phosphorus, and continued for months after the symptoms have disappeared. In obstinate cases accompanied by laryngospasm calcium should be given. The author recommends the subcutaneous injection of magnesium sulphate, 0.2 gram per kilo of body weight in 8 per cent. solution, as being often successful in cases of prolonged spasm. If a child with spasmophilia develops an acute infection meningeal symptoms often follow, and the cerebro-spinal fluid is under pressure. Lumbar puncture gives good results.

410. Cardiac Asthma.

S. WASSERMANN (*Wien. Arch. f. inn. Med.*, January 5th, 1926) summarizes the literature of cardiac asthma and records a number of original observations. He concludes that asthma may occur in the course of dilatation of either side of the heart; dilatation of the left side produces typical cardiac asthma, while that of the right side causes pseudo-asthmatic attacks. Typical cardiac asthma is an acute paroxysm of dyspnoea, induced by derangement of the general circulation, involving especially the brain and medulla. Dyspnoea may be due to anaemia of the respiratory centre; this in its turn is due to enfeeblled contractions of the left ventricle, while cardiac back pressure produces pulmonary congestion. Physiologically, cardiac asthma is the reaction of the central nervous system and especially of the medulla. It is a sudden "defence reaction" produced by anaemia of the respiratory centre, and also by the dyspnoea due to pulmonary congestion. The subjective symptoms result from the mental correlation of the arterio-anaemic dyspnoea, and include a group of centrally perceived symptoms of air-hunger—namely, motor and psychomotor disturbance, restlessness and sudden impulses, with respiratory anxiety and a sensation of suffocation. The objective symptoms include all the results of stimulation of the various bulbo-spinal nerve centres by the cardiac asthmatic dyspnoea—deep, occasionally laboured respiration, the accessory respiratory muscles being called into action. The vegetative nervous system is stimulated and produces somato-visceral symptoms—pulmonary congestion, bronchial spasm, difficult and scanty expectoration, bradycardia, palpitation, pharyngo-oesophageal spasm, nausea, rectal tenesmus, dysuria, and frequent micturition. The blood

pressure sometimes rises rapidly. Cardiac asthma may be induced by nortle valvular incompetence, coronary endarteritis or thrombosis, or an infarct in the left ventricle. The prognosis is extremely grave. Usually there is spontaneous recurrence with exhaustion of the respiratory centre, Cheyne-Stokes respiration, cardiac failure, and pulmonary congestion. The treatment is purely symptomatic, and includes morphine, carbon dioxide, and vaso-dilators, such as trinitrin. In pulmonary circulatory or congestive asthma dyspnoeic attacks occur owing to the increasing failure of the pulmonary circulation, with cyanosis, dyspnoea (orthopnoea), and anasarca. Little or no increase of blood pressure occurs, but the clinical signs are those of mitral disease with progressive heart failure. Treatment includes bleeding, cardiac tonics, such as digitalis, caffeine, morphine (administered very cautiously, in minimal doses) and carbon dioxide. The prognosis is very bad and the condition is usually a terminal manifestation.

411. Erythema Arthriticum Epidemicum.

E. H. PLACE, L. E. SUTTON, JUN., and O. WILLNER (*Boston Med. and Surg. Journ.*, February 18th, 1926, p. 285) issue a preliminary report upon an epidemic, the dominating picture of which was acute sudden onset with fever, vomiting, malaise, and headache. From the first to the third day a blotchy morbilliform eruption appeared, mainly about the joints and extensor surfaces of the extremities, accompanied by a multiple arthritis, often severe in degree. During the latter half of January, 1926, 45 cases were studied. Petechial haemorrhages were frequently noted on the dorsum of the feet, on the toes and soles, many days after the eruption had faded from the arms and hands, and desquamation, occasionally profuse on the backs of the hands and wrists, sometimes followed. Involvement of two or more of the large joints usually appeared on the third day and was often exceedingly painful and crippling, with fluid in the knee-joint in at least six cases. In two cases a slightly flocculent yellow fluid was obtained from the joints from which a Gram-negative rod-shaped organism was cultivated, and a similar organism was isolated from the blood in ten out of twelve cultures. In many cases the throat showed a diffuse dull redness extending over the soft palate. The heart was normal in all the patients except one, who had an old endocarditis; there was never any glandular enlargement, and in only one case was the spleen palpable. The epidemic was confined to a small locality, about half a mile in length along the river; though the milk supply was suspected nothing was found to indicate disease in any of the dairies, and samples were bacteriologically negative. The age incidence varied from 8 months to 50 years, the 8 months baby being the only case suggesting contagion and known not to have consumed the milk. The association with the milk supply, the arthritis, eruption, toxic symptoms, and irregular fever closely simulated Malta fever. Further studies upon the organism isolated are to be reported later.

412. Visceral Leishmaniasis in Spain.

G. PITALUGA (*Rev. med. de Barcelona*, January, 1925, p. 42) states that since 1912 more than 300 cases of infantile kala-azar or visceral leishmaniasis have been observed in Spain. His personal experience and the data collected by his collaborators and pupils as well as by pediatricists show that an endemic of visceral leishmaniasis exists in Spain and even throughout the Iberian peninsula. The endemic is far from being confined to the sea coast, as more than a hundred autochthonous cases have occurred in the central and western provinces of Spain, such as Madrid, Toledo, and Caceres. The northern provinces, however, have hitherto escaped. In spite of the predominance of these cases in early life (from a few months to 10 or 12 years of age), a large number have been found in adolescents and adults. The term "visceral leishmaniasis" is therefore preferable to that of "infantile kala-azar." Of 364 cases 43 per cent. occurred in males and 57 per cent. in females. The great majority of the children affected belong to poor families; a fair number of cases, however, are found in well-to-do and even prosperous families. Defective hygienic conditions are all-important factors in the spread of the disease. Until a few years ago only very severe cases of advanced leishmaniasis were seen. Pitaluga, however, has for some time maintained that there are numerous mild cases of infantile kala-azar of slow course, in which the diagnosis can only be made by bacteriological examination of the spleen. The actual prevalence of visceral leishmaniasis

is probably much greater than is supposed, and a certain number at least of the cases of anaemia, pseudo-leukaemia, splenomegalic anaemia, and marasmus which are assigned as causes of infantile mortality are really examples of leishmaniasis. Treatment by preparations of antimony, especially by the double tartrate of antimony, and potassium or sodium is said to be very effective.

413. Combined Schick Test and Diphtheria Prophylactic.

A. T. GLENNY and HILDA WADDINGTON (*Journ. Path. and Bact.*, January, 1926, p. 118) remark that the Schick dose of toxin has a small immunizing effect upon animals already immune, but its antigenic value as a primary stimulus is negligible. A preparation that would give a satisfactory Schick reaction and at the same time net us an immunizing agent would have a distinct advantage as it would reduce the number of subsequent prophylactic injections from three to two. It would also act as the commencement of a second course of immunization in the small number of children who, tested after a first series of inoculations, continue to be Schick-positive. As the result of a number of experiments during the last few years Glenny and Waddington have been able to produce a combined diagnostic and prophylactic agent containing the equivalent of 1/10 L+T.A.M. in 0.2 c.cm.—that is, equivalent to the amount in 1 c.cm. of the ordinary prophylactic toxin-antitoxin mixture, and also corresponding in diagnostic value to a Schick toxin. Tests are as yet incomplete, but the work is being continued. Probably the chief difficulty will be the increased number of pseudo-reactions, but this can be overcome by making the mixtures more dilute. The authors have also been making clinical trials with a combined diphtheria-scarlet fever prophylactic, in which the proportions of the two constituents are so arranged that the amount of scarlet fever toxin does not depress the immunizing efficiency of the diphtheria toxoid present.

414. Koplik's Spots.

G. PETÉNYI (*Monatsschr. f. Kinderheilk.*, February, 1926, p. 533) states that though Koplik's spots are generally regarded as diagnostic of measles, some cases are on record of their occurrence in other diseases. Thus Asa-Falk reported three cases in which they were found in children with influenza, and similar cases were described by Manasse, Müller, and Widowitz. Petényi now records three cases of exanthema subitum showing Koplik's spots. Measles could be excluded, and in two of the cases had occurred several years previously. He concludes that Koplik's spots are a non-specific phenomenon and may occur in other diseases besides measles.

Surgery.

415. Perineal Prostatectomy.

P. SYMS (*Journ. Amer. Med. Assoc.*, January 23rd, 1926, p. 244) records the result of twenty-five years' experience with his own technique of perineal prostatectomy, which he claims to be simple, without danger to the rectum, and affording ample exposure. Under sacral anaesthesia a Little's lithotomy staff is introduced into the bladder with the patient in the lithotomy position. Through a median incision extending from just behind the bulb to a point just in front of the rectum the membranous urethra is opened to the apex of the prostate with a narrow scalpel in the groove of the staff, and the prostatic urethra is dilated by passing the index finger into the bladder. A Young's tractor having been introduced into the bladder, all the tissues overlying the rectum are pushed back by blunt dissection, exposing the dome-shaped sheath of the prostate, through which a vertical incision is made on each side of the middle line, exposing the prostatic lobes. These are enucleated through the vertical openings, care being taken to work close to the lobes so as not to tear the sheath containing the venous plexus. After exploring the bladder with the finger for intravesical lobes a catheter is introduced through the open urethra and a light gauze packing inserted into the spaces left by the lobes. The catheter is temporarily secured to the upper part of the wound by a silk-worm-gut suture, and a single suture, tied loosely, is placed near the middle of the wound. Syms reports 198 consecutive cases without a death, and claims that the final functional results are as good as, or better than, those following the suprapubic operation, while convalescence is much shorter and more comfortable. The patients are able to get up within forty-eight hours, regaining bladder control, and being able to get about in comfort within a week.

728 B

416. Surgical Treatment of Acute Pericarditis.

M. DUGUET (*Bull. et Mém. Soc. Nat. de Chir.*, January 16th, 1926, p. 4) records the case of a patient with acute pericarditis of about six weeks' duration. Radiographic examination showed marked enlargement of the pericardial shadow. It was decided to open the pericardium and evacuate the fluid. This was accomplished under local anaesthesia after resection of portions of the fifth, sixth, and seventh costal cartilages. The pericardium was incised (it was found roughened with sero-fibrinous exudate) and about half a litre of fluid was evacuated. The wound was then closed in layers without drainage. The patient made satisfactory progress for nine days, when the fluid reappeared in the pericardium and disappeared spontaneously through the scar. A fistula resulted which became infected and resulted in the death of the patient. Duguët thinks that the operation was delayed too long, and that for success it should be performed earlier. In view of the risk of infection drainage is strongly contraindicated in such cases. The fluid removed in this case was sterile on culture and showed no tubercle bacilli present; inoculation tests were negative. The author believes that in spite of the absence of organisms the disease was probably tuberculous in origin, as this is the more frequent cause in young subjects. He adds that the case emphasizes the importance of early operation.

417. Recurrent Pain after Operations on the Biliary Tract.

H. FLÖRCKEN (*Dent. Zeit. f. Chir.*, January, 1926, p. 181) states that the primary mortality in 552 operations on the biliary tract at St. Mary's Hospital at Frankfurt was 4.5 per cent., and in uncomplicated cholecystectomies 1.8 per cent. Of 329 patients investigated after their discharge from hospital 72.6 per cent. showed no symptoms, 16.5 per cent. had only slight symptoms, and 8.2 per cent. were not relieved. Of 273 patients with gall stones 75.9 per cent. were freed from all their symptoms, 15 per cent. had only slight symptoms, and 6.5 per cent. were not relieved. The cause of the symptoms was mainly a residual cholangitis. Of 55 patients who had suffered from chronic cholecystitis, pericholecystitis, or congestion of the gall bladder apart from calculi, 58.9 per cent. were completely cured, 23.7 per cent. had only slight symptoms, and 16 per cent. were not relieved. The cause of the symptoms in these cases was usually an ulcer or splenoptosis. Many of the milder symptoms which lasted two years after operation subsided spontaneously and complete recovery took place. The best results were obtained in simple cholecystectomy without complications, 80 per cent. of the patients being completely cured of all their symptoms. In 54 cases of choledochoduodenostomy the mortality was 3.7 per cent., the results being very good in 71 per cent. and satisfactory in 17.8 per cent. Successful treatment of the recurrent pain following operation depends on the cause. Residual cholangitis is often improved or cured by repeated duodenal intubation with injection of magnesium sulphate. In cases showing Head's areas paravertebral injection of novocain, tutocain, or dolantin, as recommended by Lauen, is indicated.

418. Nephrectomy for Renal Tuberculosis.

CONDAMIN (*Journ. d'Urol.*, January, 1926, p. 31) points out that the results of removal of the kidney for unilateral renal tuberculosis are extremely good. Statistics show a steady improvement owing to better technique, earlier diagnosis, and estimation of the functional value of the kidneys. The operative mortality has fallen from 25 to 4 or 5 per cent., and continuous series of thirty to forty nephrectomies without a death are recorded. The ultimate results, however, are clouded by a mortality which is usually the result of a tuberculous lesion elsewhere in the body. The late results show a mortality of 31 per cent. in three years and 14 per cent. in seven years. The majority of patients with renal tuberculosis have tuberculous affections elsewhere, either in the lungs, genital tract, or joints, and this ultimately causes their death. When the disease is entirely confined to the kidney Condamin finds that 62 per cent. of patients are finally and completely cured. When there exists in addition an extrarenal focus of tuberculous disease there were only 47 per cent. of ultimate cures. The prognosis is not so good in a patient giving a history of antecedent tuberculosis. Tuberculosis elsewhere in the genital tract rather increases the operative mortality, whereas urinary tuberculosis does not appear to influence the prognosis to any degree. Lesions coexisting in the lungs show the highest mortality and increase the gravity of the ultimate result. Extrarenal tuberculosis, then, appears to influence the prognosis after removal of the kidney, and in some cases may lead to infection of the remaining kidney. Lung infection is the most serious condition, whilst genital tuberculosis may delay recovery.

319. Fractures of the Head and Neck of the Radius.

C. W. CUTLER, JUN. (*Annals of Surgery*, February, 1926, p. 267), points out the importance of these fractures, as they not infrequently cause permanent disablement of the elbow-joint. In fifty collected cases the incidence was about equal in the sexes; they are not common in children. Falls on the elbow were responsible for 40 per cent. of the cases. The degree of injury ranged from a simple crack in the head of the radius to splitting of the head into two or more pieces. Six of the cases were complicated with a dislocation or fracture of the upper end of the ulna. The symptoms were uniformly pain in the elbow and some form of disability. Swelling was present in about two-thirds of the patients. The diagnosis rests on the history of a fall, followed by limitation of movement and pain in the elbow-joint; the x-ray picture is confirmatory. The prognosis depends on the severity of the injury and the question of proper treatment; in simple cases flexion and supination has given satisfactory results. In fragmentation Cutler thinks it is probably wiser to excise the fragments, as full and useful function of the arm is not otherwise obtained. If flexion and supination can be secured union and restoration of function are possible. It appears to be best to treat these cases without operation in the first place unless definite indications for removal of the fragments are present. Recourse can be had to operation later if conservative treatment fails.

320. Parabiliary Stenosis.

UNDER this title N. LAGRAVINESE (*Riv. Policlinico*, January 15th, 1926, p. 13) reports five cases, with radiograms, illustrating certain changes occurring in the colon and duodenum as a result of operation. These changes are due sometimes to a periduodenitis contracting and deforming the duodenum. One patient was a man who had been operated upon two years previously for gall stones, a cholecystectomy being performed. Two months later he began to suffer severe pain three or four hours after food, which was ascribed to fresh gall stones; but there was no evidence of this, and eventually he was treated as a neurotic and became a morphine addict, passing from one clinic to another. As haematin was found in the faeces, a final diagnosis of duodenal ulcer was made and laparotomy was performed. No trace of ulcer was found, but adhesions and marked periduodenitis was noted; the adhesions were freed and a posterior anastomosis was performed. After this the patient made a rapid recovery and had no more trouble. The four other cases illustrate various types of periduodenitis and serve to draw attention to the condition which is sometimes congenital in origin. The author adds a bibliography of recent literature on the subject.

Therapeutics.**321. Radium Therapy in Tumours of the Naso-pharynx.**

SARGNON (*Arch. Internat. de Laryngol., Otol. et Rhinol.*, January, 1926, p. 38) points out that there occur in the naso-pharynx true fibromas, malignant tumours outwardly resembling fibromas, and diffuse malignant tumours which arise and are restricted to the lateral wall of the naso-pharynx—the peritubal growths. The malignant tumours may be sarcomata or epitheliomata, but only the latter ever cause secondary glandular involvement. Among the objections to surgical measures is the tendency to haemorrhage, which may require a laryngotomy and a primary or a secondary ligature of the external carotid artery. Complete removal of the growth is difficult and the packing of the naso-pharynx is always likely to cause otitic trouble. Secondary haemorrhage is not a rare complication, and is usually very severe. Recurrence is frequent and often causes death from cachexia before there is any appreciable tumour formation. Any second intervention is still more difficult, and the bleeding is even more copious than on the first occasion. For these reasons the author has given up surgical measures and has employed radium. When this substance is used in association with operation through the mouth or nasal passages the tubes are applied by inserting them in the post-nasal packing and removing them together. If the operation has been by the lateral nasal route the tubes are easily placed against the area of detachment of the growth and can be removed at any time by the nasal passages. Radium can be employed before an operation and lessens the amount of haemorrhage at the operation; it may be applied in tubes or in needles. The ideal procedure is to introduce the radium carrier into the tumour itself, but this is often very difficult owing to the hardness of the tumour and its tendency to bleed on handling. The needles are best fixed into the growth through the nose under visual control by posterior rhinoscopy and are then safely retained; if placed in the tumour through the mouth there is risk of their coming loose and being swallowed. The

author introduces a sound through the nose, followed by a thread which passes out through the mouth, and is tied to form an endless thread. On to this he fixes tubes of radium and draws them into position so that one is in the naso-pharynx and the other is in the posterior part of the nasal passage. A little packing is placed in position to steady the tubes and to control any slight haemorrhage. Removal of the radium is not followed by haemorrhage, as the salt has a sclerosing action on the blood vessels. Doses of 50 or 100 milligrammes are employed. In cases of epithelioma, and especially where there is glandular enlargement, a collar of radium is applied to the neck and lower part of the face, about twenty tubes being used. The result of this form of treatment is that the patient has no more bleeding and the tumour gradually shrinks, taking several months to disappear. The disagreeable results may be perforation of the palate, which may be closed by a dental plate, and necrosis of the posterior part of the vomer, which causes little inconvenience except a rather fetid discharge.

322. Serum Treatment of Spirochaetosis Ictero-haemorrhagica and Acute Poliomyelitis.

A. PETTIT (*Progrès méd.*, February 20th, 1926, p. 279) states that in Japan the mortality from spirochaetosis ictero-haemorrhagica is 95 per cent., as compared with about 5 per cent. in France. The difference in the rates is to be attributed to the fact that only the severe cases are diagnosed in Japan, whereas in France all forms of disease, including a large proportion of mild cases, are diagnosed. In France, therefore, serum treatment has only a limited application in spirochaetosis ictero-haemorrhagica, being merely required for severe cases. Its effect is to inhibit the multiplication of the spirochaetes, though it is not so active as could be desired, and the recurrence of the fever is not prevented. The serum also furthers elimination of the spirochaetes and the duration of spirochaeturia is shortened. The jaundice, on the other hand, is hardly at all affected, for the blood corpuscles are destroyed. The haemorrhage, however, is checked, the intoxication is diminished, and the prostration becomes much less. Lastly, the blood pressure rises, headache diminishes, and convalescence takes place much more rapidly than in untreated cases. The administration of the serum is modelled on that of other serums. The serum should be given as soon as possible, the daily dose for an adult of 70 kilograms being 60 c.c.m. for three to five days. In poliomyelitis the serum, generally speaking, is indicated only in the acute stage and should be given very early. It should be injected intraspinally in doses of 10 c.c.m. after removal of the corresponding amount of cerebro-spinal fluid. If the patient's condition continues to be alarming, a second, third, and even fourth injection will be required. The action of the serum is as follows. It inhibits the advance of poliomyelitis, and in bulbar disturbances the respiration rapidly becomes normal after injection of serum. Moreover, the lesions of the cells are brought to a standstill and convalescence is more rapid than in untreated cases.

323. Treatment of Tuberculosis by Sanocrysin.

V. BIE (*Acta Medica Scandinavica*, February 11th, 1926, p. 220) describes the results of his treatment with sanocrysin of cases of acute febrile tuberculosis. Some patients received in addition intramuscular injections of the special serum, and others intramuscular and intravenous injections. Adult patients were usually given doses of 0.25, 0.50, 0.75 gram, and four doses of 1 gram, at intervals of at least five days, to a total for each series of 5.25 to 5.50 grams. Children received doses, in a similar progression, of 1/2 to 2 g. per kilogram of body weight. Bie introduced an interval of three to four weeks between the series of injections. Most of his patients vomited after injections of sanocrysin, but not to any serious extent. He considers the exanthem phase an indication for interrupting treatment, but not albuminuria in acute tubercle, since he has found that such albuminuria disappears with the termination of the course. He found that in chronic phthisis albuminuria might be set up with small doses of sanocrysin and was apt to persist; injections of serum neither prevented the appearance of albuminuria nor cured the condition. He records the case of a girl, aged 6, with acute tuberculous pleurisy. After injections of 0.75 and 1 gram of sanocrysin the temperature fell rapidly, and he gave an injection of serum on each occasion from fear of a collapse. With further experience he doubts if the serum was necessary. A second course of injections followed four weeks after the first, but without serum. Nine months after the commencement of treatment radiograms showed no signs of tubercle. A boy, aged 15, with signs of a lobar pneumonia of the right lower lobe and tubercle bacilli in the sputum, received serum injections with the first and third injections of sanocrysin, an intramuscular injection on the following day, and an intravenous injection with the

sauocrysin. The patient tolerated the second intravenous injection of serum well in spite of the short interval between it and the first injection, and the consequent risk of anaphylaxis. He does not, however, recommend such a procedure as a routine, and notes that his attempts at desensitization have failed. The patient had a full second course of sanocrysin and a third, both without serum. A short fourth course was given before the patient, nine months after the commencement of treatment, was well enough to be sent to a sanatorium with a normal temperature and slight expectoration, which, however, still contained tubercle bacilli. He quotes three more cases of females, aged 24, 21, and 16 respectively, the first two with tuberculous pleurisy, and the last with pulmonary tuberculosis; all responded well to treatment with sanocrysin. The last two patients had no serum.

424. Intravenous Sulpharsphenamine in Syphilis.

M. F. LAUTMAN (*Arch. Derm. and Syph.*, February, 1926, p. 234) states that the ill effects and sensations resulting from the injection of neo-arsphenamine and arsphenamine tend to prevent some patients from continuing the course of treatment. He has therefore made use of sulpharsphenamine, which, though not so efficient as the older arsenicals, is less noxious, does not give rise to dermatitis, and produces practically no constitutional reactions. The cases which he selected for treatment were those in which a negative Wassermann reaction had been obtained by previous treatment with other drugs, and therefore a less potent preparation was able to maintain the improved condition. More than four hundred injections of sulpharsphenamine were given by him to eighty-three of these patients, and in all of them the results were fully as good as those obtained by the older arsenicals. The drug was dissolved in 30 c.cm. of distilled water and injected into a vein. It was readily soluble and caused but little irritation if any of the solution leaked into the subcutaneous tissue; no tendency to thrombosis was observed. The first dose given was 0.4 gram, followed by seven subsequent ones of 0.6 gram, given every fourth day. These injections were combined with a similar number of 0.01 to 0.016 gram of mercury oxycyanate. Lautman has found this treatment particularly efficacious in neural syphilis, of which there were twenty-three cases in his series; the results were superior to those usually obtained with the other preparations. In those cases in which severe lancinating pains were present a distinct increase in the severity was observed immediately after an injection; the pain continued for about thirty-six hours and then subsided, becoming less than before the treatment. It is suggested that this increase in pain was due to the selective action on the nerve roots which sulpharsphenamine is said to possess.

Disease in Childhood.

425. Infant Feeding.

H. B. SHEFFIELD (*Med. Journ. and Record*, January 20th, 1926, p. 106), in discussing the difficulties of maternal nursing, states that the common practice of giving food to babies every three or four hours for exactly twenty minutes at a time, and waking the baby for this purpose, is to be condemned. This method only too often leads to painful and cracked nipples, with the possibility of breast abscess, in the mother, and to dyspepsia, insomnia, and excessive irritability in the baby. He suggests that the latter condition may, indeed, act as a primary cause of spasmodic pyloric stenosis, since this affection is more common in breast-fed babies. He proposes that the child should be fed at each breast alternately from five to ten minutes at a time every three or four hours when awake, and should not be awakened at specified times. If the breast milk agrees with the baby it usually suckles for about five to ten minutes and then falls asleep at the breast. Referring to the general opinion that breast-fed babies are more immune to infectious diseases than are bottle-fed babies, Sheffield reports that he has observed more cases of whooping-cough in the newly born and young breast-fed infants than in those who were bottle-fed.

426. Infantile Acetonaemia.

H. MEMBRAT (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, February 10th, 1926, p. 102) states that cyclic, periodic, persistent, and recurrent vomiting, with acetonaemia, form a morbid entity in infants and children. Marfan has described it as an infantile disease characterized by attacks of vomiting, the elimination of acetone and of ketone bodies in the urine and expired air, usually occurring in healthy subjects, lasting for a few hours or days, and ceasing suddenly, to give place to perfect food tolerance. The attacks commence usually

between the ages of 1 and 10 years, but cases occurring within the first year of life have been recorded. The disease is frequently familial and hereditary, and occurs more often in boys and among town-dwellers, particularly among children of the professional classes. It may be induced by dentition, overstudy, dietary faults, and by acute febrile diseases. An attack may occur suddenly, but more frequently it is preceded by headache, lassitude, constipation, and anorexia. During the attack there is an odour of acetone in the breath, the patient is pale and prostrate, the skin dry and parchment-like; it may be followed by jaundice. The prognosis is usually good, but some fatal cases have been recorded; in these there was fatty degeneration of the liver and subacute nephritis. Many theories of the origin of acetonaemia have been advanced, ranging from hysteria to anaphylaxis, but it would appear that the liver is the source of acetone and ketone bodies. Mellanby suggests that acetonaemia is due to intestinal toxæmia. An attack may be ushered in by severe headache and recurrent vomiting of the cerebral type, sometimes followed by epileptiform convulsions, rapid wasting, somnolence, and torpor; obstinate constipation completes the "meningitic tripod." Rigidity of the neck, severe headache, photophobia, and Kernig's sign are seen occasionally; it must not be forgotten that these may be due to cerebro-spinal or tuberculous meningitis. Epidemic oncephalitis may be simulated by the lethargic type, although its onset is usually more gradual and the vomiting less severe; acetonaemia is absent. Lumbar puncture may be necessary to distinguish acetonaemia from meningitis. Careful clinical examination is required, especially of the urine for acetone and for diacetic and β -oxybutyric acids. The early appearance of acetonaemia in cases of recurrent vomiting is a valuable aid to differential diagnosis. The majority of French authors state that lymphocytosis is found in acetonaemia, as well as in tuberculous meningitis, epidemic encephalitis, and cerebral syphilis. Finally, examination of the cerebro-spinal fluid for acetone may be required for differential diagnosis. It is probable that a certain number of reported cures of tuberculous meningitis were actually cases of acetonaemia.

427. Acute Nephritis in Children.

R. SOUTHEY and B. L. STANTON (*Med. Journ. of Australia*, January 30th, 1926, p. 127) examined the clinical histories of 103 children suffering from acute nephritis, with special reference to renal efficiency tests. They found that cases with sudden onset, and especially if there was an obvious source of infection, such as tonsillitis, impetigo, pneumonia, and measles, usually ran a short sharp course with complete recovery without any late results, while those with insidious onset without ascertainable cause often ran a protracted course ending in chronic invalidism. The urea concentration test proved to be of considerable value as an aid to prognosis, but the blood urea and urinary diastase estimations were of no assistance. Of 83 patients the urea concentration test indicated an unimpaired renal efficiency in 69, and all of these were found later to be clinically well and the urine free from albumin, casts, and red blood cells. Red blood cells alone are often found in the urine in the early stages, and also when the acute inflammation is subsiding, the casts and other cellular material having disappeared. The authors consider that diet is unimportant in influencing the duration of the illness, but that complete rest is essential. They found that the oedema responded fairly rapidly to pulv. jalapae co. and saline purgatives, or, in more obstinate cases, to potassium citrate, theocin sodium acetate, or Guy's pill, while hot packs and hot baths were valuable aids. Uræmic convulsions responded at once to venesection or lumbar puncture. In their opinion decapsulation is of little use and is rarely if ever justified.

428. Tuberculous Disease of the Wrist in Children.

E. SORREL (*Bull. et Mém. Soc. Nat. de Chir.*, February 6th, 1926, p. 86) states that in localized tuberculosis of the wrist-joint in children recovery may follow, with complete range of movement. He describes the case of a child, aged 10, in which this occurred. Even in the presence of abscess and fistula the condition may completely clear up in children. Six other cases are also mentioned, all of which had a satisfactory termination. This condition is not at all uncommon, and when there has been prolonged suppuration the surgeon may be tempted to excise the wrist-joint. In some cases this may be justifiable, but Sorrel maintains that in the localized form it is never necessary to perform a resection. The localized carpal tuberculosis of early life does not appear in adults, in whom the infection spreads to all the small joints of the carpus, and usually ends in ankylosis; or resection may become necessary. Radiograms and photographs illustrate the good results that have been obtained by conservative treatment in children.

Obstetrics and Gynaecology.

329. The Scar after Cervical Caesarean Section.

M. WETTERWALD (*Zentralbl. f. Gynäk.*, March 6th, 1926, p. 592) thinks that rupture of the scar of a Caesarean section is much less likely to occur in labours following a cervical than a corporeal (classical) Caesarean incision. According to Eardley Holland's collected statistics, the proportion of ruptures of the scar after high Caesarean section is as great as 25 per cent. in subsequent spontaneous births; Wetterwald's statistics from the St. Gallen Kantons-spital show that the proportion after the cervical operation is 3 per cent. If the percentages of rupture are reckoned as following Caesarean operations and not subsequent labours, the figures are from 1 to 4 per cent. for the high and, at the most, 0.28 per cent. for the low operation. Wetterwald has found in the literature records of 3,600 transperitoneal cervical Caesarean sections with only 10 recorded cases of rupture, during labour, of the scar, and 3 records of rupture of the uterus elsewhere. It is to be noted that in some of these 10 cases the accident cannot be attributed certainly or exclusively to diminished resistance in the cervical scar. In some the body also was torn at the time of rupture; in some the incision was lacerated during extraction of the foetus at the first operation; and in several the second pregnancy was accompanied by placenta praevia, in which erosion by chorionic cells possibly contributed to the yielding of the cervical scar. Wetterwald records a personal case—the only one, he thinks, in which the rupture of the uterus has concerned the cervix only with normal placental insertion. The Caesarean operation for persistent mento-posterior presentation was followed by an afebrile convalescence, and the rupture occurred at term (five years later) when the second stage of labour had been almost completed; the patient died after supravaginal hysterectomy. The author's clinic has recorded, after 100 cases of cervical Caesarean section without sterilization, labour in 45 patients, with 40 births *per vias naturales* among 26 women, and only one case of abnormal third stage of labour in the majority of the 13 repeated cervical sections the scar was unrecognizable, and in none were adhesions present. In spite of the favourable expectation in pregnancy following cervical Caesarean section, it is essential that the patient be kept under close medical supervision during both pregnancy and labour.

330. Induction of Labour by Pituitrin.

M. H. G. A. THOLEN (*Nederl. Tijdsch. v. Geneesk.*, February 6th, 1926, p. 525) states that A. Stern in 1920 drew attention to the value of the administration of castor oil by mouth, followed by intramuscular injections of very small quantities of pituitrin, for inducing labour in women at or beyond full term. Tholen employs the following method in his clinic at the Hague. The patient is given two spoonfuls of castor oil and two hours later 0.1 c.cm. of pituitrin intramuscularly. The injections are repeated hourly until labour pains occur regularly; not more than five injections of 0.5 c.cm. are given. Tholen used this method in 48 patients, of whom 17 were primiparae and 31 multiparae. In 3 of the primiparae the membranes were broken and in 14 intact, and of the multiparae 11 had their membranes broken and 20 intact. In 76 per cent. of the primiparae and 77 per cent. of the multiparae a favourable result was obtained. Patients who had not reached full term showed only false pains, and sometimes the uterus did not react at all.

331. Pulmonary Tuberculosis and Pregnancy.

E. W. BRIDGMAN and V. NORWOOD (*Bull. Johns Hopkins Hosp.*, February, 1926, p. 83), having examined 14,000 obstetrical histories, report that among these patients 134 were found to be suffering from pulmonary tuberculosis. They obtained no evidence that pregnancy increased the incidence of tuberculosis, though it seemed probable that gestation and the puerperium might be a final factor in the breakdown of the patient's resistance. The authors point out that when it is remembered that the child-bearing age corresponds with the age period at which pulmonary tuberculosis ordinarily appears, and that the female incidence rate at this age is below the male, except between the ages of 20 and 30, it seems likely that the association of tuberculosis and pregnancy is largely accidental. Of the 134 patients the diagnosis was not finally confirmed in 50, and in 17 pregnancy was associated with definite but inactive pulmonary disease, unilateral in 10 cases. Ten patients were still alive six to twelve years after delivery; one had two recurrences of the disease (one year and two years after delivery), and one had four subsequent pregnancies within five years, during which her tuberculous lesions remained quiescent, though eleven years later she went to a sanatorium. Another patient

developed active tuberculosis four years after delivery, requiring sanatorium treatment, but two years later she was again in good health. Of the 10 patients 7 were quite well from six months to five years after delivery, and all except 2 of the 17 patients had full-term children. These patients were all in poor circumstances, but the majority were not made worse by pregnancy, nor did they subsequently require treatment. In 31 cases pregnancy was associated with active tuberculosis; the short time between the onset of this disease and the pregnancy excluded 11 from consideration, but of the remaining 20, 2 were improved, 8 unimproved, and 10 had died one year after delivery. These figures, compared with those of tuberculosis in non-pregnant women, indicate a 10 per cent. worse prognosis, and it is not disputed that the occurrence of pregnancy in patients with active tuberculosis is disastrous. In a fourth group of 12 cases pregnancy was associated with tuberculosis, and therapeutic abortion was performed between the second and third months. Three patients could not be traced beyond two weeks subsequently, but of the remaining 9, 2 were living and improved at the end of one year; 2 living, but unimproved; and 5 had died within one year. It is suggested that operative procedures make the prognosis worse. In 19 cases pregnancy and tuberculosis were associated with other diseases, such as syphilis, chronic nephritis, and morbus cordis. The prognosis in such conditions was uniformly bad. The authors add that where the tuberculous lesion is fibroid, and has been quiescent for at least three years previously, the risks of pregnancy are not prohibitive if suitable rest and freedom from household duties are obtained.

332. Complete Post-partum Uterine Inversion.

J. SARF (*Presse Méd.*, February 17th, 1926, p. 212) records a fatal case of this rare complication, which occurs, according to various Continental authorities, once in 180,000 to 400,000 cases. Sarf believes that although it is a rare complication it is encountered more frequently than this. He advises that its possibility should be borne in mind in every abnormal delivery. Sarf's patient was a primipara, aged 19, and labour lasted for about eighteen hours, no instrument being used. Half an hour after the birth of the child the placenta was in the vagina and its delivery was attempted by slight traction on the cord. A bulky tumour, to which the placenta was adherent, appeared suddenly at the vulva. There was severe haemorrhage and alarming symptoms of shock. Half an hour later the placenta was peeled off, the aorta was compressed, and the inversion completely reduced. In spite of subcutaneous injections of camphorated oil and an intravenous administration of 500 c.cm. of physiological serum, the patient failed to rally and died three and a half hours after the birth of the child.

333. Formation of an Artificial Vagina.

R. FRANZ (*Zentralbl. f. Gynäk.*, February 27th, 1926, p. 545) states that between 1904 and 1923 the mortality was one in five among fifty-three operations for the formation of an artificial vagina by the method of Hachérin, Baldwin, and Mori. In this operation a piece of small intestine is made to serve the purpose of the congenitally absent vagina. An equal number of cases were operated on between 1911 and 1923 by Sehnert's method, in which the large intestine is similarly utilized. Cases of congenital absence of the vagina in which more than the rudiments of a uterus are present are rare, and in only four cases has a haematometra been implanted into an artificial vagina derived from the large intestine; of these, two patients died, one had a vagino-colic fistula, while one operation was entirely successful and pregnancy followed. O. S. PARSAMOW (*ibid.*, p. 550) records the case of a married woman, aged 23, in whom an artificial vagina was constructed from a piece of small intestine. Three years later the vagina was found to be 9 cm. long and there was no sign of dyspareunia. The patient in the meantime had married again, and the second husband was unaware that an operation had been performed, or that the patient did not menstruate.

334. Pernicious Anaemia and Pregnancy.

DEVRAIGNE and G. BLUM (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, No. 2, 1926, p. 114) describe a case of pernicious anaemia which proved fatal in the fifth month of gestation. The patient had had an early miscarriage four months after her marriage in August, 1923, but menstruation had since been regular until April, 1925. Pallor and debility came on insidiously, and the patient was admitted to hospital in September, when the blood examination showed a typical picture of pernicious anaemia. The Wassermann reaction was negative. Abortion followed three weeks later. No other pathological condition was found at the necropsy though only four months had elapsed between the onset of the disease and its fatal termination.

Pathology.

435. The Cerebro-spinal Fluid in Encephalitis Lethargica.

A. HANCOCK (*Journ. Ment. Sci.*, January, 1926, p. 58), in an investigation of twenty-three cases in the chronic stage of this disease, the duration varying from five years to four months, found the Wassermann reaction always negative. Pandey's test for globulin was positive in one case of five years' duration, and of the Parkinsonian type; two other cases showed faint reactions, but twenty of the series were negative. Only five cases showed a protein content above 40 per cent. The colloidal gold reaction (Lange) showed some change in ten of the twenty-three fluids examined; these changes were in all cases slight—usually "1" or "2"; in one case only was a change up to "3" shown. The sugar content was estimated in nineteen of the fluids, the method employed being Calvert's blood-sugar method adapted for cerebro-spinal fluid. In 58 per cent. of the cases the sugar present was above 0.05 per cent. (0.04 to 0.06 per cent. being the normal). In no case was the figure lower than 0.05 per cent. Hancock thinks that the importance of these figures lies chiefly in the fact that the sugar does not in any case show a decrease in amount, as is the case in tuberculous meningitis. The chlorides present were estimated in sixteen of the cases. No great variation from the normal 0.70 to 0.76 per cent. was found, as contrasted with tuberculous meningitis, where the figure is usually below 0.60 per cent.

436. Rare Fungus Infections.

L. BELLUCCI (*Arch. Ital. di Otol., Rinol. e Laringol.*, January, 1926, p. 1) reports three cases of mycosis in oto-rhino-laryngology. The first was a case of *Acremonium potronii* infection of the tonsil—an exceedingly rare condition. The patient was a woman, aged 35, who suffered from frequent attacks of peritonsillitis. On examination the right tonsil was found to be much reddened, swollen, and covered with small yellowish-white spots. Some were situated at the mouth of the tonsillar crypt, some in the tissue, but superficially placed; the majority were found on the upper pole of the tonsil. The uvula and the pillars were infiltrated and red, the left tonsil was quite normal. A bacteriological examination revealed the presence of fine filaments, and culture showed a profuse growth with folded surfaces of a transparent pinkish colour which was identified as *Acremonium potronii*. The condition did not respond to treatment with glycerin of iodine and recurred after destruction by the galvano-cautery. It finally yielded to treatment with potassium iodide. In the second case on three separate occasions cultures were made from the crusts of a typical long-standing case of ozaena. The fungi found were numerous colonies of *Penicillium crustaceum*, colonies of other *Penicillium*, *Aspergillus glaucus*, *Sclerotocystis nigra*, and, on one occasion, *Oospora*. The author remarks that *Penicillium* is difficult to recognize by means of an ordinary microscope examination, but the presence of *Sclerotocystis nigra*, which can be easily identified, shows the genus of mycelium to which the infection belongs. The third case was that of a man, aged 25, who complained of pain, tinnitus, and deafness in the left ear following rheumatism. He had treated himself with hydrogen peroxide, which had cured the pain but gave rise to a febrile condition and discharge from the ear. The mastoid was not tender. The external meatus was red and sore to the touch, and there was a perforation of the postero-inferior quadrant of the drum. Small yellowish-white spots were seen on the lining of the meatus. Cultures were therefore made and *Sclerotocystis nigra* was found. Treatment with potassium iodide was completely successful.

437. Ultra-violet Radiation and the Alkali Reserve of the Blood.

C. DE GHELDERE and M. DE ROOVER (*C. R. Soc. de Biologie*, March 26th, 1926, p. 784) have found that ultra-violet light exerts an influence on the alkali content of the blood. Rabbits, whose backs had been shaved, were exposed in a small cage to a mercury vapour lamp 20 cm. away; the lamp was of the Hewitt pattern, and was running under 120 volts and using 5 amperes. Specimens of blood were taken at intervals from the marginal vein of the ear, liquid paraffin being used to protect them from the air. The blood was centrifuged at high speed for ten minutes; 0.5 c.cm. of the serum was then titrated by the method described by Bouckaert. The animals were kept fasting for some hours prior to the exposure, and were secluded in a dark room so as to avoid the effects of daylight. Neither fasting nor obscurity had any influence on the alkali reserve, as tested by preliminary experiments. The exposure of a rabbit for three hours under the conditions described resulted in a marked fall of the alkali content of the blood. In a typical experiment 0.5 c.cm. of serum before irradiation neutralized

1.37 c.cm. of N/100 sodium bicarbonate solution; after three hours' exposure it neutralized 1.03 c.cm. and an hour later only 0.83 c.cm. Recovery of the normal titre was complete in twelve to forty-eight hours. Control animals, screened from the light by lead or glass, remained unaffected. Ordinary daylight apparently had no action on the alkali reserve. From these facts, and from the circumstance that a fall in voltage deprived the light of its action, the authors conclude that the lowering of the alkali content of the blood is a function of the wave-length employed.

438. Propagation of Foot-and-Mouth Disease.

C. KLING and A. HÖJER (*C. R. Soc. de Biologie*, March 12th, 1926, pp. 613, 615, and 618) have investigated the epidemiology of foot-and-mouth disease in Sweden, with particular reference to its mode of transmission. Since 1875 there have been twelve outbreaks; the last one, which started in November, 1924, is still in progress. Up to May, 1925, no fewer than 4,000 herds of cattle had been attacked. About 90 per cent. of the outbreaks in this last epizootic have commenced in the urban areas—that is, within a radius of 20 kilometres round the eight largest towns. The larger farms have suffered far more frequently than the smaller ones. From careful examination of the available evidence they conclude that infection is not carried by the air, nor by imported foodstuffs, nor, as a rule, by infected cattle, since the movement of animals is severely restricted. The earliest outbreaks have occurred round the four chief centres of population—Helsingborg, Kertlinge, Malmö, and Ystad; and it was shown that twenty-nine of the thirty-three farms that were first attacked had been in relation with these towns immediately preceding the outbreak. This incidence in close connexion with the main centres of traffic leads the authors to conclude that infection is carried by man. The further spread from the primary to the secondary centres is likewise explicable on this hypothesis. The evidence suggests that the virus gains access to the mucosae, on which it can remain viable for some days, man being a healthy carrier of the disease. It seems very unlikely that the virus is capable of being carried on the clothes. Occasionally man is himself a victim of the disease; this possibility has been demonstrated experimentally as well as naturally. After recovery his blood contains viruliferous antibodies, which have been used to prove the nature of the infection. Most of the carrier incidence is thought to be due to the consumption of infected milk, not to contact with infected cattle; but it appears probable that infection may occur from one healthy human carrier to another. These carriers are the chief method by which the disease is spread amongst cattle.

439. The Inheritance of Acquired Immunity.

O. HERRMANN (*Zentralbl. f. Bakt.*, March 1st, 1926, p. 81) has made experiments on the inheritance of acquired immunity to rabies in rabbits. It was found that the young were often immune, even when born as long as three and a half months after the active immunization of the mother had been completed. Such animals resisted the subdural inoculation of street virus; but the number of young that were immune depended on whether one or both of their parents were immune. When the mother alone was immune about 33 per cent. of the young proved to be resistant to the virus. When both father and mother were immune about 88 per cent. of the young were resistant. The experiments from which these results were obtained were, however, not strictly comparable. In the first series pregnancy did not supervene till some time had elapsed since the active immunization of the mother; in the second series pregnancy occurred during the course of immunization. No relation was found between the immunity of the young and the colour of their hair. The results are not sufficiently numerous to determine whether the inheritance of acquired immunity followed the Mendelian law, but the author thinks that they favour this interpretation.

440. A Mycological Test for Sugar in the Urine.

A. CASTELLANI and F. E. TAYLOR (*Journ. Amer. Med. Assoc.*, February 20th, 1926, p. 523), who have previously reported that the classical yeast fermentation test for glucose is not specific, since ordinary samples of yeast will ferment levulose, maltose, galactose, saccharose, lactose, and other carbon compounds as well as glucose, now give further details of the mycological test which they recommend in its place. For the identification of glucose in the urine they suggest using a fungus (*Monilia balcanica*) which only ferments glucose; *Monilia krusei*, which ferments only levulose in addition to glucose, may be used if the former fungus is not obtainable. The mycological test can be used further to differentiate a mixture of carbohydrates in the urine, and a tabular classification of the action in this respect of various fungi and bacteria is given. Reference is made to the authors' article in the *BRITISH MEDICAL JOURNAL* (1917, vol. ii, p. 855), which describes the test in detail.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

441. The Mechanism of the Cardiac Rhythm.

E. DONZELOT (*Presse méd.*, February 17th, 1926, p. 211) criticizes the generally accepted theory that cardiac rhythm originates in a single impulse provided by the sino-auricular node situated at the junction of the superior vena cava and the right auricle and the atrio-ventricular node situated in the septum in the auriculo-ventricular region and prolonged as the bundle of His. Donzelot suggests that these septal structures act as an accessory node or centre, and that in cases of injury or disease of the sino-auricular or atrio-ventricular node or the bundle of His, causing interruption of conduction, this accessory centre can initiate rhythmic impulses and thus prevent ventricular paralysis. But this rhythm, peculiar to the ventricles, is itself subject to more or less prolonged blocks which cause serious disturbance arising from ischaemia of the nerve centres (vertigo, syncope, epileptiform crises, resulting in the Stokes-Adams syndrome). Hence appears the necessity for the third hypothesis, which regards the pneumogastric nerve as an important factor in this problem; this nerve contains inhibitory (depressor) fibres which are the conductors of sudden inhibitory impulses resulting in prolonged and quite definite ventricular arrest. Moreover, the pneumogastric fibres pass from auricle to ventricle, following the course of the bundle of His. A fourth hypothesis explains how, if that bundle is severed by a lesion, the inhibitory fibres can still arrest ventricular contraction. It has been found that the nerve fibres are more resistant than the neuro-muscular tissue of the bundle of His, which may be destroyed while the nerve fibres in close proximity still retain their conductivity. The author rejects the theory of a single stimulus; he believes that the cardiac rhythm is produced by two independent stimuli—one auricular, the other ventricular. Further, these two stimuli are normally regulated by certain factors, among which variations in intracardiac pressure play a predominant part. These automatic auricular and ventricular structures are stimulated by variations of intracardiac pressure, playing the part of condensers, and interposed between the intracardiac nervous system and the contractile fibres. Finally, the sensitiveness of these different structures—nervous, connecting, and contractile—is itself regulated by the intensity and rapidity of the exchanges between the cells and the blood in the coronary circulation, and by the tone of the vago-sympathetic system. To sum up, the only direct connexion between the auricular and the ventricular systoles is the stroke of the auricular pump which enables the ventricles to attain, almost instantaneously, the internal pressure which determines the sudden contraction.

442. Sequels of Insulin Treatment.

A. T. B. JACOBSEN (*Ugeskr. f. Læger*, January 21st, 1926, p. 66) has studied the records of some 45 diabetic patients treated in hospital over a period of more than two years. There were 8 deaths, one of which was due to abscesses caused by the insulin, and 3 of which were due to coma. Of the survivors, 7 had been comatose and 4 had been threatened by coma. Yet the survivors were fit for work; only 2 complaining of a much reduced capacity. With regard to the amount of insulin required by the survivors, some still required the original dosage and others could manage on less, but, as a rule, in severe cases it had been found necessary to increase it. In several of the moderately severe cases the patients had become tired of the injections and had discontinued them for months, but had had to return to them, taking about two injections a week. While abscesses were frequent when solid insulin was used, they had become rare since the introduction of liquid insulin. These insulin abscesses increased the concentration of sugar in the blood and provoked glycosuria and acidosis: two patients had to be admitted to hospital with coma resulting from insulin abscesses. In only one case was severe poisoning from an overdose of insulin observed. C. HOLTEX (*ibid.*) has studied the fate of 73 diabetics treated in hospital with insulin before October, 1924. There were 17 deaths, all of which occurred from a few hours to four weeks after the institution of insulin treatment. All were complicated cases, the complications being such conditions as pneumonia and heart disease. Of the 56 patients who were discharged, 10 were able to discontinue the insulin, while 46 had to continue it at home; of these 4 had died and 4 could not be traced. The surviving 38 were still fit for work.

Sea-Sickness.

443.

R. RIBOLLA (*Journ. Trop. Med. and Hygiene*, February 15th, 1926, p. 59) discusses the pathogenesis of sea-sickness. He accepts a modification of Nolf's theory, and concludes that the condition is a functional disturbance due to hyperaemia of the vestibular apparatus, produced by the constant changes in the position of the body on the ship in movement (movements which have an opposite direction in pitching and rolling) by which at first the semicircular canals and the endolymph simultaneously follow the movements of the body, but when the movement is in the opposite direction the endolymph continues to be carried in the direction produced by the first impulse and then goes inversely to the movements of the semicircular canals. Thus the endolymph impinges on the ampullae and stimulates the vestibular nerve; the vagus nerve is stimulated reflexly and vertigo results. This does not exclude the view that the automatic centres of equilibration of the body are also concerned in part, sea-sickness being a phenomenon of consciousness, and absent in sleep. On this theory Ribolla advocates the use of vagal sedatives and the introduction into the external ear of tampons to produce local ischaemia.

444.

Duration of Infectivity in Measles.

F. REDLICH (*Klin. Woch.*, January 29th, 1926, p. 185) states that the discordant views expressed by various authorities as to the duration of the infectivity of measles has induced him to record his observations at the Lemberg children's ellipse on the occasion of prophylactic inoculation of children against measles with Caronia's vaccine. He found that while the prodromal stage was highly contagious, twenty-four hours after appearance of the eruption none of the children exposed to infection developed the disease. The objection that the children were insusceptible owing to a previous attack did not hold good, as they subsequently contracted the disease after exposure to infection by children in the prodromal stage.

Surgery.

445.

Osteomyelitis of the Frontal Bone.

A. E. BULSON (*Journ. Amer. Med. Assoc.*, January 23rd, 1926, p. 246) calls attention to osteomyelitis of the frontal bone as a complication of frontal sinusitis. Of 55 cases recorded in the literature 28 occurred as a complication of chronic suppuration, with 21 deaths, and 27 as a complication of acute suppuration, with 16 deaths. Of the 28 complicating chronic suppuration the osteomyelitis was subsequent to operative intervention for the sinusitis in 20 cases, while of the 27 acute cases osteomyelitis was discovered at the operation in 18. Three of the acute cases were fulminating and developed coincidentally with the acute sinusitis; they were all fatal. Pneumococcal and streptococcal infections ran the most violent course, were most difficult to control, and were most liable to end fatally. The disease may extend to the temporal, parietal, and occipital lobes, and, while operation for the removal of the disease focus may sometimes result in complete recovery, the relief is usually only temporary, since fresh foci may appear. The best results followed open treatment, with ventilation and drainage after thorough removal of all diseased bone, and the local use of mercurio-chrome. Bulson adds that once the disease has become established radical resection of the whole area of the diseased bone, extending beyond the obvious limits of the disease, affords the only means of cure, and in doubtful areas it is safer to remove bone than to leave it.

446.

Fatal Maxillary Necrosis in Chronic Benzol Poisoning.

J. LÖWY (*Med. Klin.*, March 12th, 1926, p. 404) has found records of thirty-one fatal cases of benzol poisoning prior to 1925. The main clinical manifestations are stated to be numerous subcutaneous and submucous haemorrhages resembling those of scurvy, with anaemia, leucopenia, and lymphocytosis. Löwy now reports the case of a motor-tyre repairer, aged 43, who had followed his trade for eighteen years. He used a rubber paste containing benzol and other chemicals as well as carbon disulphide. Two or three weeks before his admission to hospital the patient had had pain and swelling of the right cheek, with tenderness on pressure over the superior maxilla; later symptoms were right amblyopia, vertigo, anorexia, and pyrexia. He had been very pale for two months.

The urine contained albumin, urobilin, and urobilinogen. The pupils were equal and reacted briskly. Over the right superior maxilla there was a definite tender swelling extending to the zygoma and the inferior maxilla, with fluctuation on pressure. The breath was very fetid, the teeth were defective and septic, and three upper molars were loose. Many submucous haemorrhages were present. There was some dullness at the right pulmonary base with generalized rales. The area of cardiac dullness was normal, but a loud apical systolic bruit was heard. The liver was enlarged and tender. A skiagram showed that the outlines of the right antrum were obscured and an ophthalmoscopic examination showed retinal haemorrhages. The viscid sputum contained reddish-brown flakes and many Gram-positive cocci; no tubercle bacilli were found. The blood pressure was 82 mm. Hg. The blood picture showed a great deficiency of erythrocytes and haemoglobin, with leucopenia and a definite leucocytosis. Death occurred from heart failure. The necropsy showed profound anaemia, fatty degeneration of the heart muscle and of the liver, septic osteitis of the right superior maxilla, antral empyema, aspiration pneumonia, pulmonary oedema, and gangrene, with acute splenitis. Löwy points out that this case clearly indicates that maxillary necrosis may occur in benzol workers as well as in those who handle phosphorus and mercury. The septic condition of the teeth greatly aggravated the initial gingivitis set up by the inhalation of the poisonous vapour, and the three loose upper molars were the route by which the septic infection travelled to the maxillary antrum.

347. Splenic Abscess in Typhoid Fever.

C. MOREL, C. DAMBRIN, and J. TAPIE (*Ann. de Méd.*, January, 1926, p. 5), who report a case in a woman aged 27 successfully treated by operation, state that since the first case recorded by Lemaître in 1848 only thirty cases of splenic abscess in typhoid fever have been published. The complication is not peculiar to severe forms of typhoid fever, but may occur in moderate or even mild cases. The date of its appearance ranges from the third week to a long time after apparent recovery from the disease. Bacteriological examination of the contents of the abscess has not always been made, but the typhoid bacillus has always been found when it has been carefully looked for. The abscess is usually situated in one of the poles of the organ, and almost always the upper pole. The abscess may be single, but multiple abscesses are not exceptional. The size of the abscess varies from that of a hazel-nut to that of two fists. Pain is a constant symptom, whether spontaneous or caused by palpation only, continuous or paroxysmal. Its violence explains the dyspnoea and immobility of the base of the thorax on one side. Fever may be continuous or intermittent. The abscess may invade the pleura and lungs or give rise to peritonitis or rupture into the colon. As regards the diagnosis, splenic abscess must be distinguished from abscess of the abdominal wall, pyonephrosis, subpyrene abscess, and empyema. Radiological examination will often clear up the diagnosis, but exploratory puncture is not of great value. Of thirteen patients treated by operation only one, reported by Rokitsky, died, a splenectomy having been performed; all the others, treated by splenotomy, recovered.

348. Abscess of the Larynx.

J. C. SCAL (*Med. Journ. and Record*, February 3rd, 1926, p. 182) reports three cases of abscess of the larynx, two of which ruptured spontaneously and the other was cured by incision. He states that the condition is usually idiopathic, though trauma of the larynx, inhalations of noxious vapours, and exposure to wet and cold have also been cited as causes. In children it may be due to infectious diseases and be mistaken for retropharyngeal abscess. The symptoms are a choking sensation, hoarseness, pain on swallowing, dyspnoea, and general malaise. The usual site of the abscess is the anterior surface of the epiglottis, the aryepiglottic folds, or the arytenoid cartilage. Rapid recovery is usual after rupture or opening of the abscess, but the condition must always be considered serious, since it may lead to asphyxia, involvement of the lungs or mediastinum, or septicaemia.

349. Periarterial Sympathectomy.

G. M. GUREWITSCH (*Zentralbl. f. Chir.*, February 27th, 1926, p. 521) refers to the employment of periarterial sympathectomy in tuberculosis of joints, and also in the case of fractures. It has been attempted in epilepsy and migraine, although the etiology and pathology of these diseases are unknown, as are also the anatomical and physiological bases of the operation itself. After reviewing the recent literature, the author describes a theory of segmental vascular innervation, and relates the case of a pale but well built boy, aged 16, who had had chronic ulcers of both legs for more than a year. Leriche's periarterial sympathectomy was performed on both

femoral arteries. At first the ulcers showed rapid improvement, but this was not maintained, and it was subsequently found that at the sites of operation the arteries were surrounded by dense scar tissue, with adhesions to the neighbouring muscles. In other cases more or less extensive necrosis of the arterial wall at the site of operation has occurred. Gurewitsch concludes that periarterial sympathectomy is so uncertain in its ultimate results that it is contraindicated in all diseases.

Therapeutics.

350. Treatment of Acute Chorea.

DEREUX (*La Vie Méd.*, March 5th, 1926, p. 393) observes that chorea is an organic nervous disease with an infectious origin. Three infections may induce an attack—namely, acute articular rheumatism, hereditary syphilis, and lethargic encephalitis. The treatment of acute chorea depends upon the nature of the infection. Most cases in children are due to rheumatism, usually to an acute rheumatic arthritis. These require the administration of large doses of chemically pure sodium salicylate, especially if arthritis or endocarditis is present. Dereux finds that children can take the usual adult doses, intolerance being most frequently due to impurity of the salt; it should be dissolved in alkaline fluids and its elimination in the urine he tested with ferric chloride. If rejected by the stomach, sodium salicylate should be given by the rectum; or, in very serious cases, it may be injected intravenously. The treatment must be continued for some time after apparent cure. Aspirin is sometimes useful, as an alternative, and arsenic has been largely employed, either in the form of arsenious acid (in 1 in 1,000 aqueous solution) or organic arsenical compounds. Arsenious acid should be given in rapidly increasing doses, commencing with the equivalent of 10 mg. and increasing the dose to 25 or 30. Toxic symptoms may occur at this stage, when the doses should be reduced gradually to the initial amount. Hutinel and Babonnoix never give arsenic to children under 6 years of age; they never give larger doses than 15 mg. Dereux advises that the child should be under constant medical supervision, confined to bed, and restricted to a milk or milk and vegetable diet. The arsenic may also be given mixed with fresh butter and spread on bread, when it is usually well tolerated. Such organic preparations as sodium cacodylate or methyl arsenate are sometimes useful, and arsenobenzol has been used very successfully; it should be given intravenously, 10 to 20 cc. every six days being the average dose. Antipyrin is sometimes useful, but is contraindicated by renal disease; sedatives recommended include chloral, bromides, and camphor monobromate. Warm baths and wet packs have a sedative effect. Dereux adds that chorea is an obstinate disease, which frequently recurs unless treatment is continued long after apparent cure. Many French authors believe that it may have a syphilitic origin. The chorea of pregnancy is frequently a recurrence of that of childhood, though some cases are due to lethargic encephalitis.

351. Tryparsamide in Neuro-syphilis.

P. A. O'LEARY and S. W. BECKER (*Med. Journ. and Record*, March 3rd, 1926, p. 305) record observations upon 207 cases of neuro-syphilis, 113 of which were treated with at least two full courses, each of ten injections, of tryparsamide. From 1 to 3 grams were administered at weekly intervals in conjunction with potassium bismuth tartrate and 0.2 gram of butyn every five days, or with mercury succinimide, 1/6 to 1/4 grain five times a week for six weeks, or with mercury salicylate, 1 to 2 grains once a week. If the interval between the courses was two months or less no other treatment was given, but if longer, mercurial inunction was used. While the drug appeared to be of value in the treatment of the parietic type of parenchymatous neuro-syphilis, it was not found to be as successful as the treatment of general paresis with malaria, but the authors recommend it for patients unsuitable for the latter treatment. As the result of observations based upon subjective and serological improvement they are of opinion that certain patients with early paresis are markedly benefited by tryparsamide. In seven cases a complete return of the spinal fluid reactions to normal occurred, but without any associated clinical improvement, and it was not possible by clinical and serological criteria to determine beforehand which patients with paresis would improve. The intramuscular injection of bismuth in connexion with tryparsamide appeared to give better results than those obtained by either drug given alone. The authors consider that tryparsamide is a valuable aid in the treatment of early general paresis in view of its low cost, availability, and small percentage of complications and reactions.

452. **Insulin in Suprarenal Insufficiency.**

G. MARAÑÓN (*Arch. de med., cir. y esp.*, January 23rd, 1926, p. 145), who records several illustrative cases, comes to the following conclusions. Suprarenal insufficiency gives rise to a special hypersensitiveness with regard to insulin, severe and even fatal symptoms occurring in subjects of Addison's disease after apparently harmless injections of this drug. This hypersensitiveness bears no relation to the general condition of those suffering from Addison's disease, since it does not occur in other states of cachexia even when the blood pressure and glycaemia are low. Evidence of antagonism between adrenalin and insulin suggests that the deficient secretion of adrenalin is the cause of this hypersensitiveness. The physiological remedy of these symptoms, therefore, appears to be adrenalin. There is a striking clinical resemblance between the syndrome of hypoglycaemia following injection of insulin and certain severe symptoms occurring spontaneously in the last stage of Addison's disease, which suggests that a sudden hypoglycaemia may play a part in the production of the so-called "Addisonian encephalopathy." Recent observations made by Marañón showed that in patients who died of diabetic coma in spite of insulin treatment, which had caused a disappearance of hyperglycaemia and acidosis, there were severe lesions in the suprarenals. This factor, therefore, should be considered in cases in which coma develops after cure of the acidosis, as has been recorded by Campbell, Weinberger, and Marañón himself.

453. **Antimony Trichloride in Lupus.**

J. DARIER (*Bull. de Derm. et de Syph.*, February, 1926, p. 72) recommends for rapid improvement of old-standing but not extensive lupus the use of an elective canalic, and suggests the following formula: Freshly prepared antimony chloride 2 grams, salicylic acid 2 grams, official creosote 4 grams, norocain 4 grams, lanoline 8 grams. This is rather milder than Unna's "green pomade." If the lupus has not already ulcerated, the epidermis should be removed with the galvanocautery or by light curetting. The ointment is applied every other night in a layer as thick as a kalte-blade, being washed off in the morning with sterilized water and replaced by zinc ointment. Darier claims that usually fewer than ten applications are needed, and that in thirty years' experience he has had very few relapse cases, although patients have to be watched at first for early recrudescences.

Dermatology.454. **Etiology of Recklinghausen's Disease.**

P. DOTTI (*Bull. del. Sc. Med.*, November-December, 1925, p. 337), who records numerous illustrative cases, maintains that Recklinghausen's disease is much more frequent than the cases published would indicate, as among 170 patients at the hospital for chronic diseases at Bologna he had found ten complete forms (cutaneous pigmentation and neurofibromata) and four cases with neurofibromata only. The theories put forward to explain the pathogenesis of the disease are as follows: (1) Elnedel's embryonic theory, which is based on the common ectodermic origin of the nervous system and the skin. According to this theory the coexistence of changes in both these systems is regarded as a developmental anomaly of the ectoderm at a very early stage of embryonic life. In support of this view is the frequent occurrence of hereditary and familial forms. (2) Recklinghausen's infective theory, according to which the disease is due to the action of a micro-organism on the nerve trunks, in the same way that leprosy is caused by Hansen's bacillus. (3) The endocrino-sympathetic theory, according to which the disease is due to affection of some gland of internal secretion, especially the suprarenals, or of the sympathetic, or of both. Dotti's experience supports the embryonic theory, as in five of his cases the disease assumed an hereditary and familial form; in three instances it appeared in three generations, and in two in two generations. Another argument in favour of the embryonic theory was that in one family skeletal malformations and congenital lesions in the form of mitral stenosis, angiomata, and craniofacial asymmetry were present.

455. **Eczema.**

H. C. MARTIN (*Med. Journ. of South Africa*, January, 1926, p. 155) calls attention to the psychological factor in the causation of eczema, realising that it is a possible external irritant there the really eczematous factor, characteristics generally of an anxious and worrying disposition. Another internal factor which may be present is toxic, including such poisons as gout and rheumatism, and others of intestinal origin. Martin describes his own experience as

a sufferer since 1908, with a period of eight years' immunity following x-ray treatment. Recurrence followed a period of worry and anxiety, combined with the injudicious use of antiseptics. The x-ray treatment consisted of a small dose weekly, then fortnightly, and then monthly; at the end of a year the condition was apparently cured, and remained so for eight years. His experience has convinced him of the necessity for early and vigorous treatment, and that in intractable cases remaining unchanged for over a year, in spite of ordinary treatment, recourse should be had to x rays or ultraviolet light. He adds that if the condition is allowed to drift the psychological factor, with its feeling of despair, will diminish the chance of cure. He does not consider any restriction of diet necessary, except as regards pickles, sauces, and salt, which latter he found especially harmful; the prohibition of alcohol in the case of a patient who is moderate and who has been accustomed to it for years he regards as harmful.

456. **Symmetrical Dysmenorrhoeic Dermatitis.**

J. TRAGANT (*Rev. med. de Barcelona*, December, 1925, p. 538), who reports an illustrative case, states that since Matzenaner and Pollard first described this disease in 1912 not many examples of it have been recorded. The first thing noticed by the patient is an intense burning sensation in the part affected. The eruption consists of a moist dermatitis, an articular erythema, or a spontaneous necrosis. Any part of the body may be attacked, but only exceptionally the scalp, as in Tragant's case. Matzenaner and Pollard attribute the disease to passage into the blood of toxic metabolic products due to lesions of the ovarian follicles. Kreibich, on the other hand, believes that the lesions have an angio-neurotic basis. Tragant's patient was a woman, aged 46, who suffered from a mild form of the disease from the age of 14 to 18, but after ovariectomy for bilateral annexitis at the age of 31 she had a more severe attack, which was not affected by ovarian treatment.

457. **Ringworm of Scalp in the Adult.**

H. FOX (*Arch. Derm. and Syph.*, March, 1926, p. 398) reports a case of ringworm of the scalp in an adult, and remarks upon the rarity of this condition; he has been able to collect records of only 53 cases, of which three were in his own practice. He believes that cases may be overlooked by failure to use the laboratory; in his own cases the clinical diagnosis was confirmed by microscope examination and culture. The case described occurred in a coloured domestic servant, aged 25 years. She gave a history of circinate eruption of the neck two months previously, which had cleared up at once with iodine treatment. A week later, however, the eruption occurred on the occipital region and presented the appearance of a pustular ringworm of the kerion type. Cultures proved the infection to be due to *Microsporon audouinii*, an organism which is not usually pyogenic. The author's two previous cases were also in negroes.

Obstetrics and Gynaecology.458. **Retroversion of the Gravid Uterus.**

LAURENTIE (*La Vie Méd.*, February 19th, 1926, p. 281) states that retroversion may occur under two distinct conditions. In the first of these the uterus is primarily retroverted, and pregnancy is a secondary development. Retroversion of the uterus is not an absolute cause of sterility, especially if it is not associated with congestion or inflammation of the uterus or adnexa, or fibrous degeneration of the uterine wall, or sclero-cystic changes in the ovaries. In the second condition the uterus is primarily in a good position and retroversion is secondary, the large size of the pelvis and looseness of the ligaments being predisposing causes. One of four events may ensue, the first two being common, and the last two exceptional. (1) Retroversion does not give rise to any symptoms apart from some lumbar pain or, less frequently, vomiting of a severe type. Spontaneous rectification occurs in the second or third month, and pregnancy pursues a normal course. After delivery the uterus usually becomes retroverted again. (2) Abortion occurs in the second or third month, with or without retention of the placenta. (3) Incarceration of the uterus may occur after three or four months of pregnancy. The complications then are principally vesical—namely, retention of urine, haemorrhagic, purulent, or gangrenous cystitis, and ascending pyelonephritis. (4) Symptoms of incarceration are absent, and reduction of the uterus apparently takes place owing to enlargement of the anterior wall of the uterus, while the posterior wall remains fixed in the hollow of the sacrum. This is the condition of pseudo-reduction described by Piquard and Segond, Convelaire and Potocki. As regards treatment,

reduction is not required in every case, but is necessary on the occurrence of persistent sterility or repeated abortions in otherwise healthy women. In most cases the reduction must be operative and consist in removal of adhesions and fixing the uterus in a good position. Expectant treatment includes prolonged rest in the ventral decubitus or genu-pectoral position, and frequent evacuation of the bladder and rectum. Incarceration requires evacuation of the bladder and manual reduction under chloroform. If this fails laparotomy is necessary. In cases of pseudo-reduction Caesarean section is indicated.

359. Suture of the Uterus after Caesarean Section.

W. BLAIR BELL (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter No., 1925, p. 727) refers to his original article on suture of the uterine wound in Caesarean section (*ibid.*, 1921, p. 530), and now reports an improvement in the technique with a view to making uterine sutures sub-peritoneal, so as to avoid post-operative adhesions. He states, however, that uterine adhesions have been found at subsequent sections in very few cases when the operation had been performed according to his previous method. In his more recent procedure a large, slightly curved Reverdin needle is passed through the peritoneum and uterine musculature, half an inch below the angle of the incision in the uterine wall, and as deeply as possible without puncturing the lining membrane of the cavity. A fairly long strand of No. 2 tanned catgut is attached, and the needle is withdrawn. It is then passed through the musculature and peritoneum on either side of the incision from within outwards, perforating the peritoneum at points a quarter of an inch from the apertures through which the suture had first been drawn, and one inch beyond the margin of the incision. The catgut is tied and a mattress suture is then formed, with the knot within the uterine wound. The remainder of the mattress sutures are inserted similarly, a space of three-quarters of an inch being left between them. The deep parts are thus brought into apposition throughout the length of the incision. The last suture is placed in exactly the same way as the first, and includes the portion of the uterine musculature beyond the incision. If required the uterus is washed out before the last suture is tied. The middle and superficial parts of the musculature are now closed by the utilization of the long ends of catgut left after the first layer of sutures has been tied for a future series of more superficial mattress sutures. In this way the whole of the divided musculature is brought together to form a very broad strong ridge. The peritoneum is finally sutured by means of a turning-in stitch. The author believes that rupture of the Caesarean scar is due more often to faulty technique in the closure than to sepsis.

360. Treatment of Cancer of the Cervix.

L. AUBERT (*Rev. méd. Suisse rom.*, February 25th, 1926, p. 65), who records three illustrative cases in women aged 58, 44, and 34, states that the association of radium treatment with operation increases the chances of recovery from cancer of the cervix. In some cases, indeed, which at first sight appear hopeless, it allows a permanent cure to be obtained. In such cases radium by itself may produce so much improvement as to suggest a cure. Operation, however, is indicated since a recurrence is otherwise certain. More or less latent new growth which cannot be entirely sterilized by radium can be removed by hysterectomy. In two of Aubert's cases the carcinoma remained active after applications of radium, and in the third case the growth seemed to have disappeared as the result of radium applications, but subsequent histological examination showed that the recovery was not complete. Hysterectomy, therefore, was performed in all three cases and complete recovery followed.

Pathology.

361. The Phenolsulphonephthalein Test in Renal and Circulatory Diseases.

C. LUNDSGAARD and E. MÖLLER (*Acta Medica Scandinavica*, February 11th, 1926, p. 242) have investigated the renal excretion of phenolsulphonephthalein and of water in different diseases, giving 1 litre of water by the mouth at the same time as they injected 6 mg. of phenolsulphonephthalein intravenously. They have considered an excretion of 70 per cent. of the dye in the first two hours, or of water in the first four hours, after administration as the lowest limit of the normal zone. In most cases of uncomplicated cardiac disease without signs of circulatory insufficiency at rest, the excretion of the dye was below normal. The authors attribute this to a change in the renal circulation. The decrease was still more frequent and marked in heart disease with absolute circulatory insufficiency. There was more often a decreased excretion

of the dye than of water, for which reason the phenolsulphonephthalein test must be regarded as a very sensitive indicator of circulatory insufficiency, both general and renal. In essential hypertension there was a decrease in the phenolsulphonephthalein excretion which was if anything more frequent and greater than in heart disease. The cases of hypertension with absolute circulatory insufficiency showed a still greater decrease, but in 4 cases of cardiac neurosis excretion was normal. Of 18 patients with various kidney diseases the excretion and blood pressure were normal in 8; 4 of them were pure chronic nephrosis cases with only tubular symptoms. Of the 10 with decreased excretion 2 had normal blood pressure but had greatly decreased water excretion; the remaining 8 all had hypertension. Two patients with orthostatic albuminuria had normal excretion when kept in bed and decreased excretion when up. In a series of cases it was shown that phenolsulphonephthalein does not pass over into the ascitic, spinal, hydrothoracic, or subcutaneous oedematous fluids, indicating a fundamental difference between the phenolsulphonephthalein and Strass's water tests. The authors contest Rowntree and Goraghty's view that the phenolsulphonephthalein test is a specific renal test. Maroulis held that the test registered accurately modifications of cardio-renal equilibrium. The present authors go further and state that the test is only valid for indicating nephritis when circulatory disturbances, including arterial hypertension, can be excluded, and when the water excretion is not too diminished. Later investigations have shown that the liver is concerned also, there being decreased excretion in liver disease.

362. Differentiation of the Streptococcus Group.

N. STOLYGO (*Centralbl. f. Bakt.*, March 1st, 1926, p. 1) draws attention to the difference in behaviour of the pneumococcus and the haemolytic streptococci on heated blood agar, the former term comprising all chain-forming cocci which cause α -haemolysis on fresh blood agar plates (the pneumococci proper and the *Streptococcus viridans* type). Examining 182 cultures of streptococci of different origins from the human body, he found that 159 were able to decolorize chocolate blood agar, and gave α -haemolysis on fresh unheated blood agar; of the remaining 23, 22 gave β -haemolysis on fresh blood agar, but were unable to decolorize chocolate agar. The remaining culture was a completely non-haemolytic strain, which likewise had no action on chocolate agar. By their decolorization of chocolate agar the author thinks that the pneumococci can be certainly distinguished from the haemolytic streptococci. He considers this test even more valuable than the nature of haemolysis on fresh blood agar, for alterations that occur in the ability of strains to haemolyse fresh blood do not seem to be accompanied by any change in their action on heated blood.

363. Calcium Metabolism and Parathyroid Extract.

L. BERMAN (*Journ. Lab. and Clin. Med.*, February, 1926, p. 412) reports that by extracting the parathyroid glands of oxen with acidified water or alcohol, and removing lipins and proteins from the extract, a crystalline substance was obtained. This substance, when dissolved in Ringer's solution and injected into the circulation, was found to increase definitely the calcium content of the blood, thus supporting the theory that the parathyroid glands are concerned in calcium metabolism. When animals from which the parathyroids had been removed were treated with this substance, it was found that certain typical symptoms of parathyroid deficiency—malaise, anorexia, hyperphosphaemia, tremors, and tetany—were relieved. The animals were kept alive by daily injections, and died when this treatment was stopped. All these animals showed deficiency in the blood calcium content and increased nerve excitability, which was remedied by the use of the crystalline extractive.

364. Heredity and Cancer.

MAUD SLYE (*Paris Méd.*, March 20th, 1926, p. 257), as the result of investigations in mice, concludes that the resistance and susceptibility to cancer are transmitted as simple Mendelian units, as is also the site of occurrence of the lesion, but that these may be modified by selective breeding. Similar conclusions were reached as regards cancerous metastases. She states that susceptibility is the recessive character, resistance acting as a simple dominant. In mice the first cross between dominant and recessive types never produced cancerous offspring. In the mice studied chronic leukaemia sometimes appeared, and then followed the same rules of heredity. In the experimental work cancerous cachexia seemed to be due to necrosis of the growth or to secondary infection, and was not related to the size of the tumour. The growth of cancer in the mammary gland was found to be retarded by uninterrupted pregnancies, in contrast with the infectious diseases studied. No evidence was obtained that cancer is infectious.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

355. The Prophylaxis of Measles.

S. ANDERSEN and F. WULFF (*Ugeskr. f. Læger*, March 4th, 1926, p. 216) reports from the Blegdams Fever Hospital in Copenhagen the results of giving prophylactic injections of the serum of convalescents to 91 children exposed to measles in hospital. There were as many as twenty-five different sources of infection. Only 5 of the 91 contracted measles, and the immunity effected in the remaining 86 cases was the more striking as most of the children were at a very susceptible age: 49 were over the age of 3, 18 were aged between 1 and 3 years, 11 were between 6 and 12 months, and only 13 were less than 6 months of age. The duration of the passive immunity thus conferred was probably quite short, for three of these children subsequently developed measles two and a half, three, and three and one-third months after the injection of serum of convalescents. The dose of this serum found to be most suitable was 5 c.cm. for children under 1 year, 10 c.cm. for children between 1 and 3 years, and 15 c.cm. for children over 3 years. The serum was obtained by venesection of convalescent patients between the seventh and ninth days after the fall of the temperature to normal. The serum was taken and prepared at the State Serum Institute. The author concludes that this procedure is of most value in hospitals where children already admitted for other complaints can be protected from infection with measles by cases admitted by mischance. E. LEXSTRUP (*ibid.*, p. 218) gives an account of three aborted epidemics of measles in the Queen Louise's Hospital in Denmark. On the first occasion three cases of measles occurred on May 14th, 1925. In the same ward there were seven children who had not had, and four who had had, measles. The seven were treated with the serum of convalescents, from 5 to 10 c.cm. being injected into the muscles of the thigh; none of these seven developed measles. An involuntary control was a boy of 5 who was not given serum because, by mistake, it was assumed that he had already had measles. It transpired, after he developed measles, that this assumption was wrong. On the second occasion a child developed a measles rash in hospital. The eleven children, who had been in contact with her, were treated with serum, and ten did not contract the disease; the remaining child developed it after her return home. On the third occasion a child who developed measles in hospital had evidently been infectious for five or six days before serum was given to the seventeen contacts, twelve of whom were effectively immunized. The disease ran a very mild course in the other five cases. On none of the three occasions referred to were any ill effects from this prophylactic treatment observed.

356. The Significance of Pleurisy.

D. R. HASTINGS (*Minnesota Med.*, March, 1926, p. 114) has examined the case records of 1,182 tuberculous patients in a sanatorium and found a history of fibrinous pleurisy or of pleurisy with effusion in 55.7 per cent. Fibrinous pleurisy, he points out, may be the first symptom of pulmonary tuberculosis, and therefore pleuritic patients should be warned of this danger. He thinks that pleurisy with effusion should be considered clinically as a tuberculous process unless this etiology can be definitely excluded; treatment for tuberculosis should be undertaken at once. Apart from tuberculosis the causes of pleurisy are pneumonia, typhoid fever, nephritis, heart conditions, pyogenic infections, and new growths. In the treatment of effusion it should be remembered that since the process is probably of an immunizing origin the fluid should not be aspirated without some special indication such as the removal of a specimen for laboratory examination, the occurrence of pressure symptoms, or mediastinal displacement, delayed absorption, or the presence of an effusion on both sides of the chest. Hastings adds that empyema occurs more frequently after removal of the fluid, and that the "splitting" of a tuberculous lung by fluid gives some measure of rest to the part and may thus be beneficial to the patient.

357. Occurrence of the Sign of Duroziez.

I. MAHAIN (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, February, 1926, p. 86) discusses the occurrence of the sign of Duroziez, an intermittent murmur in the femoral arteries, and describes the case of a workman, aged 54, who had had precordial pain and dyspnoea on effort for two years. The

arteries were tortuous and thickened, the pulse forcible, the area of cardiac dullness normal, but the second aortic sound was accentuated. In the femoral arteries there was a double (systolic and diastolic) bruit. No cardiac bruit could be elicited after exercise, whether the patient sat or lay on his back; there was considerable dyspnoea. A skiagram showed hypertrophy of the left ventricle, and the aorta was very opaque but not dilated. Subsequently Mahain has examined a large number of patients systemically and has found the sign of Duroziez in fifteen cases. Duroziez recognized the existence of a venous systolic bruit, only present when the femoral artery is compressed lightly; rather more pressure causes this to disappear, while still greater compression produces another arterial bruit. Duroziez also described a diastolic venous bruit, present only in tricuspid regurgitation when the right auricle is dilated and hypertrophied. The sign of Duroziez is not always found in aortic regurgitation. Mahain states that in searching for this sign it must be established that the vascular diastolic bruit is not of venous origin. Pressure with the stethoscope increases the intensity of the arterial diastolic bruit and rapidly extinguishes a venous bruit coinciding with the diastole. The exaggeration of the diastolic ascent and elevation of the systolic pressure correspond with the production of the femoral double bruit in aortic incompetence. The bruit is absent in rheumatic aortic incompetence when the systolic pressure is only slightly raised, even if the diastolic ascent is exaggerated. The bruit is chiefly heard in arterial incompetence in which both the diastolic ascent and the systolic pressure are raised. Mahain adds that in the absence of any aortic incompetence, as shown by auscultation, the double femoral bruit is found occasionally; this is the case in hyperpiesis, when the pulse is bounding, the diastolic ascent exaggerated, with aortitis and a hypertrophied left ventricle, and secondary mitral regurgitation. Its presence in such circumstances probably indicates a functional aortic incompetence, as yet unrecognizable clinically.

358. Antityphoid Inoculation.

W. SPÄT (*Med. Klin.*, February 26th, 1926, p. 328) states that in the autumn of 1914 inoculation against cholera and typhoid fever was made compulsory in the Austrian army. About a fortnight after introduction of inoculation against cholera, the epidemic of cholera came to an end. Almost at the same time, however, there was a subsidence of the cholera epidemic in the Russian army, which had not been inoculated. The subsidence of the epidemic, therefore, could not be attributed to inoculation. No inoculations were carried out against dysentery, and its incidence, which had greatly exceeded that of typhoid fever, fell in 1915 to a fifth, and in 1916 to a tenth, of the typhoid fever cases. As regards typhoid fever, although there was a steep fall in the incidence of the disease after the introduction of inoculation, a similar steep fall occurred in the Franco-Prussian war of 1870-71 without inoculation. Similarly in the American war of independence (1860-66) the number of typhoid cases fell from year to year without inoculation. Spät, therefore, concludes that there were no grounds for attributing the decline in the incidence of typhoid fever to inoculation. On the other hand, he brings forward figures to show that inoculation may cause an increased susceptibility to typhoid fever, especially during the first three months following the operation.

Surgery.

359. Sequels of Resection of the Stomach.

M. ASCOLI (*Il Policlinico*, Sez. Chir., March 15th, 1926, p. 117), who had formerly studied the changes in the gastric chemistry after gastro-enterostomy, records his observations on the gastric chemistry of eighteen patients who had been operated on in the surgical clinic of the University of Rome. Seventeen of these had had a gastric or duodenal ulcer, and one an epithelioma of the pyloric region. The operations performed were as follows: (1) Polya-Balfour resection—7 cases, including the case of epithelioma; (2) Billroth I resection—5 cases; (3) medio-gastric resection—5 cases; (4) canceriform resection of ulcer—1 case. With the exception of one case in which the examination was made five years after the operation, all the patients were examined from twenty to twenty-five days after the operation. The results were as follows. In the Polya-Balfour resection there was

a fall of total acidity and a complete disappearance of hydrochloric acid. These changes were attributed to removal of a certain amount of gastric surface secreting hydrochloric acid and pepsin; to entrance into the stomach of the alkaline duodenal juice as shown by the presence of bile pigment; and to rapid evacuation of the contents of the stomach. In medio-gastric resection no changes worth mentioning were noted. In the Billroth I operation two distinct changes might occur, according as the absence of pyloric alkaline secretion was accompanied or not by an absence of bile and alkaline duodenal juice.

470. A. CIMINATA (*Arch. Ital. di Chir.*, January, 1926, p. 21), having determined experimentally the absorption of fats and proteins in normal dogs, has investigated the absorption in dogs which had undergone the Billroth II gastric resection, and examined the pancreas histologically. He also studied the external secretion of the pancreas after Billroth II resection by means of a permanent pancreatic fistula. The results were as follows: (1) In animals in which the Billroth II resection had been performed the capacity for absorption of fats studied up to two months after the operation was diminished compared with that of normal animals; this diminution, however, was of slight degree. (2) The same animals showed no change in their capacity for absorption of proteins. Glycosuria was never noted. (3) Animals with a permanent pancreatic fistula showed a slight diminution of the external secretion of the pancreas for a few days after Billroth II gastric resection, but subsequently the secretion increased until by the eighteenth day the normal quantity was re-established, while the lipolytic function of the pancreatic juice did not show any change. The only modification noted was that the maximum velocity of secretion was observed from the third to the fifth hour of digestion instead of at the second hour, as is found in the stage before operation and in the normal condition. (4) The histological structure of the pancreas on examination three months after the operation did not show any changes.

471. Insulin in Surgery.

V. ORATOR (*Deut. Zeit. f. Chir.*, March, 1926, p. 57), as the result of his experience of insulin in about eighty cases at the Graz University surgical clinic, comes to the following conclusions. When an operation is indicated in a diabetic patient the urine should be made as free as possible of acetone and sugar by insulin. The operation itself should be performed without a general anaesthetic, and an intravenous injection of glucose and insulin should be given at the same time. By this means the length of the starvation periods can be reduced and post-operative acidosis prevented. Apart from the general treatment of diabetes, insulin in surgery can be employed with advantage in the following conditions: (1) Convalescence from operation in greatly debilitated persons—for example, after gastric resection, prostatectomy, and nephrectomy. (2) As an intravenous injection in association with glucose for the nourishment of cachectic patients, especially when feeding by mouth, should be restricted or stopped entirely, particularly after severe gastric resection, intestinal obstruction, and perforative peritonitis. Similar experiments with insulin in inoperable conditions, such as multiple caries, tumour metastases, and septicæmia, were ineffective. Intravenous injections of insulin and glucose proved of value in acidosis following inanition, shock, and operations. Insulin was of no avail in acidosis following pancreatic diseases and uræmia. Insulin was of value in shortening the period before operation in cases of severe Graves's disease and in hastening recovery after the operation. Orator adds that insulin is not wholly without danger for subjects of severe arterio-sclerosis.

472. Treatment of Pott's Disease in Adults.

L. BÉRARD and J. CREYSSEL (*Lyon Chir.*, January-February, 1926, p. 1) discuss the treatment of spinal caries in adults by Albee's operation and indicate how the best results may be obtained with the least risk to the patient. They advise a lateral or curved incision in preference to the median incision, since thereby pressure on the scar is avoided when the patient lies in bed. A lateral graft has also proved satisfactory in their cases, and they do not consider it necessary to use the bone grafts, one on either side. The bone graft has been taken from the tibia, and this is the strongest and best graft obtainable in their experience. A general anaesthetic was always employed and the operation divided into three stages: First of all the graft is cut with an Albee saw; it should always be of good length. The patient is then placed so that he lies on his abdomen, and the spinal site is prepared to receive the bone graft. Finally, the graft is applied to the denuded bony surface. Where the spinal curvature is very marked the graft is nicked, so that it will bend and adapt itself; it is fixed in position with catgut

sutures. The patient is kept in bed for from six weeks to two months; in bad cases a longer time may be necessary. The chief complications after operation are infection of the wound, while in rare cases the graft may become loose or even fracture. The authors find, however, that most cases have a successful issue, with no untoward result, and it is exceptional to meet with any serious complication after this operation.

Therapeutics.

473. The Treatment of Diphtheria.

H. HECKSCHER (*Ugeskr. f. Læger*, February 18th and 25th, 1926, pp. 149 and 187) analyses the diphtheria statistics of the Blegdams Fever Hospital in Copenhagen during the period 1921-25, in which 4,819 cases were treated. The cases of diphtheria of the larynx without stenosis were included in this analysis, but not the cases of genuine croup. Antitoxin was given to about two-thirds of all the cases. An attempt was made to give the serum by the intravenous route as a general rule, but the choice between the intravenous and the intramuscular routes had, in practice, to depend on the size and position of the veins in the arm, the patient's condition, and the amount of the required dose. When a large dose was required, a little was given by the intravenous route and the rest by an intramuscular injection. The amount of the intravenous doses ranged from 10,300 to 42,500 units, the minimum and maximum intramuscular injections being 27,900 and 193,000 units respectively. In two cases which terminated fatally serum disease proved a dangerous complication. The mortality was the lowest on record. Of the 96 patients who died, 28 succumbed to associated conditions such as pneumonia and tuberculosis. There were 11 other patients who were moribund on admission, and who died within twenty-four hours of it. Thus there remained only 57 deaths which were due to the diphtheria, and which occurred in spite of hospital treatment—a mortality of 1.2 per cent. This low mortality was the more satisfactory as over 10 per cent. of all the cases were most severe. Discussing the possibility of further reducing the mortality, the author advocates closer co-operation between the general practitioner and the hospital, and he suggests that every patient with a pseudo-membranous sore throat and in an alarming general condition should at once be given antitoxin without the delay entailed by waiting for a report on the bacteriological examination. He adds that this rule is the more necessary as the bacteriological examination is not infrequently negative in just those cases of diphtheria which are most serious.

474. Insulin in Skin Diseases.

M. FEROND (*Le Scalpel*, March 6th, 1926, p. 221) maintains that since it has been ascertained that insulin favours, not only the metabolism of carbohydrates, but also that of fats and, probably, of some stable bodies like cholesterol, there has been to some extent a rational indication for its use in dermatology. In 1925 he had to treat six patients whose legs were almost covered by large varicose ulcers. Unexpectedly rapid benefit followed a combination of injections, compresses, and an ointment of insulin, especially in patients who were diabetic or hyperglycaemic. These results were sometimes transitory and the cases tended to relapse if the circulatory conditions were disturbed. Psoriasis is a disorder in which certain patients show a chronic excess of glucose or of cholesterol in the blood; in eighteen cases of the kind the author obtained exceptionally good progress with insulin treatment. In one case the cholesterinaemic figure was reduced from 0.24 per cent. almost to normal (0.16 per cent.).

475. Vaccine Treatment of Typhoid Fever in Children.

N. SPIROPOULOS (*Arch. de Méd. des Enf.*, March, 1926, p. 150) records his observations on 50 cases of typhoid fever in children aged from 2 to 15 years who were treated by intravenous vaccine therapy in the pediatric clinic of Athens University, an autogenous vaccine being used in the majority of cases. The results were as follows: (1) In 32 cases a single intravenous injection yielded an immediate result, shown by a gradual fall of temperature to normal and a remarkable improvement in the general condition. Convalescence was rapid in all. (2) In 12 cases a single intravenous injection produced only an encouraging result, shown by a remarkable improvement in the general condition and a shortening of the course of the disease. (3) In 4 cases the first injection had little effect, but a second injection two to four days later had a decided result. (4) In 2 cases the effect was nil. The author maintains that the reaction produced by an intravenous injection is much better tolerated in the child than in the adult, and that the earlier the vaccine is given the better are the results.

Protein Therapy in Eyo Infections.

376. H. F. SHORNEY (*Med. Journ. Australia*, February 13th, 1926, p. 177) discusses the use of protein therapy in eye diseases, and advocates the use of cow's milk injections, especially in the treatment of gonorrhoeal ophthalmia. After boiling the milk for not more than five minutes the injection is made deeply into the gluteal region in doses of 2 c.cm. for a newborn infant, 5 c.cm. for a child of 6, 8 c.cm. for a child of 10, 10 c.cm. over that age, and 15 c.cm. for adults. If there is no good reaction, as evidenced by a rise of temperature from 101° to 102°, the dose is repeated the next day but omitted on the third day, though if necessary 10 to 15 c.cm. may be given on the fourth and fifth days in severe cases. Shorney has found the routine use of milk injections in perforating wounds of the globe very useful in preventing the occurrence of sympathetic ophthalmia, and excellent results were obtained in acute inflammations of any part of the uveal tract. He states that an injection given early in wound infection after cataract extraction may avert a panophthalmitis, but that it is inadvisable to give an injection as a prophylactic after every cataract operation with a view to anticipating infection, because the resulting reaction is not good for elderly people. The injections should be given with the usual aseptic precautions and the milk should not be boiled for more than five minutes; longer boiling coagulates and changes the albumin, interfering with the resulting reaction.

Neurology and Psychology.**477. The Pupils in Somatic and Visceral Disorders.**

J. BYRNE (*Journ. Nerv. and Ment. Dis.*, February, 1926, p. 105) has previously shown that on the afferent side pupil dilatation is effected mainly by the affective (pain-bearing) system of nerves, whereas the mechanism of pupil contraction is activated mainly by the critical (proprioceptive) system. He found experimentally that after lesions of the peripheral somatic nerves such as the sciatic and the brachial plexus, true paradoxical dilatation and pseudo-paradoxical dilatation might be observed in the pupil having the closer functional relations with the injured nerves. He considers the pseudo-paradoxical phenomenon to be more clinically important than the true paradoxical form, which can only be elicited after the injection of adrenaline and a period of incubation of eight to twelve days after lesions below the umbilicus and of five to eight days after lesions above that level. The pseudo-paradoxical phenomenon has no period of incubation and may be seen within twenty-four hours after the lesion; it persists for weeks, although it may diminish or disappear during the period in which the paradoxical dilatation can be elicited. During or immediately after lesions such as moderately crushing one sciatic nerve, the contralateral may be the larger pupil, but a few hours later, when the effects of the stimulus have passed off, the contralateral will be found to be the smaller pupil if the animal be quiet and untouched. On slight excitement, however, the contralateral becomes at once the larger pupil. This is the pseudo-paradoxical phenomenon, which resembles the true paradoxical but which, in its most characteristic part (namely, the dilatation), has a mechanism altogether different from that of true paradoxical dilatation. In the instance given the diminution in size of the contralateral pupil when the animal is quiet is explained by diminished inflow of dilator impulses as the result of functional impairment, in the bodies mostly, of the primary affective neurones (axonal reaction phenomena) more seriously involved in the operative lesion, whereas the dilatation upon excitement results from overdischarge of the less seriously injured (overstimulated) primary affective neurones. In somatic or visceral disease it is often possible to elicit the dilatation component in a quiescent patient by pressure upon the diseased part. Byrne states that, in general, lesions of one lung, kidney, ovary, or testis, and unilateral lesions of such tubular viscera as the heart, great vessels, and gastrointestinal tract, induce the pseudo-paradoxical phenomenon in the homolateral pupil when the organ injured receives its afferent supply through nerves which took origin chiefly from segments above the tenth thoracic level. The phenomenon occurs in the contralateral eye where the affected organ derives its original afferent supply from nerves which mostly left the cord below that level; and this is complementary of the rule found to obtain in somatic lesions. As a localizing sign of visceral disease the pseudo-paradoxical pupil phenomenon is to be taken in conjunction with referred pain and the associated areas of referred hyperalgesia, superficial and deep, the areas of deep hyperalgesia having as much or even more significance than the areas of superficial hyperalgesia. The author instances several cases of the occurrence of this pupil phenomenon. Among the somatic lesions are: (1) Laceration of the fifth,

sixth, and seventh left cervical roots; in the painless intervals the left was the smaller pupil; during paroxysms of pain the left was dilated much more than the right. (2) Bullet wound of the right tibial nerve; the bullet was removed by operation, and for some time after the patient had intense hyperalgesia in the region of the skin distribution of the tibial nerve, during which period the left was usually the larger pupil. Two years later, when the hyperalgesia had cleared up, the left was the smaller pupil and the right foot showed marked sensory impairment. The visceral lesions include: (1) Ulcer of the anterior (left) wall of the stomach; during a paroxysm of pain the left was the larger pupil. (2) Left cystic ovary. During freedom from pain the pupils were equal or the left was slightly the smaller; pressure on the tender ovary caused both pupils to dilate, the left much more so than the right. (3) Right traumatic epididymitis; when the patient was at rest the pupils were equal or the left was slightly the smaller, but on squeezing the right epididymis the left pupil became at once the larger. (4) Cardio-aortic disease with pseudo-angina attacks; in the intervals between attacks the left was the smaller pupil, while during attacks and for a short time thereafter the left was the larger pupil.

478. Pathogenesis and Treatment of Mongolism.

J. VAS (*Jahrb. f. Kinderheilk.*, December, 1925, p. 51) states that in the out-patient department of the Budapest University children's clinic mongolian imbeciles constitute 0.05 per cent. of all the out-patient cases and 22 per cent. of all mental defectives. According to English statistics mongols form 5 per cent. of all mental defectives, and in Dutch statistics the incidence is 5.5 per cent. As, however, the English and Dutch statistics include older children and adults, and Vas's figures apply to young children only, the incidence of mongolian imbecility is probably the same in all three countries. Various causes have been suggested for the occurrence of mongolism. Probably the etiology is not identical in all cases; it embraces factors which not only exclude the development of a healthy foetus *ab ovo*, but also give rise to a number of various abnormalities in the developing organism as well as mongolism, such as congenital heart disease, congenital cataract, congenital dislocation, syndactylia, atresia, and the like. Not infrequently transitional forms are observed in which mongolism is accompanied by myxoedema or an endocrine disturbance, such as infantilism or acromegaly, in the same individual. A closer study of the mongolian syndrome also reveals the presence of endocrine changes. The hypotonus, which not only involves the limb muscles but is also generalized, suggests suprarenal hypofunction, and the hypoplasia of the genitalia indicates a hypofunction of the genital glands. As mongolism appears to be associated with endocrine disturbance, various observers have employed opotherapy and reported mental and physical improvement as the result. Pineal gland extract has been used by Dana, Berkeley, Goddard, and Cornet. Thyroid preparations by Thorstield and Stöltzner, thymus extract by Barnes, and a combined extract of pineal gland, thyroid hypophysis, and testes by Berkeley. Vas himself employed a preparation consisting of extracts of thyroid, testes, suprarenal, and pituitary for males, and thyroid, ovary, suprarenal, and pituitary for females, in doses of a half to two tablets weekly. Generally speaking, a certain progress was observed both mentally and physically. As only eight children aged from 6 months to 6 years were treated, the results could not be regarded as conclusive, but seemed sufficiently encouraging to justify a further trial.

479. Juvenile Mental Disorder.

MÖNCKMÖLLER (*Med. Klin.*, February 5th, 1926, p. 202) maintains that mental derangement in the young has increased much in the last decade, owing to the many and diverse evil influences of the war. Premising that all classifications of mental abnormality are rather artificial, he distinguishes three types—the depressive, the manic, and the indolent. Those of the first type are by nature shy children, sensitive to the sad side of life, feeling isolated even in their home circle, intelligent and proficient scholars, fond of solitary meditation. Unready in an emergency, they fail in practical matters, being haunted with the fear that some task will be required of them that they are unable to perform. They do not tend to suicide, however. As these incline to melancholia, so do the manic children to a slight chronic mania. These latter are always in excited motion, have always something to say, want to take part in everything and finish nothing. Lack of power of attention makes them fail at school, and they sleep very poorly. As they grow up they tend to be happy-go-lucky, alcoholic, and sexually uncontrolled. The children of the indolent type are dull, indifferent, and unpopular. They are unmoved by adverse school reports and do not join in games. In later life they come little into conflict with society.

Obstetrics and Gynaecology.

580.

Ovarian Malignancy.

R. F. MATTERS (*Med. Journ. Australia*, February 13th, 1926, p. 181) considers ovarian malignancy with special reference to Krukenberg tumours, and states that carcinoma in this site is generally secondary to carcinoma elsewhere, while sarcoma is usually primary. The type of carcinoma known as the Krukenberg tumour is a pure carcinoma always secondary to carcinoma of the gastro-intestinal tract or of the gall bladder. The ovary is possibly a very receptive medium for invasion of malignant cells, and therefore such cancer cells, falling into the abdominal cavity, may be more liable to produce metastatic growths in the ovaries than elsewhere. These cancer cells, being of the secreting type, are said to continue to produce secretion which distends the cells, pushing the nuclei to one side and so forming the Krukenberg "signet ring" cells. In several cases it has been shown by Sampson Handley that a primary cancer of the breast has produced secondary deposits in the ovary, the cancer cells travelling through the fascial planes to the abdominal cavity. Since it would seem that the ovary must be regarded as a possible site for metastases in abdominal malignant diseases, Matters concludes that before considering an ovarian carcinoma as primary the possibility of its being secondary to a uterine, abdominal, or breast carcinoma must be eliminated.

581.

Insufflation of the Fallopian Tubes.

P. ROMEO (*Riv. d'Ostet. e Ginecol. Prat.*, February, 1926, p. 92) is more favourably impressed with the diagnostic than the therapeutic utility of insufflation of the Fallopian tubes by Rubin's method. He records a series of 241 cases of sterility lasting three years or more after marriage; in 12 per cent. there was a history of gonorrhoea and in 7 per cent. of syphilis. Unilateral tubal obstruction was found in 8 per cent. and bilateral in 3 per cent. Within the seven months following treatment by insufflation 4.8 per cent. of the patients became pregnant, and except in two syphilitic cases went on to term. Of the remaining cases pregnancy followed in 9 per cent. within the seventh to fourteenth months after insufflation—apparently in response to medical treatment, topical applications, minor operative interventions, or opotherapy. Within the ensuing three months another 7 per cent. became pregnant. In testing tubal patency Romeo dispenses with radiographical examination, and instead of relying on locating the pain prefers to draw his diagnostic conclusions from careful bimanual examinations before insufflation and immediately afterwards, the cervix being temporarily occluded in certain cases. With regard to contraindications the author believes that there is greater risk of lighting up old pelvic inflammation in apparently spent streptococcal than in old gonorrhoeal infections.

482. Van den Bergh's Test in Pregnancy Diseases.

H. EUFINGER and C. W. BADER (*Zentralbl. f. Gynäk.*, February 27th, 1926, p. 514) have estimated by van den Bergh's test the bilirubin in the serum of 123 patients during the last months of gestation, labour, and the puerperium. They find that in normal pregnancy a direct prompt reaction is never given, but the indirect test shows somewhat increased amounts of bilirubin, reaching their highest values during labour. Applying the test to cases of pernicious vomiting, they find it to be of great value in distinguishing the organic from the functional components of the disorder. Of 20 cases of hyperemesis gravidarum 8 gave a direct prompt van den Bergh reaction and were characterized by a clinical course of great severity; the other cases quickly responded to ordinary therapeutic measures. In certain cases in which the induction of abortion appeared imperative on clinical grounds a diminution in intensity of the direct reaction was taken as justifying conservative treatment and the favourable expectations were fulfilled. In 10 cases of pregnancy nephropathy a negative reaction was invariably found, but of 15 cases of eclampsia 8 gave a positive direct reaction. All patients of the pre-eclamptic state in whom the direct test was positive were found subsequently to suffer from eclamptic convulsions in spite of treatment by rapid termination of pregnancy or by Stroganoff's method; in the overwhelming majority of other pre-eclamptic cases convulsions were avoided. The authors recommend that the van den Bergh test be performed in all cases of pregnancy toxæmia.

483. Pregnancy, Protein Shock, and Hepatic Colic.

G. PARTURIER (*Rev. de Méd.*, No. 7, 1925, p. 614) states that while pregnancy creates a predisposition for cholecystitis, and especially for cholelithiasis, gall-stone colic is rare until after delivery, when it reaches its greatest frequency in women. Of 26 women who were subject to gall-stone colic only 3, or 11.5 per cent., complained of any symptoms refer-

able to the gall bladder during pregnancy, whereas 23 of the 26 women during their pregnancy lost all symptoms suggestive of gall-stone colic, but had a recurrence of them after full-term delivery or miscarriage. Widal, Abram, and de Gennes have made similar observations in the case of asthma, and Jean Lépine in the case of epilepsy. Since 1907 Wallich has drawn attention to the peculiarly sensitive condition of women at the time of delivery, in contrast with their stability in pregnancy. He was the first to describe the condition of puerperal shock, which is characterized by a sudden onset, transient duration, profound asthenia, cold sweat, pinched expression, anticipation of imminent death, considerable fall of blood pressure, and subnormal temperature. While pregnancy entails a local immunity which prevents the uterine mucosa from undergoing its usual degeneration, as well as a general immunity to certain infections and anaphylactic shocks, gall-stone colic may be regarded as an anaphylactic phenomenon which is rare during the period of ovarian inactivity, but develops as soon as the genital gland resumes its activity after delivery. A fresh analogy is thus found between gall-stone colic and what Widal and his school have described under the name of "protein shock."

Pathology.

484. The Coagulation of Egg-yolk by a Bacterial Diastase.

E. LAGRANGE (*Ann. de l'Inst. Pasteur*, March, 1926, p. 242) relates how eggs exported from China are frequently spoiled by reason of a coagulation of the yolk which occurs on the journey to Europe. The eggs are broken and the whites separated from the yolks. The latter are beaten up and sifted, placed in metal boxes in cold storage, sometimes treated with a salt such as sodium fluoride, sodium benzoate, or sodium borate, and finally packed in barrels for export. On arrival in Europe many of them are found to be completely coagulated and to give out a sour smell. The author has shown that this coagulation is due to the proliferation of an organism which he calls *B. sinicus*. Besides secreting a diastase acting on the yolk, it forms acetic and butyric acids. To test the action of the diastase a 1 in 5 to 1 in 20 emulsion of the yolk in saline is placed in a tube, and a small quantity of a filtered broth culture of the organism is added to it. The homogeneous emulsion first becomes turbid and then commences to flocculate; small particles separate out and either collect into a surface pellicle or sink to the bottom. The liquid that remains is perfectly clear. Heating of the filtrate to 56° C., or the addition of alkali or acid, destroys the diastase or prevents its action. The effect of salts on the process of coagulation has been studied. The coagulation occurs in an oxalated medium in the entire absence of calcium in contrast with the coagulation of blood plasma or of milk. The author proposes to call this enzyme vitelase; the substance it acts on vitellogen; and the coagulated protein vitellin. The diastase acts only as a coagulant; it does not digest the egg-yolk.

485. The Spleen and Basal Metabolism.

G. C. PERACCHIA (*Arch. di Patolog. e Clin. Med.*, February, 1926, p. 53) has studied the effect of removal of the spleen in dogs on their rate of metabolism. Preliminary experiments showed that for dogs of 5 kilograms the heat loss was about 2.1 calories per kg. an hour; the variation in different animals was slight, not exceeding 5.8 per cent. Twenty animals were chosen and divided into two groups: in the first group the animals were young and their spleens were probably in full functional activity; in the second group they were old and their spleens showed signs of atrophy. Twenty days after splenectomy, when the animals had recovered, estimations showed that in the first group the basal metabolism had risen by 20 to 25 per cent.; it persisted at this level for five to six weeks and then fell very slightly. In the second group the basal metabolism rose only about 12 to 16 per cent. A similar rise after splenectomy was found in a child by Licotta. Peracchia deduces from these results that the spleen, especially when young and active, has a controlling influence on metabolism, and suggests that this action is probably due to the production of an internal secretion. It has been held by some authors that the spleen has an antagonistic action on the development of the sexual organs. Splenectomy performed in young persons may result in hypertrophy of the testicles or ovaries. The author has found that the effect of castration in dogs is to lower the basal metabolism to about the same extent as splenectomy raises it. He therefore concludes that the spleen is an endocrine gland, secreting a hormone that depresses basal metabolism and retards the development of the sexual organs.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

486. The Inheritance of Peroneal Atrophy.

MADGE T. MACKLIN and J. T. BOWMAN (*Journ. Amer. Med. Assoc.*, February 27th, 1926, p. 613) report a case of peroneal atrophy, with special reference to the hereditary factor. A man, aged 22, presented the characteristic atrophy of the peroneal and calf muscles in contrast with the normal musculature of the trunk, face, and arms. The family history through five generations showed that of 101 persons 21 were so affected, the disease not being transmitted by persons who did not have the disease either manifest or latent. From the chart of the five generations the conclusion is drawn that it is possible for a parent to transmit the disease to offspring and for the parent to die before developing it, though, had he lived long enough, the condition would have become manifest. Thus, persons in whom no signs of the disease have yet shown themselves may procreate offspring to whom they transmit the complaint. The authors state that males and females are equally affected and probably transmit equally; the presence of the disease does not appear to affect longevity. It appears that half the offspring of an affected parent are apt to be affected provided the family is large and lives long enough to develop the disease; this applies to those in whom the disease is present at the time of procreation as well as to those who have not yet developed it but who have the hereditary taint. The condition is apparently dominant to the normal and is not sex-linked. Eugenically it is pointed out that it would be better for those who belong to affected families, whether they themselves are affected or not, to refrain from having children, as this is the only way to eradicate the disease, and the mental burden will be considerably lightened for such by a clear explanation of the disease.

487. The "Fourth Disease" or Scarlatinella.

K. HOCHSINGER (*Wien. klin. Woch.*, February 4th, p. 154, and February 11th, 1926, p. 126), who states that he has seen several cases of the "fourth disease," especially during the last three years, draws the following distinctions between it and scarlet fever: (1) The onset of the fourth disease is not accompanied by vomiting or considerable gastric disturbance. (2) The facial erythema in the fourth disease is not diffuse, but consists of bright red or pink papules, which become confluent in a few hours. The circumoral and circumnasal regions are as rule free of erythema, but are never so sharply marked off from the erythematous areas as in true scarlet fever and never present an icteric tint. (3) The general involvement of the bucco-pharyngeal cavity characteristic of scarlet fever is absent, but there is only a slight redness of the palatal and tonsillar mucosa, and even this is often completely absent. During the first two days the tongue has a greyish coating, but rapidly becomes clean without showing a strawberry appearance or desquamation. Cutaneous desquamation and the characteristic late syndrome of scarlet fever, consisting in pyrexia, cervical adenitis, and nephritis, are completely absent. The eruption is always of a bright pinkish-red colour and consists of minute papules, which become thickly spread over the trunk and extremities in twenty-four to thirty-six hours, and are only of short duration, beginning to fade in forty-eight hours and disappearing completely at the end of four days. The incubation period is about a fortnight. An attack of the fourth disease confers no immunity to scarlet fever. The distinction of the fourth disease from rubella is much easier than from scarlet fever. In the first place, the enlargement of the occipital glands, which is always present in the prodromal stage of rubella, is absent in the fourth disease. Secondly, the initial catarrhal symptoms of rubella, mild as they are, are absent. Thirdly, the morbilliform appearance of the rash is absent. Hochsinger suggests substituting the term "scarlatinella" for "fourth disease" on the analogy of "varicella" and "variola."

488. The Possibility of curing Diabetes.

M. LABBÉ (*Bull. de l'Acad. de Méd.*, April 5th, 1926, p. 336) records twenty-four cases of diabetes treated for two or three years with insulin, and discusses the question whether there is yet any definite evidence that diabetes is curable, and that the islands of Langerhans can be regenerated. Of his twenty-four patients twelve had died at the end of two or three years, but this, as he points out, represents a 50 per cent. improvement on the pre-insulin days, when all such

patients died within a year or two. The deaths in his cases were due to coma in five, to emphysema and infection in three, and to pulmonary tuberculosis in four. Neglect of the insulin treatment after a temporary improvement was the cause of coma and death, particularly in the summer months when supervision of the patients was less easy. Labbé concludes that, though prolonged treatment by insulin does not arrest the progress of grave diabetes, yet it retards it considerably. In three of his cases, however, the disease appeared to be progressively overcome, the patients improved steadily and seemed to be well on the road to complete recovery. Labbé, therefore, considers that there is some indication of the possibility of diabetes being cured; he doubts whether histological regeneration of the pancreas occurs, though he agrees that evidence is accumulating that functional regeneration can be established.

489. The Paraplegic Forms of Epidemic Encephalitis.

C. REBOUL (*Thèse de Montpellier*, 1925, No. 69), who records several illustrative cases, comes to the following conclusions: Epidemic encephalitis, far from being confined to the mid-brain, may show a predilection for the spinal cord, spinal roots and nerves, thus giving rise to spinal and peripheral forms of the disease. Among the spinal forms the following clinical types may be distinguished: those resembling disseminated sclerosis, acute anterior poliomyelitis, spastic paraplegia, Landry's disease, and tabes. Peripheral involvement gives rise to radiculitis or polyneuritis, which may be confined to the lower limbs, involve all four limbs, or take on an ascending course. Lastly, in some cases the virus may act on the muscles and nerve terminals, thus creating a neuro-muscular form of the disease. The commonest forms—or, at least, those of which most examples have been recorded—are the radiculitis and polyneuritis forms. The disease usually ends in complete recovery, even when the attack appears to be particularly violent. The ascending form is the most dangerous.

490. Bradycardia due to Athletic Training.

E. KAUF (*Wien. klin. Woch.*, February 18th, 1926, p. 212) conducted experiments on athletes to ascertain the cause of the bradycardia so often seen in the trained sportsman. He examined 35 men, ranging in age from 19 to 32, who had trained for various sports (football, running, boxing, rowing) over a period of one and a half to five years. After a rest period of five minutes, the pulse frequency was counted during the next five minutes and the average rate determined. The athlete was only then informed that he was to have an injection, and 1 mg. of atropine was given subcutaneously. In 33 cases no definite increase in the pulse frequency was noticed, while the non-trained adult showed an increased frequency from 18 to 46. At a subsequent date 9 of the men were injected with 2 mg. of atropine, and rise in pulse frequency of an average of 25 (5 to 35) was noted. These experiments suggested that the bradycardia was due to increased vagus control, which could only be removed by twice the amount of atropine required to remove the vagus control in the non-trained individual. To ascertain whether the accelerator nerves to the heart played a part in this bradycardia, the author injected 1 mg. of adrenaline subcutaneously in 7 of the cases; this was followed by an increase in the pulse frequency of 5 to 30, which figures are comparable with those occurring in untrained persons. The author therefore concludes that as the accelerator mechanism is normal and that twice the amount of atropine is required to remove the vagal control, in athletes the vago-accelerator ratio is pushed towards the vagal side.

Surgery.

491. Submucous Resection of the Nasal Septum.

C. C. FOX (*Therapeutic Gazette*, January 15th, 1926, p. 6) states that the operation for submucous resection of the nasal septum is comparatively free from complications even though the structures involved are in close proximity to areas very sensitive to injury and infection. Complications may arise before the operation is begun if the patient has an idiosyncrasy towards cocaine. Fox points out that a great number of these patients are very nervous and excited and should therefore be given more consideration than is usually granted them. The incision itself is rarely likely to lead to

complications, but the elevation of the muco-perlecondrium or removal of the deflected cartilage or bone requires particular care. He states that it is quite possible to carry the dissection too far back and thus lay bare the cribriform plate of the ethmoid bone, while the elevator may even be carried through the plate. Haemorrhage is almost a negligible factor except where a blood dyscrasia is present. Infection is a more common occurrence, the organisms being carried back into the cranial cavity along the courses of nerves, blood vessels, or lymphatics, and giving rise to meningitis; the organisms most commonly found are pneumococci and streptococci. Septal abscess is not uncommon, and secondary complications of pharyngitis, tonsillitis, and ear affections may arise. In order to minimize the complications he suggests that the field of operation should be prepared by the use of nasal antisepsis for several days previously, the operation being performed under aseptic conditions. Any packing of the cavity should not be too tight or protracted. After the operation, when the packing has been removed, daily treatment with saline and oil solutions will prevent infection and assist healing.

492. Mesenteric Cyst in a Child.

P. MATHIEU (*Bull. et Mem. Soc. Nat. de Chir.*, February 13th, 1926, p. 164) records a case of a mesenteric cyst in a child aged 3 years and 6 months, treated by operation. He points out that lymphatic cysts in the mesentery of children are not uncommon, and that they are probably similar in origin to the lymphatic tumours sometimes seen in the neck. These cysts exhibit the curious characteristic that they may increase in size and then suddenly diminish in volume. Mesenteric cysts are liable to certain complications, the chief being haemorrhage into the cyst. The diagnosis is frequently difficult on account of the associated digestive disturbance, pain, and pyrexia, and if the tumour is not recognized as such a diagnosis of acute appendicitis may be made. In the case recorded the condition was diagnosed as a mesenteric or retroperitoneal cyst. Extirpation of the cyst itself is the ideal treatment, but this is often difficult or impossible because of the blood vessels of the mesentery. If the vessels are accidentally divided a resection of intestine may be inevitable. In such cases it may be safer to "marsupialize" the cyst; this, however, has the disadvantages of delayed convalescence, due to prolonged discharge and suppuration. In recorded cases, however, this appears to be the safer procedure and has a lower mortality than extirpation.

493. Fracture Dislocation of the Cervical Vertebrae.

D. GIORGACAPULO (*Zentralbl. f. Chir.*, February 27th, 1926, p. 533) describes the cases of two young men, aged 25 and 17, who dived head first into the sea and struck their heads on the sandy bottom. The first patient did not go to hospital immediately, but on the next day, as he had persistent pain in his neck, increased by movement, he went to hospital, and a skiagram showed a fracture dislocation of the arches of the fourth and fifth cervical vertebrae. He had no symptoms of compression of the spinal cord. A fixation apparatus was applied and worn for a fortnight, after which he was discharged. The second patient sustained a precisely similar injury. He was stunned at the time, but on recovering consciousness felt no pain in his neck. Next day, however, he went to hospital, where a skiagram showed a similar fracture dislocation. The same treatment was employed as in the first case.

494. Diagnosis of Ulcers of the Leg.

H. GOODMAN (*Amer. Journ. Surg.*, March, 1926, p. 63) brings forward certain points in regard to the localization of ulcers of the leg, and remarks that no attention appears to have been drawn to the importance of noting, as a point in differential diagnosis, whether the right or left limb is involved. With regard to the relations of the veins and arteries of the legs, he points out that the left common iliac vein is compressed against the fifth lumbar vertebra by the right common iliac artery; clinically, thrombophlebitis occurs in 90 per cent. of cases on the left side, while varicose veins are also more common on the left. Goodman has carefully investigated a series of 64 cases of ulcer of the leg, and states that a diagnosis of syphilitic ulcer will be correct twice out of three times if the lesion is on the lower right leg alone, and of non-syphilitic ulcer if it is on the left leg alone. In cases of ulcers of both legs the diagnosis is not possible except by a Wassermann test.

495. Early Operation for Club-foot.

H. L. ROCHER (*Gaz. hebdomadaire des Sci. Méd. de Bordeaux*, February 28th, 1926, p. 140) mentions that in equino-varus of congenital origin he used to prescribe at first massage and corrective manipulations, and fixing in the improved position by flannel bandages, or even by a splint of wood. Only when the infant

was 5 or 6 months old would he perform an operation, by which time all the adduction was already corrected and some of the supination. The operation consisted in dividing the Achilles tendon and putting the foot up in plaster. Latterly, however, it appeared to him that the bandage seemed to lessen the plasticity of the parts, and that as it was necessary to make allowances for negligence in carrying out the preliminary treatment it would be better to operate under a month old if possible. He describes a case of double club-foot in which the operation mentioned was performed on one side at 20 days and a week later on the other; the result was very good.

Therapeutics.

496. Insulin in Infantile Malnutrition.

L. FISCHER and J. L. ROGATZ (*Amer. Journ. Dis. Child.*, March, 1926, p. 363) have investigated the use of insulin in twenty-seven malnourished infants. Three types were considered. Infants with acute atrophy and intoxication and requiring an immediate effect by the quickest possible absorption to save life were treated by injections into the longitudinal sinus through the anterior fontanelle of one-third to one-half ounce of a 20 per cent. glucose solution per pound of body weight, to which had been added 15 units of insulin per 100 c.cm. of solution. In cases of atrophy in which acute intoxication had not yet set in insulin was administered with 15 per cent. glucose intraperitoneally or subcutaneously. Dystrophic babies with stationary weight were treated with insulin subcutaneously or intracutaneously in conjunction with feedings. In 63 per cent. of the cases marked gain in weight and improved nutrition resulted, and of five cases of acute atrophy with intoxication four recovered. No bad effects were observed, and in those cases reported as successful there were no changes in diet or management, other than the use of insulin combined with glucose, to which improvement could have been attributed. The authors add that repeated small doses of insulin appear to be cumulative, culminating in a rise of temperature, anorexia, and loss of weight. They think that the effectiveness of the treatment in properly selected cases in their hands renders it worthy of trial when other methods of feeding and management have failed.

497. The Indications for Acetylorthocresotinic Acid.

G. CARRIÈRE and E. GÉRARD (*Bull. Soc. de Thé.*, March 10th, 1926, p. 77) state that acetylorthocresotinic acid, which is a higher homologue of acetosalicylic acid, presents the advantage over the latter in that it does not cause any gastrointestinal disturbance or pharyngeal pain, and is not affected by the gastric juice, but becomes dissociated on contact with the intestinal juice, setting free a physiologically active orthocresotinic acid. The drug possesses undoubted antirheumatic and analgesic properties, and without being a hypnotic properly so called produces sleep. The authors' results were excellent in chronic rheumatism and neuralgia of all kinds, from toothache to sciatica. The drug was very useful in the thoracic pain of tuberculosis. The results were much less definite in the insomnia and general aching of febrile patients. Very favourable effects were obtained in migraine and asthma. The drug was employed in doses of 0.5 gram given in cachets. As a rule the effect produced lasted for seven or eight hours, after which another cachet was required. A dose of 2 grams a day is usually sufficient, but this may be considerably exceeded if necessary; as the drug is only very slightly toxic and is rapidly eliminated from the system.

498. Absorption of Atophan through the Skin.

H. HÖRSTERS and H. ROTHMANN (*Med. Klin.*, April 9th, 1926, p. 582) report that atophan is effective when given by innaction; they have tried it in chronic rheumatism and lumbago, where it was not tolerated by the stomach. They used two kinds of ointment—one with a salicylate and the other with a camphor base. Three chemical tests of the urine were made at varying periods after the application of the drug. In all cases they found that the drug was excreted three to six hours later, and that a definite improvement in the patients' condition resulted. The authors particularly emphasize the point that the ointment must be rubbed in not only over the affected part but over a considerable area of the body.

499. Colloidal Iodine in Tuberculosis of the Female Genital Organs.

E. TONEFF (*Gynéc. et Obstét.*, 1926, xiii, 3, p. 205) writes favourably of the effects of intramuscular injections of colloidal iodine in cases of abdominal tuberculosis coexisting with tuberculous disease of the female genital organs. This

treatment he believes to be preferable to laparotomy in cases with ascites, and to the performance of more or less radical operations on the adnexa; in any case the iodine treatment deserves, he thinks, trial before operation. In a number of cases reported three to sixteen injections given at two- to five-day intervals have been followed by rapid disappearance of peritoneal effusions, marked reduction in size of adnexal tumours, return of the menses, and speedy restitution of general health. The treatment is said to be contraindicated by the presence of active tuberculosis in the lungs.

500. Ammonium Tartrate in Lime Burns of the Cornea.

E. WOLFF (*Brit. Journ. Ophthalmol.*, April, 1926, p. 196) describes two cases of lime burn of the cornea treated by a 10 per cent. neutral ammonium tartrate solution with very good results. Lime burns of the cornea are usually of grave significance. The caustic effect of the lime destroys the corneal tissue, and the lime combines with the tissue of the cornea, depositing particles of calcium carbonate. It is this second element of the condition which can be so markedly improved by means of neutral ammonium tartrate solution; this converts the insoluble calcium carbonate into the more soluble calcium tartrate, which is washed away. The reaction occurs slowly, so that prolonged treatment is necessary. The cornea is washed with the solution by means of an undine for fifteen minutes daily. This treatment should be continued for some months.

501. Administration of Arsphenamine.

J. H. STOKES (*Journ. Amer. Med. Assoc.*, March 20th, 1926, p. 840) refers to the complaints made by patients receiving intravenous injections of arsphenamine and its derivatives of an unpleasant taste of garlic or an odour of ether. In some cases the discomfort amounts to pronounced nausea and precedes gastro-intestinal reaction. He has found that by allowing a wafer impregnated with oil of wintergreen or a clove to dissolve on the tongue during the injection of the drug complete relief from this symptom is obtained without unfavourable results. He suggests the use of such wafers as a routine, though he is uncertain whether the effect is due to the volatile essence or merely to the diversion of the attention of nervous patients.

Ophthalmology.

502. Cerebral Aneurysm causing Ocular Symptoms.

J. A. CONWAY (*Brit. Journ. Ophthalmol.*, February, 1926, p. 78) describes two cases of this condition; he points out that it is not so very uncommon and that it occurs quite frequently in youth. Cases of cerebral aneurysm can be divided into three groups: (1) Those in which death ensues suddenly from an apoplectic seizure without any preceding symptoms. (2) Those presenting symptoms of cerebral disturbance, which are often very slight and equivocal but are followed by an apoplectic seizure. (3) Cases in which the aneurysm was an accidental finding at a necropsy. The cases he describes were of the second group, and the ocular symptoms consisted in disturbances in the visual field. In one of the cases after great loss of field a considerable degree of recovery followed and was thought to be due to thrombosing of the aneurysm. The field losses were of the hemianopic type, though differing in the two eyes and varying from time to time. Conway adds that cerebral aneurysm is almost impossible to diagnose with certainty, and the occasional intermittent character of the symptoms is probably the most suggestive feature.

503. Retinal Haemorrhage Synchronous with Onset of Menstrual Period.

E. N. NEULEN (*Amer. Journ. Ophthalmol.*, February, 1926, p. 85) describes the case of a woman who had a central retinal haemorrhage which occurred at the onset of the menstrual period. A week previously her eyes had been examined for glasses and both fundi were found normal. The haemorrhage in the right eye eventually cleared up completely and vision was at the last examination G9. A few months after the occurrence of the retinal haemorrhage she suffered from an attack of scleritis in the left eye. Frequent attacks of scleritis occurred subsequently and an exacerbation in the scleritis was usually noticed at the menstrual period. Further examination revealed evidence of tuberculosis, and she was treated with tuberculin. The left eye slowly deteriorated during the period in which she was under observation and the cornea became nebulous. The right eye, however, remained unaffected and no further retinal haemorrhage occurred.

504. Exostosis of the Orbit.

A. KNAPP (*Arch. Ophthalmol.*, March, 1926, p. 128) describes a case of this condition in which he successfully removed the growth. It is important to distinguish between an encapsulated osteoma, which is a tumour occurring in an accessory nasal cavity and secondarily extending into the orbit, and an exostosis, which is a circumscribed new bone formation arising from the surface of the orbit. The osteoma tends to grow towards the brain, and may cause cerebral symptoms complicated by a sinusitis. An exostosis usually arises from the upper and inner orbital walls and extends outwards, displacing the eyeball. It grows slowly, and there is frequently a history of trauma; by reason of its growing outwards the prognosis for life is good. X rays afford the most definite method of diagnosis. Surgical operation is the only treatment. If the attachment is broad and hard it may be necessary to drill holes and saw the intervening parts, or to divide the normal bone around the attachment of the tumour.

505. Anomalous Duct of Lacrymal Gland.

W. P. LING (*Amer. Journ. Ophthalmol.*, January, 1926, p. 1) describes a case of anomalous duct of the lacrymal gland occurring in a Chinese boy. This boy was somewhat underdeveloped and showed some asymmetry of his face, the right side being smaller than the left. There were some pedunculated masses in front of the tragus of the right ear, and the lids of the right eye were separated at the outer canthus, the resulting intervening space being covered with skin. Immediately external to the malformed external canthus there was an oblique opening through which tears dropped. The vision of both eyes was fully normal and the conjunctiva and cornea of the right eye were unaffected in any way. This anomalous duct was excised under local anaesthesia, a complete cure of the condition resulting. Microscopically the duct was found to be lined by stratified squamous epithelium.

Obstetrics and Gynaecology.

506. Vesicular Mole and Chorion-epithelioma.

R. HUGUENIN (*Bull. Soc. d'Obstet. et de Gynecol.*, No. 2, 1926, p. 109) discusses the questions whether there is any criterion of the malignancy of a mole and whether a mole can lead to a fatal chorion-epithelioma. He points out that histologically there are two distinct types—the common form and the mole which is filled with large islets without stroma and ill defined cells with large irregular multilobular nuclei, having mitotic figures; this type appears to be definitely malignant. L. DEVERAINE and R. A. SUZOR (*ibid.*, p. 111) report two cases of patients, aged respectively 32 and 29, in whom the histological findings were regarded as definitely malignant. In the first case hysterectomy was refused by the patient, and under local expectant treatment the menorrhagia ceased and the uterus returned to its normal size. Subsequent menstruation was regular and the general health remained excellent. In the second case curetting was followed by apparent recovery; but hysterectomy was subsequently necessary for cancer of the body of the uterus. BRINDEAU (*ibid.*, p. 113) thinks that the gravity of a mole has been greatly exaggerated. Many patients subsequently became pregnant. He adds that it is often very difficult to base prognosis on histological examination. Couvelaire has reported a case in which the histological appearance of an expelled mole, together with the uterine hypertrophy and menorrhagia, led to a diagnosis of chorion-epithelioma. Hysterectomy was performed, but the tumour did not extend beyond the mucosa and there was no ulceration or sign of any metastases. Though morphologically malignant, the mole was benign in its clinical development.

507. Chronic Gonorrhoea in Women.

F. MONTUORO (*Riv. d'Obstet. e Gynecol. Prat.*, February, 1926, p. 110) points out that the diagnosis of chronic gonorrhoea in the female is difficult, yet of great importance. The history is often fallacious: frequently an acute attack is experienced without being recognized by the patient, for the urethra may escape infection, so that dysuria is lacking. The first symptom to attract attention may be leucorrhoea, but excessive vaginal discharge may pass unnoticed in a person habituated to a daily discharge. Nevertheless, in every gynaecological examination the presence of latent gonorrhoea should be borne in mind. It is important that micturition should not immediately precede the examination lest a purulent urethral discharge should escape observation. The important signs are: (1) the presence of such a discharge; (2) redness around the urethral opening, possibly accompanied by small condylomata; (3) purulent secretion from Skene's tubules and Bartholin's glands; (4) the presence of Sanger's macules near the

openings of Bartholin's ducts; (5) the association of some or all of these signs with the presence of adnexal inflammation. Microscopical detection of gonococci will clinch the diagnosis, but their absence in smears is far from conclusive. Montnoro points out that minor operative interventions in the genital organs of patients suffering from chronic gonorrhoea which has not been recognized are very apt to be followed by acute and serious pelvic inflammatory conditions which may entail prolonged illness and necessitate very careful treatment.

508.

Chorea Gravidarum.

K. V. LEHOCZKY-SEMMELWEIS (*Zentralbl. f. Gynäk.*, March 6th, 1926, p. 608) states that the prognosis of chorea in pregnancy is considerably worse than that of chorea minor, the mortality being from 17 to 25 per cent. Its origin has been described to a pregnancy toxæmia, to reflex nervous influences, and, owing to its not infrequent association with polyarthritides and endocarditis, to infection. This last view is supported by the necropsy findings reported by Schuster—namely, recent endocarditis with thrombi and haemorrhages in the central and frontal gyrus. In this case *Staphylococcus pyogenes aureus* had been found in the blood before death. A case recorded by the author is taken as supporting the infective rather than the toxic origin of chorea of pregnancy. The patient, a 2-para aged 23, suffered in the seventh month of pregnancy from severe chorea in association with fever and polyarthritides; she died two days after induction of labour, and the necropsy showed well marked perivascular infiltration (chiefly with lymphocytes and plasma cells) in the corpus striatum, optic thalamus, and substantia nigra, as well as degenerative changes in the putamen and globus pallidus, with considerable proliferation there of the neuroglia.

509.

Treatment of Carcinoma of Cervix.

H. H. BOWING (*Amer. Journ. Obstet. and Gynecol.*, March, 1926, p. 400) states that the combination of surgery, radium, and x rays in the treatment of carcinoma of the cervix is usually very effective provided that the disease is recognized sufficiently early, since at least six or eight weeks are required for the tissues to respond effectively to treatment by radium. The response to treatment is subject to individual variations, and the correct dosage can therefore only be established by experiments. He thinks that radium should be applied by the broken or fractional method rather than by the use of the destructive single dose, since the former enables the treatment to be modified according to the patient's response. With the patient in the knee-chest position and the employment of a Sims speculum and direct illumination, a silver tube applicator, containing 50 mg. of radium element, is inserted into the substance of the tumour, or into the cervical and uterine canal, and allowed to remain in position for from fourteen to twenty hours. The treatments are given about twice a week for from three to six weeks, the aim being to employ about a total of 3,000 mg. hours of radium for each 2.5 cm. depth of involved tissue. These radium treatments may be supplemented by x-ray treatments, using high voltage, with copper and aluminium filtration over the anterior, posterior, and lateral areas, one area being exposed each day until all have been treated. Bowing classifies cases into five groups, according to the location and extent of the disease. In the first group are cases with early or operable lesions in the cervix, and in the second group borderline cases with the disease limited to its vaginal surface. The third group contains the inoperable cases with the disease involving the vaginal walls, broad ligaments, and lymphatic glands, with some degree of fixation, and the fourth group includes recurrences. The fifth group is made up of cases in which previous treatment was incomplete, the disease being modified but not eradicated. The therapeutic procedures adopted vary in the different groups.

510.

Basal Metabolism during Pregnancy.

GARIPUY, LASSALLE, and SENDRAIL (*Gynéc. et Obstét.*, 1926, xlii, 3, p. 172) remark that the augmentation of basal metabolism which is well known to occur during pregnancy, attaining a maximum of about 35 per cent. towards the thirty-eighth week, has been frequently explained as due to increased activity of the thyroid gland. That it is in reality due to influences from the foetus is suggested, however, by its notable augmentation in multiple pregnancy and by its return to normal after death of the foetus in the uterus. The latter view is supported by their observations on fifteen pregnant patients showing no clinical signs of increased thyroid activity. In these the oculo-cardiac reflex was almost invariably of normal type. Little or no acceleration of the pulse occurred after intramuscular injection of 1 mg. of adrenalin, and slowing of the pulse after the intramuscular injection of 1 c.cm. of pituitary extract was exceptional.

Pathology.

511.

Bacteriology of the Common Cold.

G. S. SHIBLEY, F. M. HANGER, A. R. DOCHÉZ, and KATHERINE C. MILLS (*Journ. Exper. Med.*, March, 1926, p. 415) have studied the flora of the nose and throat of thirteen patients over periods of five to nine months, noting changes in the numbers and nature of the bacteria in health and during catarrhal and throat infections. They found that in healthy nostrils *Staphylococcus albus* and diphtheroids were almost invariably present in some patients, while in others *Staphylococcus albus* and *citreus* were the characteristic organisms. From time to time Gram-negative cocci and non-haemolytic streptococci made their appearance. In the throat Gram-negative cocci and non-haemolytic streptococci were regularly present, and in some cases large Gram-positive cocci, *B. influenzae*, and diphtheroids. Transient organisms were *Staphylococcus citreus*, *aureus*, and *albus*, pneumococci, and haemolytic streptococci. In the early stages of nasal catarrh no bacteria were found which seemed to be definitely causative; during colds the bacterial content of the nose was often reduced in the early stages, and the throat also showed reduction of numbers or change in predominance of the normal flora. Certain organisms prominent in colds but usually appearing late were *Staphylococcus aureus*, haemolytic streptococci, and *B. influenzae*; pneumococcal infections were not found in any case. Inflamed throats showed a striking incidence of streptococci of the haemolytic type, which replaced the Gram-negative cocci present in health.

512. Filterable Forms of B. typhosus in the Stools of Convalescents.

P. HAUDUROY has stated that he had found organisms closely resembling *B. typhosus* existing in water in the form of invisible filterable bodies, which, on frequent subculture, developed into the usual bacillary forms (*Epitome*, March 27th, 1926, para. 355). Arguing from this that it must have gained access to the water from the faeces of patients suffering from typhoid fever, he now reports (*C. R. Sec. de Biologie*, March 19th, 1926, p. 661) the result of examining the stools of convalescent patients after typhoid fever. A small portion of faeces was incubated in ordinary broth for twenty-four hours, filtered through a Chamberland L3 candle, and the filtrate itself incubated. At the end of two or three days as a rule the filtrate became opalescent, or sometimes showed the presence of granules. Subculture into liquid media was successful, but on solid media growth did not occur for some time. After several subcultures the colonies on solid media became more and more normal, and the organisms of which they were composed passed from a granular to a typical bacillary form. The stools of three convalescent patients from typhoid were examined in this way. From one an enterococcus was obtained, from another a Gram-negative vibrio, and from the third a bacillus that was culturally indistinguishable from *B. typhosus*, though it failed to agglutinate with specific serum. From these observations the author concludes that filter-passing forms of typhoid bacilli may be found in the stools of patients and convalescents, and that these may gain access to water, by which they may be conveyed anew to man. It is possible, therefore, that they are concerned in the etiology and the epidemiology of typhoid fever.

513.

A Test for Metabolic Variations.

R. PORAK (*Rev. de Méd.*, 1925, No. 8, p. 753) has devised a simple test to indicate changes in metabolism. The patient lives as he likes and is submitted to no restraints, but he is told to enter in a notebook everything that he does during the day. He micturates when he feels the need, and records the times of successive micturations together with the amounts of urine. With these data a curve is constructed from which the amount of urine excreted a minute can be calculated. The method is designed to give the same information as that obtained by ureteral catheterization. Having worked out the normal curve for the patient, the author then studied the effect of alterations in diet, in drink, in exercise, in exhaustion, and in other factors on the curve. In this way he was able to form an opinion on the extent to which the liver in particular was performing its work. He found that nervous exhaustion lowered the quantity of urine secreted very considerably. The effect of walking was first to increase the rate of excretion, and then to lower it. After a period of rest excretion rose again, but if the walk was such as to cause exhaustion the excretion remained low for some time, and did not regain its normal amount till after a thorough rest. If a large quantity of beer was drunk during the course of a heavy dinner the post-prandial diuresis was lowered; this the author considers to be due to retention of water in the liver. Sleep came only with difficulty, and diuresis did not set in till the early morning hours.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

514.

Fatal Asthma.

F. M. RACKEMANN (*Boston Med. and Surg. Journ.*, March 25th, 1926, p. 531) reports a fatal case of trno spasmodic asthma with the necropsy findings. The patient was a woman, aged 43, otherwise apparently in good general health; there was a previous history of attacks of hay fever between the ages of 14 and 31. Positive skin reactions were obtained to timothy grass and ragweed. After the hay fever ceased she began to have attacks of asthma, at first with long intervals between them; they subsequently increased in frequency and in severity. Death occurred during a paroxysm. Although the cutaneous tests were positive, no extrinsic cause of the asthma was determined, and seasonal variations or changes in environment did not affect the course of the malady. Clinical evidence suggested no cause of death other than asthma, and at the necropsy only acute dilatation of the right ventricle was found, with emphysematous changes in the lungs. The author refers to six deaths in asthma patients reported by Huber and Koessler, and to another fatal issue described by Lemicre. Rackemann has seen five other fatal cases of asthma, but necropsies were not performed. He adds that a bad prognosis must be given in the case of severe asthmatic attacks commencing in well nourished women more than 30 years of age if the evidence of specific sensitiveness to foreign substances is small and the condition does not respond to general treatment.

515.

Acute Aseptic Meningitis.

A. WALLGREN (*Wien. Arch. f. inn. Med.*, February 10th, 1926, p. 297) states that in the large group of diseases constituting acute meningitis a syndrome may be isolated characterized by an acute onset, definite meningeal symptoms, a sterile cerebro-spinal fluid usually showing lymphocytosis, short duration, and favourable course without any sequelae. Its occurrence is sporadic as a rule, but the presence of several cases in one place makes it probable that it is an infectious disease. As far as is known, the first epidemic of the kind occurred in France in 1910-13, and the next appearance of the disease was in Scandinavia in 1922-24. Sporadic cases have occurred in most European countries, but no examples have yet been reported from England, Germany, or the east of Europe. It appears certain that the disease of 1910-13 was identical with that of 1922-24, and as it is neither clinically nor epidemiologically possible to identify it with any known infectious disease it is most probable that these cases of meningitis were examples of a hitherto unobserved disease of the central nervous system. Whether this view is correct or otherwise will be determined by subsequent outbreaks of the disease, and the experiments on animals now in progress will contribute to the solution of the problem.

516.

Carbon Monoxide Poisoning.

D. C. WALTON, W. A. ELDRIDGE, M. S. ALLEN, and M. G. WITHERSPOON (*Arch. Intern. Med.*, March 15th, 1926, p. 398) have endeavoured to determine the relative value of the present methods of treatment of carbon monoxide poisoning. From dogs treated with pure carbon monoxide samples of blood were taken at intervals of ten minutes and the percentage of haemoglobin saturated with carbon monoxide estimated. Controls were allowed to breathe ordinary air and the others were treated through a face mask connected with rubber balloons attached to large cylinders containing the different remedial mixtures to be tested. The rate of elimination under treatment was noted for (1) oxygen only; (2) oxygen and 5 per cent. carbon dioxide; (3) oxygen and 10 per cent. carbon dioxide; (4) air and 5 per cent. carbon dioxide; and (5) air and 10 per cent. carbon dioxide. Since the period of danger in carbon monoxide asphyxia is reached when the saturation of the blood is over 30 per cent., it is necessary that the treatment used shall be capable of reducing such saturation to 25 per cent. with the greatest safety and rapidity. It was found that the rapidity of reduction by the above methods occurred in the following order: oxygen and 10 per cent. carbon dioxide; oxygen and 5 per cent. carbon dioxide; oxygen alone; air and 10 per cent. carbon dioxide; and air and 5 per cent. carbon dioxide. The first and fourth mixtures are dangerous for practical use owing to the possible overtaxing of a weakened heart by the violent respiratory efforts induced, and while there is but little difference between treatment by oxygen alone or combined with 5 per cent. carbon dioxide these are much superior

to treatment by air with 5 per cent. carbon dioxide. Since oxygen treatment is more readily available its use is advised especially where transportation is difficult, though for resene in inaccessible mines, or in military operations, treatment by air and 5 per cent. carbon dioxide should be of value.

517.

Hilum Tuberculosis.

D. ZACKS (*Journ. Amer. Med. Assoc.*, February 27th, 1926, p. 598) discusses the relative value of symptoms, physical signs, and x-ray findings in the diagnosis of bronchial gland tuberculosis based on a study of 2,285 school children, of whom 1,176 gave a positive Pirquet reaction, 1,109 being negative. Underweight for age and height was found to be the most important symptom, others being a tendency to tire easily, nervous irritability, frequent "colds," sweating, night terrors, cough, and hoarseness. In 70 per cent. of the suspected cases interseapular dullness and a feeling of resistance were present, elicited best by light percussion over comparable areas. X rays usually showed a moderately thickened hilum with shadows within this thickened area which are interpreted as being bronchial or mediastinal glands. Linear markings or beading running from the hilum into the deep parenchyma and circumscribed discrete areas of density in the lung parenchyma, interpreted as calcified or fibroid tubercle, are said to be of special significance. Zacks believes that diagnosis of hilum tuberculosis rests upon a conservative evaluation of symptoms and physical signs controlled by x-ray examination and the tuberculin test. He holds that in the presence of a positive reaction appropriate dietetic and hygienic treatment should be instituted so as to prevent the development of tuberculosis in later life. The highest percentage of reactions to the Pirquet test occurs in patients who are under weight, being 29.2 per cent. as compared with 14 per cent. when the test was applied to the whole school population of a small town. Of other signs, rales were found twice as often in the non-reactor as in the reactor group, and the same applied to cardiac murmurs.

Surgery.

518.

Total Gastrectomy.

E. SCHWARZ (*Zentralbl. f. Chir.*, March 6th, 1925, p. 578) records two cases in which this operation was performed in the Rostock University surgical clinic in 1925. (1) A woman, aged 44, had carcinomatous infiltration of the stomach, with a secondary growth in the gastro-splenic omentum. Total gastrectomy and splenectomy was performed in March. The pyloric end of the duodenum was closed and the lower end of the oesophagus fixed laterally in the jejunum by means of a triple row of sutures behind the colon. The patient's temperature fluctuated for some time and a left subphrenic abscess formed. The patient lost weight and left hospital three months after the operation. In September she was very emaciated and many intra-abdominal metastases were found. (2) A man, aged 51, had multiple carcinomatous growths in the stomach and one near the cardiac end could be palpated; there was no evidence of metastasis. Total gastrectomy was performed with closure of the pyloric end of the duodenum, and retrocolic junction of the lower end of the oesophagus with the jejunum by end-to-side anastomosis. Three rows of sutures were inserted. There was an initial loss of weight of 20 lb., but subsequently this was regained and the patient was discharged two months later. Three months subsequently his condition was still satisfactory. Schwarz estimates that in those patients who survive the operation there is a retardation of digestion of approximately 40 per cent. He has found 55 recorded cases of total gastrectomy; the immediate mortality in these was 50 per cent., but he thinks this estimate too low; it was probably nearer 70 to 80 per cent. He points out that Wrede and Ribera had a patient who lived for four years, and Moynihan's patient lived for three and a half years after the operation; a larger number were alive one year or more after total gastrectomy. Schwarz agrees that his own case is too recent for a definite conclusion, but he considers that since these patients are suffering from an inevitably fatal and frequently painful disease total gastrectomy is justifiable in suitable cases.

519.

Colonic Polyposis.

R. C. COFFEY (*Annals of Surgery*, March, 1926, p. 364) states that in no benign process is there a higher incidence of malignancy than in colonic polyposis, which results from

an antecedent inflammatory or ulcerative condition of the mucous membrane of the colon. Treatment is necessary for the haemorrhage, diarrhoea, and because of the danger of malignancy. It may be conservative, consisting in caecostomy, irrigations, or radium, or radical, which involves excision of the polyp-bearing area. A case is recorded in which excision of the colon and rectum was performed. Coffey states that in this operation it may be advisable to perform the ileostomy first as a preliminary operation and the colectomy at a later date. He finds ileostomy a satisfactory procedure and more comfortable to the patient than a colostomy. The colon is not essential to the perpetuation of life, and in the case recorded satisfactory recovery ensued.

520.

Prostatectomy.

G. CATTANEO (*Arch. Ital. di Urol.*, March, 1926, p. 293) records his observations on a hundred cases of Freyer's prostatectomy. The ages of the patients ranged from 47 to 80, the great majority being between 61 and 70. Only one case ended fatally. The clinical forms were as follows: complete retention, acute or chronic, septic or aseptic, 34 cases; chronic incomplete retention, septic or aseptic, 60 cases; incomplete septic retention with distension and ischuria paradoxa, 6 cases. In only 18 cases was the urine aseptic. In all the others the bladder was infected and several had haemorrhage due to dirty catheters, large adenomata, calculi, papillomata, or vesical diverticula. The weight of the prostates removed ranged from 5 to 60 grams and over. Cattaneo's conclusions are as follows: (1) Retention of urine is the chief indication for prostatectomy; if it is aseptic waiting is justifiable, especially if the patient can be examined periodically to determine if the retention tends to increase. (2) Septic retention, even though not severe, is an indication for operation, because no palliative treatment can cure vesical sepsis when once it is established. (3) The formal indications for prostatectomy are repeated haematuria, suspected cancerous degeneration, primary or secondary calculus formation, papillomatous growths, and diverticula of the bladder. (4) Prostatectomy should not be regarded as an emergency operation like epicystotomy, which may be performed in rare instances for checking prostatic haemorrhage. (5) The study of renal function, examination of the urine, determination of Ambard's constant, and the phenosulphonephthalein test supply important data for judging of the patient's improvement, but the estimation of the physical resistance of the individual patient from a study of the general and local conditions in each case is of greater value still. (6) Prostatectomy in most cases should be performed in two stages. The operation in one stage should be reserved for small prostates, deformity of the neck of the bladder, and lesions of the musculo-fibrous part of the prostate rather than of the adenomatous elements. (7) Injection of calcium chloride is useful for checking post-operative haemorrhage, and in about half the cases renders plugging the prostate unnecessary. (8) Anaesthesia should be local in the case of epicystotomy and epidural in prostatectomy; complete avoidance of general anaesthesia has considerably improved the statistics of operation.

521.

Spontaneous Rupture of the Oesophagus.

T. H. WILLIAMS and W. BOYD (*Surg., Gynecol. and Obstet.*, January, 1926, p. 57), who report a personal case, illustrate the rarity of this condition by the fact that only thirty-three examples have been recorded since Boerhaave reported the first case in Admiral Baron Wassenaar in 1724. Fitz states that with the exception of two cases reported by Meyer and Allan and by Grammatzki no cases have been definitely established of death having been caused by this condition. It is generally agreed that death seldom occurs apart from the condition known as oesophago-malacia, sometimes known as aleoholic oesophagitis. The present authors' patient was an alcohol addict who about six or eight years previously began to have gastric trouble. Death occurred a little less than twenty hours after the onset of an attack, which started with vomiting and intense pain in the upper part of the abdomen just below the lower end of the sternum. The necropsy, twenty-four hours after death, showed a perforation 1 inch in diameter about an inch above the diaphragm in the left side of the oesophagus leading directly into the pleural cavity, which was filled in with a dark reddish-brown fluid containing numerous particles of meat and other solid food. Histological examination of the lesion showed such extensive destruction and disintegration of the oesophageal wall that it was impossible to be certain which was the inner and which the outer coat. Experiments conducted by the authors on dogs indicated that when perforation of the oesophagus was produced in a healthy animal by a Maisonneuve urethrotome these changes did not occur. The authors conclude that spontaneous rupture of the

oesophagus is preceded by some inflammatory process which weakens the oesophageal wall, and suggest that when the diagnosis of spontaneous rupture of the oesophagus is made pleural puncture and aspiration of the exudate should be performed and followed by drainage of the infected cavity.

Therapeutics.

522.

The Use of Diuretics.

P.-E. MORHART (*La Vie Méd.*, February 12th, 1926, p. 239) states that the relative proportion of water, crystalloids, and colloids in the system is regulated not only by the kidneys, skin, and lungs, but also by the central nervous system, the endocrine system, the liver, and the tissues generally. Rest in bed promotes diuresis by hastening the excretion of water. Carbohydrates increase the retention of water, while fats diminish thirst. If no salt is added to the food the body loses 15 to 25 grams of sodium chloride and $\frac{1}{2}$ to $\frac{3}{4}$ kilograms of water; a saltless dietary is therefore itself diuretic. Generally speaking, the intake of water and salt increases the quantity of water taken up by the tissues, and consequently may cause oedema. Potassium, calcium, magnesium, and strontium have a diuretic action when combined with phosphoric or sulphuric acid, though their chlorides have the reverse. The tissue reaction is similarly concerned, acidosis producing diuresis while alkalosis inhibits it. The diuretic action of theobromine is aided by simultaneous administration of stable acids and inhibited by alkalis. Large doses of the chlorides of calcium and ammonium are diuretic because they acidify the plasma, and conversely the unstable citric and malic acids have a considerable alkalinizing power. Potassium salts, especially the acetate, bitartrate, and bicarbonate, have long been employed as diuretics. Among the endocrine glands, the thyroid has a powerful diuretic action, not only in myxoedema, but also in various types of oedema. Diminished activity of the posterior lobe of the pituitary produces excessive diuresis (diabetes insipidus), while increased activity causes retention of water. The ovaries have a similar action, and during menstruation there is usually retention of water in the system. The liver is a potent factor in diuresis, its pneumogastric nerve branches inhibiting the excretion of water in the same way as follows the injection of histamine, peptone, and, hypophyseal extracts, while stimulation of its sympathetic supply has a diuretic action, similar to that of caffeine, diuretin, and hypertonic solutions. It is very probable that the diuretic action of mercury depends upon its stimulating action on the liver. The nervous centres—cortical, mesencephalic, and medullary—also play a part in diuresis. Morhart states that the part played by the kidney is now considered generally to be subordinate to that of the tissues, although most diuretics have a definite action on the kidney. The effects of calomel are usually immediate, while those of thyroid extract are delayed. The author recommends massive doses, although he states that mercury is contraindicated in cachexia and in inflammatory conditions of the alimentary canal and of the kidneys. Purin bodies, theobromine, diuretin, and also urea, are powerfully diuretic. A high blood urea concentration does not contraindicate the administration of urea, nor are renal lesions likely to be aggravated by it as by mercury. Urea gives as good results in pleuritic effusions and tuberculous peritonitis as in portal ascites, but it may produce nausea, dyspepsia, and diarrhoea, unless given in marmalade or coffee. The author recommends that diuretic treatment should include days of abstinence from food; on certain days fluids should be withheld, and on other days sugar be given.

523.

Intravenous Administration of Emetine.

V. N. DEUSKAR (*Indian Med. Gazette*, April, 1926, p. 165) reports the results of treating seventy cases of amoebiasis with intravenous injections of emetine in 1-grain doses, for nine consecutive days, followed by an interval of about six days, during which only a morning saline aperient was given; the emetine course was then repeated. In some cases intensive bismuth medication was combined with the emetine. The case mortality was about 12.5 per cent., and the series included patients with as low a weight as 5 st. 13 lb. and as low a haemoglobin percentage as 40. Tolerance was fairly satisfactory, and no toxic symptoms occurred. The author states that if rest in bed could be rigidly enforced during treatment, this method could be safely extended to patients in private practice. He adds, as the result of necropsy findings, and in view of the fact that relapses occur in some cases, that it appears that the treatment of chronic cases by this method is no more effective than when emetine is given by other routes.

524. The Treatment of Infantile Bronchopneumonia.

L. RIBADEAU-DUMAS and J. CATHALA (*Paris Méd.*, February 26th, 1926, p. 170) consider that the principal group of bronchopneumonias in infants is of the anoxaemic type, and treatment should be directed to the anoxaemia with its attendant dyspnoea and cyanosis. They recommend as stimulants the hypodermic injection of 1/10 mg. of strychnine sulphate in 1/10 c.cm. of sterilized oil, to which may be added 1 cg. of sparteine sulphate twice a day; deep injections of 1 c.cm. of ether two, three, or four times a day are also advocated, and digitalis as a cardiac tonic. Counterirritants, such as hot baths every three or four hours, fomentations, or mustard poultices are of value. In the event of hyperpyrexia tepid baths of 95° are indicated. Wet wrapping is recommended to relieve pulmonary congestion, especially when the temperature is 103° or 104° F. In infants of 18 months or over who are not debilitated, intensive oxygenation is obtained by oxygen inhalation, in a special room or otherwise, the percentage of oxygen in such a chamber being raised from the atmospheric 21 per cent. first to 40 and then to 60 per cent. The subcutaneous injection of 150 to 300 c.cm. of pure filtered oxygen has also been found useful, and intraperitoneal injection in which the absorption of oxygen is more rapid. In another group of cases, marked by a toxic syndrome with profound asthenia, stimulants such as strychnine or ether are indicated, and the need for rehydration of the body is urgent. Transfusion from a suitable donor is said to be the best method, but failing this the repeated subcutaneous injection of 10 c.cm. of blood is recommended. Other measures include the hypodermic or intraperitoneal injection of isotonic artificial serum, glucose, Ringer's solution, or antipneumococcal serum. Weil and Dufourt have reported encouraging results from the use of a polyvalent vaccine consisting of pneumococci of types I, II, and III, and of various strains of enterococci, with *M. tetragenes* and staphylococci. The present authors inject large doses of antipneumococcal serum—40 to 80 c.cm. a day over several days—but they regard it rather as a rehydrating than as a specific agent. They add that ethylhydrocuprein (optochin) has been proved experimentally to have a remarkable selective action on the pneumococcus, but against its clinical application is its toxicity, amblyopia and amaurosis having followed its use. At present, therefore, its value is limited to those cases in which a weak solution can be brought into direct contact with the infecting organism—as, for example, in purulent pleurisy, pneumococcal conjunctivitis, and perhaps meningitis.

525. Treatment of Amoebic Dysentery.

P. MÜHLENS (*Arch. f. Schiffs- u. Tropen-Hyg.*, Bd. 29, 1925, p. 491) states that hitherto emetine, like quinine in malaria, has been regarded as the only specific for amoebic dysentery. He was at first inclined to regard yatrien (a preparation of iodo-oxy-quinoline-sulphonic acid) merely as an adjuvant, but he now considers it to be the best remedy at the present time for chronic amoebic dysentery. He thinks, moreover, that in acute amoebic dysentery yatrien is at least as effective as emetine, and finds that most cases of bacillary dysentery react promptly to it. In acute cases, of both amoebic and bacillary dysentery, the drug should be given only by mouth in doses of 0.5 or 0.8 gram four to six times a day, commencing with 0.05 or 0.1 gram. In chronic cases internal treatment is usually sufficient without employing emetine. Rectal injection is chiefly required in chronic cases in which ulcers can be found on rectal examination. A combination of internal treatment and rectal injections in doses of 1 to 2 grains by the mouth and 3 to 5 grams by the rectum is particularly efficient in old-standing amoebic dysentery. Many observers have found that a single course of treatment extending over six to ten successive days is sufficient. Most writers, however, recommend two to five subsequent courses lasting from three to six days after a week's interval between each. A strict diet is not necessary during the treatment. Another advantage of yatrien is that the simplicity of its application renders it suitable for out-patient practice.

Laryngology and Otology.

526.

Peroral Endoscopy.

L. H. CLERF (*Arch. of Otolaryngol.*, March, 1926, p. 265) comments on the recent great advances in peroral endoscopy. Bronchoscopy has been found to be of great value in the treatment of lung abscess following operation. Chevalier Jackson thinks that its efficiency is due to good drainage through the mouth by bronchoscopic aspiration rather than to medication. Bronchoscopy has also been found by Lukens and Moore to be of value in the treatment of asthma with pathological changes of the trachea and bronchi. Removal

of the secretion results in improved ciliary action, which is necessary for permanent improvement. Bronchoscopic instillation of Iliodol for the x-ray examination of the lung is considered to be the best method of introduction. Of great importance are the observations by Jackson and Lee of treatment of post-operative massive collapse of the lung. In one case thick tenacious mucus was found in the right main bronchus and the middle lobe bronchus with complete plugging of the lower lobe bronchus. The material was removed with a bronchoscopic aspiration tube and the patient made a rapid and uneventful recovery. Early diagnosis of malignant disease of the lung is necessary if there is to be any chance of cure by lobectomy, and bronchoscopy supplies the only means of diagnosis in the early stages. It enables the endoscopist to observe the typical appearance of the infiltrative type of new growth, or in an endobronchial growth tissue can be removed by bronchoscopy for pathological examination. Oesophagoscopy, the one exact diagnostic method in disease of the oesophagus, should be used in all doubtful cases; it enables the source of blood in haematemesis to be localized and facilitates early diagnosis of malignant disease. Operative treatment can be undertaken with some chance of success if the disease is discovered in time. Chevalier Jackson (*JOURNAL*, October 17th, 1925, pp. 686 and 699) has drawn attention to the value of bronchoscopy in connexion with the possible presence of foreign bodies in the air and food passages. They frequently give rise to symptoms simulating such common diseases as pneumonia, bronchitis, bronchopneumonia, empyema, abscess, bronchiectasis, tuberculosis, and asthma; x rays should always be combined with careful and repeated physical examination. A loud asthmatic wheeze is frequently present, and of great diagnostic importance in certain tracheo-bronchial foreign bodies. For the diagnosis of non-opaque foreign bodies in the trachea an elaborate x-ray technique has been devised by Manges.

527. Hearing after the Radical Mastoid Operation.

J. A. KEEN (*Journ. of Laryngol. and Otol.*, March, 1926, p. 145) has studied 60 cases of radical mastoid operation. Hearing tests were made as soon as the ear was dry after operation and again after an interval of twelve months to ascertain whether, after successful operation, the hearing remained the same. Only those cases were tested in which the cavity was completely healed and dry at the time of the first test and remained so for twelve months afterwards. The author concludes that the degree of hearing which remains is quite independent of the duration of otitis prior to the operation, provided that the bone conduction remains good. Hearing tests before operation afford no indication of the extent of post-operative hearing. With the possible exception of cholesteatoma the state of the ear at the time of operation has no bearing on the final hearing capacity. The best type of operation cavity from the point of view of hearing is a large, or moderately large, cavity lined with epithellum. Of the 60 patients of the author's series one-third heard better after a year and two-thirds heard worse; improvement probably depends upon use. In the most striking case of improvement the deaf ear had been systematically used in preference to the sound ear. The bone conduction tests varied very little, while the voice and watch tests varied within wide limits. Keen thinks that the sound of a tuning-fork placed on the mastoid reaches the cochlea by true molecular transmission through bone and that the osteo-tympanic explanation of bone conduction is not satisfactory. He adds that Helmholtz's classical explanation of sound conduction does not appear to be entirely satisfactory as it does not take into account the possibility of hearing in the absence of drum and ossicles. But it has been proved that sound vibrations reach the cochlea by other ways and in exceptional cases these unusual channels are so developed that hearing is excellent.

528. Rhinocleroma of the Pharynx.

ARGUARD and LAVAL (*Arch. Internat. de Laryngol., Otol. et Rhinol.*, December, 1925, p. 1164) describe a case of rhinocleroma occurring in the pharynx. In the cases previously reported most of the patients had lived out of Europe and particularly in Central and South America, but the cases in Austria, Hungary, Poland, and Russia may almost be classed as endemic. A man, aged 68, had, forty years ago, spent four years in the Philippine Islands. In 1923 he complained of discomfort in the throat, especially on eating or speaking, and even during quiet respiration. He had a hypertrophic and deeply ulcerated condition of the right tonsil which very closely resembled Vincent's angina; the ulceration spread on to the base of the tongue. The condition improved under local treatment. Seven months later there was a distinct relapse. The tonsil, back of the tongue, and the lingual tonsil were very swollen. The lingual tonsil and the right palatine

tonsil were removed and the fragments showed a practically normal epithelium with an abundant submucosa, beneath which was a large mass of cells. In some cases the deeper epithelial cells and the underlying mass were intermingled, and it was very difficult to say where the epithelium ceased. The main mass of cells are described as plasma cells, and among them were found certain distinctive cells. One type of these special cells (cells of Russell) appears to consist of a globule of "hyaline," probably due to degeneration of the plasma cells. A second type (cells of Mikulicz) consists of cells in which the degeneration has produced a bilocular or trilocular cell with the loculi filled with "hyaline" and the nucleus centrally placed between the loculi. These cells are epithelial cells in contrast with those of Russell. Diagnosis depends on the recognition of these special cells.

Obstetrics and Gynaecology.

529. Pseudo-neoplastic Tuberculosis of the Body of the Uterus.

ACCORDING to A. A. BABES (*La Gynéc.*, January, 1926, p. 4), tuberculous disease affects the body of the uterus not only in a military form, and an ulcer-caseous form having its primary site in the mucous membrane, but also in a hypertrophic or pseudo-neoplastic form. The last named, although well known in the cervix, has been much more rarely reported as occurring in the body of the uterus. In a case described by Babes a 6-para aged 50, who complained three years after the menopause of abdominal pain and copious fetid vaginal discharge which was sometimes haemorrhagic, was suspected to have cancer of the body of the uterus: a biopsy led, however, to the diagnosis of interstitial metritis of the body of the uterus with considerable glandular but no atypical proliferation in the endometrium. After operation the uterine enlargement was found to be due to a tumour, the size of an apple, in the posterior wall of the uterus, causing a projection within the cavity, over which the endometrium was thickened and irregular and showed numerous small vegetations. On section the myometrium was found to contain several small cavities filled with pus, and numerous caseous masses were also present; the endometrium was almost entirely replaced by well preserved tuberculous granulation tissue. In other recorded cases hyperplastic tuberculous disease of the corpus uteri has caused subperitoneal tumours simulating myomata. Babes is satisfied that the condition described originates in the myometrium.

530. Pituitary Extract in Induction of Labour.

H. HOELAND (*Zentralbl. f. Gynäk.*, March 13th, 1926, p. 662) states that in 65 per cent. of cases Stein was successful in inducing labour, which terminated usually within eighteen hours, by administering in the morning a tablespoonful of castor oil and injecting intramuscularly at hourly intervals two drops of pituitrin. Eversmann, using a similar method, has been able to reduce the average duration of labour by over 50 per cent. Calmann also has had good results, but in addition administers ether in order to diminish the painfulness of the strong uterine contractions. In about 60 per cent. of cases Hoeland has succeeded in materially shortening the second stage of labour by intramuscular injection of two drops of pituitrin at hourly intervals; English preparations are said to be more effective than German ones. In a few cases he has been able to induce labour at term by injections of pituitary extract, combined if necessary with these of quinine.

531. Elephantiasis Vulvae.

J. A. VAN DONGEN (*Nederl. Tijdschr. v. Geneesk.*, March 27th, 1926, p. 1233), who records an illustrative case in a Dutch girl, aged 13, states that elephantiasis vulvae, which is frequent in tropical countries, is extremely rare in Europe. It is an affection which occupies an intermediate position between an infection and a new growth. In some cases the surface is smooth (elephantiasis glabra), and in others, as in van Dongen's patient, it is irregular and nodular (elephantiasis tuberosa). In some the growth is of firm consistence, and in others, as in van Dongen's case, soft. The surface may be affected by suppuration, rhagades, or fissures discharging lymph, or show vesicles filled with lymph, as in the present case. The growth may reach a considerable size. On histological examination oedema of the subcutaneous tissue is usually found as well as dilated lymphatics, with or without lymphangitis or perilymphangitis. Evidence of infection may be found in the subcutaneous tissue in the form of infiltration of leucocytes. The epidermis may be thickened or thinned or even absent altogether. Giant cells and plasma

cells may be present. Elephantiasis vulvae is almost confined to adults, so that van Dongen's case is a remarkable exception. Traina and Marconi have also reported an example in a child. The cause of the condition is not always the same. Sometimes elephantiasis vulvae is due to a disturbance of the circulation of blood or lymph caused by scars, thrombosis, or enlargement of the inguinal lymphatic glands. In the tropics the condition is due to obstruction of the lymphatics by *Filaria bancrofti*. Some writers, such as Tschlenov and Veit, attribute the elephantiasis to syphilis, whereas Fargue and Massabian incriminate tuberculosis. In van Dongen's case both these causes could be excluded. The lesion was probably caused by friction of the clothing giving rise to an epithelial defect which served as a portal of entry for infection. Complete recovery followed amputation of the labia.

Pathology.

532. Interaction of Tuberculosis and Cancer.

E. CENTANNI and F. REZZESI (*Rif. Med.*, March 1st, 1926, p. 195) have performed a series of experiments on mice with a view to determining the relation between tuberculosis and cancer; the cancerous material was taken from adenocarcinomata. On the whole it appeared that the two diseases were antagonistic, and that if one was well established the other failed to develop. If a mixture of the tumour and living bacilli was used for an injection the tumour cells were injured and the implanted cells failed to develop. When living bacilli and the cell emulsion were given simultaneously, but in different parts of the body (skin and peritoneum), the tumour usually failed to develop so long as the tuberculous process was active, but sometimes started when the effect of the tuberculous injections had passed off. Living bacilli injected into the substance of a tumour already established caused some necrosis, but did not prevent the death of the animal from relapse or absorption of disintegrated products. Experiments with the injection of dead bacilli showed that they did not cause any appreciable change in the tumour. This fact suggests that the influence of the living bacilli may be due to the state of allergy which active tuberculosis excites.

533. Cholesterol Content of the Cerebro-spinal Fluid in Mental Diseases.

E. G. T. POYNTER and J. RUSSELL (*Journ. Ment. Sci.*, January, 1926, p. 62) publish the results of experiments to find out whether the amount of cholesterol found in certain mental diseases bears any relation to the destruction of brain tissue, or to changes, probably of an inflammatory nature, in the meninges. The Wassermann test and Pandey's test for proteins were performed on all the cerebro-spinal fluids, any fluids which were found to contain blood corpuscles after centrifugalization being eliminated. Using alcohol as a protein precipitant, they found that only traces of cholesterol were demonstrable in the albumin-free filtrate in cases of general paralysis showing a positive Wassermann reaction. But on extracting the protein precipitate with chloroform cholesterol was found in measurable quantities in thirty of these cases, a trace was present in six cases, and none in two. There appeared to be no relation between the amount of cholesterol present and the intensity of the Wassermann reaction, nor could any relation be discovered between the amount of cholesterol and the clinical state. No measurable amounts of cholesterol were found in the cerebro-spinal fluids in cases of dementia simplex, dementia praecox, or epilepsy with insanity.

534. The Reactions of Typhoid Vaccination.

H. J. NICHOLS and A. P. HITCHENS (*Journ. Lab. and Clin. Med.*, March, 1926, p. 517) attempt to explain why recent progress in the active immunization to diphtheria and scarlet fever has not been paralleled in the case of typhoid fever and why it is not yet possible by skin or other tests to distinguish susceptible persons from the immune. The agglutination titre of the blood is not the measure of the degree of immunity in all cases, and no true toxins have yet been isolated. The authors tabulate severe vaccination reactions under two headings—namely, immediate or anaphylactic, and late or toxic; which suggests the possibility of there being two factors in a reaction—the bacterial or allergic, and the toxic. They think that there is also a considerable non-specific element which renders the problem more difficult, but they have noted in some instances that severe reactions may be foretold by immediate skin reactions. They suggest that fractional chemical investigation of the bacilli and their derivatives, together with the experimental use of these fractions in skin tests, may be a fruitful line of research, and also that a more careful classification of the clinical reactions to typhoid vaccination is required.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

535. Pulmonary Tuberculosis following Surgical Operations.

F. BEZANÇON and A. JAQUELIN (*Paris Méd.*, March 27th, 1926, p. 233) state that adult pulmonary tuberculosis may occasionally follow an infantile infection which has been reactivated by some surgical operation. Several French writers since Vernoull (1883) have recorded cases of pulmonary tuberculosis following an operation on an old tuberculous lesion, but the present authors have seen seven cases following operations (hysterectomy, appendicectomy, or herniotomy) upon organs entirely free from tuberculous lesions. The gravity of surgical procedures in cases of active tuberculosis is generally recognized, but it is less well known that patients who are free from all signs of active tuberculosis may develop a serious or fatal attack after an ordinary surgical operation. These seven cases within the last two years show that such occurrences are not rare, although the authors have been unable to find any reference to similar cases in any recent works. They believe that some anaesthetics are more toxic than others, that administration of those which have a toxic action on the liver is most likely to be followed by pulmonary tuberculosis, and finally that systematic cut-reactions among convalescents from operations show, not infrequently, a true post-operative anergy. The authors mention 4 male patients whose ages ranged from 24 to 38; of these, 2 died shortly after operations for gunshot wounds, and the other 2 patients were still living but showed signs of advanced pulmonary tuberculosis. Of the 3 female patients (aged 19, 32, and 35 respectively) 1 died of pulmonary tuberculosis a year after a double ovariectomy and 1 died of the same disease six weeks after hysterectomy. The authors conclude that both ether and chloroform anaesthesia may be followed by pulmonary tuberculosis and that nitrous oxide is free from that risk. Spinal anaesthesia is also said to be quite safe in this respect. Ether was the anaesthetic used in 4 cases and chloroform in 3 cases.

536. The Protein Content of Toxin-Antitoxin.

E. L. BAUER and H. B. WILMER (*Journ. Amer. Med. Assoc.*, March 27th, 1926, p. 942) find that the toxin-antitoxin made in accordance with Park's technique is remarkably free from the protein element both from the clinical and from the laboratory standpoint. In a series of 100,000 children twelve contracted diphtheria either during or shortly after administration of toxin-antitoxin, and were given antitoxin with no evidence of hypersensitivity. The same was true of a hundred diphtheria contacts who had not had time to develop immunity. Bauer has kept under observation for a period of from one to five years 150,000 children, most of whom had been fully immunized with toxin-antitoxin, and found that none of them gave any marked reaction with toxin-antitoxin or showed any tendency to protein sensitivity by test six months after the injections. The authors are therefore convinced that in the use of a properly made toxin-antitoxin mixture no hypersensitivity to horse protein is developed, and that it is safe and wise to give toxin-antitoxin in asthmatic persons known to be susceptible to diphtheria. To assume that hypersensitivity is developed by toxin-antitoxin it must first be proved that hypersensitivity was not present before the administration of toxin-antitoxin, since those hypersensitive to horse protein do not react to the infinitesimal amounts of protein present in the toxin-antitoxin mixture.

537. Blister Fluid in the Serum Prophylaxis of Measles.

P. MODINOS (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, March 18th, 1926, p. 404) states that since the first introduction of serum prophylaxis in measles the method has presented the following drawbacks: (1) the difficulty in obtaining convalescents' serum, (2) the uncertainty as to whether tuberculosis, syphilis, and malaria were present in the donor or not. Modinos has recently employed blister fluid from measles convalescents in doses of 3 to 5 c.cm., as it presents the following advantages: (1) it is much easier to obtain 10 to 15 grams of serum by a blister applied to a child of 6 to 10 years of age than the same quantity by puncture of a vein. (2) Therefore anyone will submit to the application of a blister, and removal of the fluid, whereas few children readily submit to removal of a much larger quantity of whole blood. (3) The transmission of malaria is excluded, as the

plasmodium is not found in blister fluid, even during severe attacks of malaria. As regards tuberculosis and syphilis, these diseases are not only more common above the age of 20, but when occurring in children are so obvious that such subjects can be excluded at once from acting as donors.

538.

Rheumatic Aortitis.

F. BEZANÇON and M.-P. WEIL (*Ann. de Méd.*, February, 1926, p. 174) review the literature and record a personal case in a girl, aged 21, who developed her first attack of acute rheumatism at the age of 14, when the heart was not affected. The following year she had a second attack, when the existence of rheumatic endocarditis was detected. The third attack, which occurred five years later, was subacute in character, almost entirely apyrexial, and principally involved the aorta. The first part of the vessel was affected not only in the valves but in the trunk as well. The ascending portion was found on x-ray examination to be the seat of a cylindrical dilatation which was revealed clinically by a thrill and a pulsation which was most prominent in the right presteral region. There was a loud systolic murmur at the base of the heart conducted towards the outer half of the right clavicle, and a less intense diastolic murmur conducted towards the xiphoid process. The aortitis was in no way affected by salicylate treatment. Two subsequent radioscopic examinations at intervals of twenty months showed the progressive character of the aortic lesions, which were accompanied by slight though persistent pains in the joints as well as by deformities of the fingers and marked amyotrophy of the small muscles of the hands.

Surgery.

539. Median Sternotomy in Mediastinal Tumours.

H. GAUDIER (*Bull. et Mém. Soc. Nat. de Chir.*, March 6th, 1926, p. 245) has recently had occasion to try the effect of median sternotomy to relieve the pressure effects in a case of a malignant tumour arising in the mediastinum. The patient had been operated on eleven years previously for carcinoma of the breast; this was followed by a recurrence in the mediastinal glands. There was much swelling of the arm on the affected side, which presented the appearance of elephantiasis; trophic ulcers developed on the fingers, and there was also severe pain. Radiographic examination showed the presence of a large mass, probably arising in the glands in the mediastinum. Treatment by deep therapy appeared to aggravate the symptoms by giving rise to pressure effects. As the conditions were becoming intolerable it was decided to attempt a decompression operation on the mediastinum. Laryngoscopy and oesophagoscopy brought to light no paralysis or obstruction, although the patient could only swallow with difficulty. The sternum was divided in the mid-line under local anaesthesia and without difficulty. A separation of 3 cm. was obtained and the symptoms were immediately relieved. The wound was closed with drainage. The condition of the patient was much improved and she could swallow and sleep with much comfort. Deep x-ray therapy was started again and caused no trouble. The operation appears one which has definite indications in such cases and there is little risk in its performance.

540.

Gaucher's Disease.

E. H. CUSHING and A. P. STOUT (*Arch. of Surg.*, February, 1926, p. 539) remark that although Gaucher's splenomegaly has striking clinical characteristics the diagnosis has rarely been made except by the microscope. The only treatment that has found favour has been splenectomy, but little is known about the late results of this operation. In forty-nine cases which have been analysed the authors find that the symptoms usually appear in childhood; sixteen patients were over 30 years of age, and females are more often affected than males. There is marked splenic hypertrophy. One of the most striking signs is the discoloration of the skin, which becomes bronze or brownish-yellow. The blood picture shows anaemia and consistent leucopenia; no abnormal cells are present, and the coagulation time appears normal. There is also a peculiar wedge-shaped thickening of the conjunctiva yellowish in colour. The liver also enlarges and there is a definite haemorrhagic diathesis. The lymph glands are not enlarged and ascites is rare. There may be destruction of the bones and an osteoarthritis with subsequent formation

of a sequestrum. The usual medical treatment for anaemia is given; transfusions and radiotherapy have failed to arrest the disease. The authors add that enough evidence is not available as yet to show that splenectomy actually prolongs life. The general health after this operation is, however, improved and the tendency to bleed is diminished. The etiology of the disease is at present unknown.

541. Myxochondrosarcoma of the Knee.

F. FEDELI (*La Chirurgia degli Organi di Movimento*, February, 1926, p. 209) publishes a case of myxochondrosarcoma of the capsule of the knee-joint in a man aged 20; the symptoms had lasted two years. The starting-point of the disease was an injury, after which the knee slowly increased in size. There was a family history of tuberculosis, and the patient himself showed signs of a chronic affection at the left apex, probably tuberculous. The skin reaction was feebly positive. The knee was painful after prolonged standing or exercise and became swollen. There was some fluid in the joint, which was slightly flexed, and movement was very limited and painful: there was some hypertrophy of the thigh muscles on the affected side. Radiography showed some rarefaction in the femoral epiphysis. The Wassermann test was negative. The temperature of the skin over the knee was not raised, but the superficial veins were visible and dilated. There were no sinuses, and the general condition of the patient was good. The thigh was amputated in the upper third and a myxochondrosarcoma was found invading the knee-joint and destroying the articular cartilage.

542. Surgery in Diabetes.

E. S. JUDD, R. M. WILDER, and S. F. ADAMS (*Journ. Amer. Med. Assoc.*, April 10th, 1926, p. 1107) report the results of four years' experience in endeavouring to minimize the mortality rate of surgery in the presence of diabetes. Insulin was given to control glycosuria, and four days before operation a diet was prescribed containing 140 grains of carbohydrate in order to build up a reserve of glycogen and thus prevent post-operative acidosis. After the operation treatment consisted in the administration of glucose by proctoclysis until post-anaesthetic nausea had disappeared; it was then continued in the form of fruit juices and ginger ale by mouth, sufficient insulin being given in repeated doses so that at least 75 grams of glucose was metabolized every twenty-four hours, the slightest clinical evidence of acidosis being the signal for active treatment. By placing all diabetics under one service in hospital no opportunity was given for any interruptions in precise dietetic and insulin treatment both before and after operation, the purely surgical problems and the choice of anaesthetic being left to the surgeon. Ether was used in the majority of cases, but the authors think that local anaesthesia is desirable provided that it does not entail any undue prolongation of the operation. It was found that the delay in the healing of operation wounds was not greater than usual provided that the diabetes was controlled; the healing of chronic ulcers may possibly be stimulated by the direct application of insulin to the wound. The authors suggest also that diabetic patients should be referred for operation to hospitals where surgeons may be able to co-operate with physicians experienced in the treatment of diabetes.

543. Strangulated Hernia.

A. J. BELLER and R. COLP (*Arch. of Surg.*, April, 1926, p. 901) discuss the viability of the intestines in the sac in cases of strangulated hernia. In two recent cases the contents of the sac were thought viable and were replaced in the abdomen; subsequent necropsies, however, showed gangrene and peritonitis. The majority of cases of strangulation occur in the fourth to the sixth decade; this is probably due to greater straining and coughing. There is usually sharp pain and vomiting and often constipation. The authors state that operation is the only treatment and that taxis is an inheritance of preaseptic surgery. Local anaesthesia is preferable. The viability of the intestine is of prime importance. In 47 doubtful cases 14 patients subsequently died from intestinal obstruction or peritonitis. The intestines appeared viable at operation, yet there was progressive destruction of the bowel wall leading to gangrene. The patients were usually over 50 years of age, and there was sclerosis of the vessel walls. In doubtful cases most surgeons are unwilling to resect, yet in such cases the mortality might be lowered by the more radical operation. Resection need not necessarily be performed in doubtful cases; the gut can be left exposed in the wound for six to eight hours before deciding its fate. Where it is gangrenous resection and anastomosis is to be preferred to enterostomy. If obstruction has been present for some time a jejunostomy may be advisable to drain the higher bowel, and this lessens toxæmia. Early operation and local anaesthesia will lower the mortality. Jejunostomy may be useful when strangulation has lasted for more than twelve hours.

Therapeutics.

544. Atophanyl in Rheumatism.

M. BOSTLUND (*Ugeskr. f. Læger*, February 11th, 1926, p. 130) has found various rheumatic conditions, including lumbago, torticollis, and neuralgia, to react very satisfactorily to atophanyl, which is a mixture of equal parts of atophan and sodium salicylate. Each ampoule, prepared by Schering of Berlin, contains 0.5 gram of each drug, a small quantity of novocain being added. During the past eighteen months the author has given more than a hundred intravenous injections to about thirty patients with uniformly good results, which in some cases are quite dramatic. In rheumatic fever this treatment not only relieved pain, but reduced the temperature. In chronic arthritis and severe forms of sciatica he had to admit that the beneficial action of this treatment was only transitory. In only one case did he give more than one injection a day, and he found the intramuscular route too painful. The intravenous injections were, as a rule, painless; when pain did occur it passed off in a minute or two after the arm was raised. The intravenous injection should be undertaken slowly, and it is well to aspirate 5 c.cm. of blood into the syringe so as to mix it with the solution before this is introduced. L. PETERSEN (*ibid.*) recommends the intravenous injection once a day of atophanyl for various rheumatic conditions, and he supplements this treatment by giving 0.25 gram of potassium iodide and 0.25 gram of urotropine by the mouth three times a day. Under atophanyl treatment pain in the joints rapidly diminishes, tophi disappear, and the excretion of uric acid is much increased. After a daily injection has been given for five days, it is discontinued for eight days, during which massage and the administration of potassium iodide and urotropine is continued. The intravenous injections of atophanyl are then repeated, five being given, one every other day. Meanwhile the massage and the exhibition of potassium iodide and urotropine are continued. More than twenty injections should not be given. The action of the atophanyl is lasting and, in the author's opinion, is much more certain than that of colchicin preparations, the toxic effects of which are not provoked by atophanyl.

545. Acriflavine in the Treatment of Gonorrhoea.

L. FERRON and COSNIER (*Gaz. Hebdom. des Sci. Méd. de Bordeaux*, April 25th, 1926, p. 260) find that diamino-methyl-acridine hydrochlorate, termed variously trypaflavine, acriflavine, and gonaerine, is a most efficient urethral antiseptic. Whereas protargol fails to arrest the growth of cultures of the gonococci in 1 in 500 solutions, acriflavine arrests development of cultures *in vitro* when diluted to 1 in 300,000. The authors have adopted Janson and Diet's intravenous method of administering acriflavine, the usual dose being 5 c.cm. of a 1 in 50 dilution every second day. It is claimed that the drug is carried by the blood stream to the epithelium of the various periurethral glands which is inaccessible to ordinary injections. Usually there is no local or general reaction, but some patients complain of a bitter taste, constriction of the throat, and flushing of the face; transient palpitation sometimes occurs, and even vomiting. Acriflavine appears in the urine within an hour after its intravenous injection, and it continues to be eliminated for twenty-four hours. The authors give details of nine cases of urethritis; of these, one had received previous injections of silver nitrate and others had had urotropine, alkalis, and potassium permanganate injections. These patients received from nine to fifteen injections of acriflavine, the average being 12.25. The average duration of treatment was twenty-six days. Eight patients were cured; in one, after fifteen injections gonococci were still present in the pus. In addition, two patients who had severe gonococcal cystitis were cured after five injections given on alternate days. One patient with gonorrhoeal arthritis of two months' duration had had hot-air baths and the actual canter without benefit. He received eight injections of gonaerine during a period of fourteen days. After the fifth injection the pain disappeared and the swelling was diminished; the patient was able to get up and walk. After eight injections he was discharged, cured. The authors state that after more than twenty years' experience of many methods they are convinced that no other treatment can yield such excellent results.

546. Insulin-Glucose Treatment in Post-operative Vomiting.

CLAUDIA POTTER (*Anesthesia and Analgesia*, April, 1926, p. 69) reports 185 operation cases in which insulin-glucose was given as a routine measure for the purpose of estimating its value in the prevention of post-anaesthetic vomiting. From this experience, as well as from its trial in selected cases in which acidosis or surgical shock might be anticipated, and in very toxic cases, she concludes that this combination appears to

be a very potent remedy in post-anaesthetic vomiting, the best results having been obtained in cases of acidosis and toxæmia. More caution in the administration of insulin is needed in the non-diabetic than in the diabetic patient, and absorption of glucose by the rectum being uncertain, the effect of insulin requires closely watching. The glucose was given by the mouth or rectum thirty to forty minutes before operation, allowing at least 2 grams of sugar for each unit of insulin when given by the mouth and 3 grams when given by the rectum. Five units of insulin were injected hypodermically twenty to thirty minutes after giving glucose by mouth, and forty to fifty minutes when given by rectum. In severe cases needing glucose intravenously 10 units of insulin were given about ten minutes later, but it is stated that this method is not advisable unless vomiting is persistent and fails to yield to the use of insulin with glucose by mouth or rectum.

Anaesthetics.

537. Anaesthesia for Upper Abdominal Operations.

J. T. MASON (*Annals of Surg.*, April, 1926, p. 453) compares the post-operative conditions following local and general anaesthesia in 100 consecutive upper abdominal operations, 50 being performed under ether and 50 under local or local and gas anaesthesia; all were performed by the same surgeon in the same hospital and with the same surgical and nursing staffs. It was found that general anaesthesia produced considerably more effect upon the kidney, liver, and lung tissues than was the case with local anaesthesia. General anaesthesia was induced by nitrous oxide gas and oxygen and continued with open ether; local anaesthesia was induced by infiltrating the anterior abdominal wall, followed by anterior splanchnic block, with a 0.5 per cent. solution of procaine in 0.6 per cent. sodium chloride with nine drops of adrenaline chloride added to each 100 c.cm. Mason states that individual sensitiveness to pain and apprehension are important factors in determining the success or otherwise of a local anaesthetic and that it is important to ensure rest, sleep, and a high glycogen reserve; a narcotic should be administered one hour before operation. Under local anaesthesia the average duration of operations was eight minutes longer than for those under general anaesthesia, but the temperature remained lower and the average stay in hospital was three days less. Vomiting occurred in 18 of the local anaesthetic cases as against 33 under general anaesthetics; in the latter it was more marked and persistent. In no case of local anaesthesia was there any sign of shock.

538. Ethylene as an Anaesthetic.

C. L. HEWER (*Brit. Journ. Anaesthesia*, April, 1926, p. 174) reviews the present position of ethylene as an anaesthetic, and concludes that it possesses advantages in certain cases and especially for operations of medium severity lasting for a considerable time. A satisfactory degree of anaesthesia can usually be obtained with a mixture of 80 per cent. ethylene and 20 per cent. oxygen, and, provided the oxygen is not cut down unduly, the changes in blood pressure, pulse rate, and respiration are negligible. Since more oxygen can be given with it than with nitrous oxide it is useful in quite young children and patients classed as "bad risks"; the ethylene-oxygen combination appears to have less effect upon the blood sugar than any other of the general anaesthetics except the mixture of pure nitrous oxide and oxygen. Its elimination is rapid and it is rare for the patient to vomit more than once, while post-anaesthetic acidosis and pulmonary complications are not greater than those following local anaesthesia. It is contraindicated in operations involving the use of naked flames or the cautery near the face, and in x-ray examinations on account of its explosiveness when mixed with more than 40 per cent. oxygen or between 75 and 95 per cent. air; among its drawbacks are its odour and the impossibility of obtaining absolute muscular relaxation; but in an average case it affords a method of rapid and pleasant induction with moderate relaxation without cyanosis, and a quick recovery with few after-effects. Hower considers that its advantages in certain cases are not possessed by any other anaesthetic agent.

539. Nitrous Oxide Anaesthesia.

E. DESMAREST (*Presse Méd.*, April 14th, 1926, p. 465) recommends nitrous oxide as the safest anaesthetic in serious cases, such as in anaemia, diabetes, severe infections, or toxæmia, as well as for patients suffering from chronic bronchitis and emphysema, with or without cardiac dilatation. The author has employed nitrous oxide in excision of the rectum and Wertheim's operation, as well as in less severe intraperitoneal operations, with complete success and without any subsequent ill effect. Desmarest employs ether in conjunction with

nitrous oxide in many abdominal operations in order to lessen the foreboding and deep inspirations which the latter induces. On account of its safety and absence of after-effects it is particularly suitable for relief of pain during the removal of gauze drains in such conditions as echinocystomy and vaginal drainage. Anaesthesia is rapidly induced and the gauze can then be removed quite painlessly, even when very adherent; similarly, it is of great assistance in the dressing of painful wounds and lacerations. Although nitrous oxide is the safest anaesthetic it requires special skill to the anaesthetist and great patience in the surgeon. The deep and forcible respiration often inconveniences the operator, while the partial asphyxiation increases the bleeding from the wound; consequently a larger number of bleeding vessels have to be secured than is usual under other anaesthetics. Desmarest has discovered that during nitrous oxide anaesthesia and for half an hour afterwards the coagulability of the blood is almost abolished; post-operative haematoma is therefore not uncommon. Post-anaesthetic vomiting is not uncommon after nitrous oxide, but it is usually controlled by ordinary methods. Desmarest has had only one death. During the performance of a gastro-enterostomy for duodenal ulcer in a man, aged 45, there was practically no bleeding from the incisions, and the author thinks that this exsanguine condition should have warned him of the impending heart failure. This was probably due to myocardial degeneration following an attack of enteric fever two years previously.

550. De-etherization with Carbon Dioxide.

ETHEL RIGHETTI (*Anesthesia and Analgesia*, February, 1926, p. 8) states that the normal carbon dioxide tension in the blood is about 40 mm. Hg; any increase produces hyperpnoea and a decrease produces apnoea. The inhalation of this gas combats respiratory depression, especially when due to anaesthesia. It has been found that after ether anaesthesia 50 per cent. of the ether content of the blood is eliminated in the first half-hour and the bulk of the remainder in from one to two hours, although traces may remain in the blood for two or three days. Even light anaesthesia usually depresses the respiration, especially if a preliminary hypodermic injection of morphine has been given. The elimination of ether from the blood can be accelerated by inhalation of carbon dioxide, which increases the respiratory rate and volume. Consciousness is usually restored in a few minutes after the cessation of the anaesthetic by administration of the gas, which is given usually for five minutes; stimulation is almost instantaneous, the face flushes, and respiration becomes deep and rapid. The author has used it in forty-six cases, and adds that the rapid return to consciousness relieves depression and lessens nausea and vomiting. She thinks that it undoubtedly prevents inhalation pneumonia by relieving the partial atelectasis of the lower lobes, which occurs in prolonged abdominal operations, and suggests that an emergency supply of carbon dioxide in the operating theatre is of more value than a cylinder of oxygen.

Obstetrics and Gynaecology.

551. Intraperitoneal Bleeding from Uterine Chorion-Epithelioma.

W. L. BUTOMO (*Zentralbl. f. Gynäk.*, April 10th, 1926, p. 1034) records the case of a woman aged 23 who, after curetting of a two months' abortion, suffered from menorrhagia with gradually increasing haemorrhage, which became continuous six months later. The bleeding was arrested by a second curetting, but the patient had repeated syncopal crises and became extremely anaemic. Examination showed a retro-uterine haematocoele, and an operation was performed for a supposed ruptured ectopic gestation. The haemorrhage was found to have come from a small tear in the posterior wall of the fundus, which was almost entirely replaced by a new growth, shown microscopically to be a chorion-epithelioma and containing abundant syncytial tissue but few Langhans's cells. The author has collected nine cases of intraperitoneal bleeding due to a similar cause: the pre-operative diagnosis was invariably ectopic pregnancy. One patient died before, and three (as also the author's patient) immediately after, the operation. In three cases, although very extensive new growth was present, the intraperitoneal bleeding was the sole symptom.

552. Functional Uterine Haemorrhage.

E. NOVAK (*Journ. Amer. Med. Assoc.*, April 10th, 1926, p. 1105) urges the importance of diagnostic curetting in the treatment of functional uterine haemorrhage of sufficient severity to cause concern, as in no other way can its cause be ascertained and uterine carcinoma excluded. In many cases curettago affords a permanent cure, though in more than half the

symptoms may recur. Daily injections of 1 c.cm. posterior pituitary extract appear to give better results than the administration of thyroid or ovarian extract, though this may be due to its action on the uterine muscle rather than to any endocrine effects. When bleeding recurs even after thorough curettage repetition of this procedure at intervals may be the best treatment in young women, since the possibility of future child-bearing has to be considered. Though careful radiotherapy will generally relieve the symptoms without any ill effects, it has to be borne in mind that there is some attendant risk to the ovaries, and many gynaecologists hesitate to resort to its use unless other measures fail. Novak advises placing the facts before the patient and her friends, and his experience is that most young women will select repetition of curettage rather than the slight uncertainty of the results of radium. In uncomplicated cases about the menopause radium therapy is, he thinks, the ideal course to adopt, hysterectomy being reserved for those cases in which there is some associated lesion necessitating laparotomy.

553. Axillary Prolongation of the Breast.

C. H. FOUCHE (*South African Med. Record*, April 10th, 1926, p. 154) describes the occurrence of an abnormally large "axillary tail" of the breast in a primipara, aged 22. Three days after delivery a painful lump appeared in the right axilla, concurrently with engorgement and pain in both breasts. On the next day the lump increased in size and a second swelling appeared between it and the upper lateral quadrant of the breast. With the establishment of the secretion of milk on the next day both swellings became less painful and softer. It was then possible to trace a broad, mobile, flattened band of breast tissue, extending from the upper lateral quadrant of the breast along the lower and outer margin of the pectoralis major into the axilla; it was incorporated with both swellings, which had the feel and consistency of breast tissue. A much smaller lump was found in connexion with the breast of the opposite side, but this caused no pain or discomfort. The author comments on this condition, termed the "axillary tail of Spence," and indicates the lines of differential diagnosis. He draws attention to the theoretical possibility of such an abnormally situated portion of mammary tissue becoming malignant, and raises the question of the desirability of its excision.

554. Pelvic Examination during Labour.

P. BAUMM (*Zentralbl. f. Gynäk.*, April 3rd, 1926, p. 846), as the result of an analysis of 854 consecutive cases of labour, finds that a vaginal or rectal examination is required in only 8 per cent. It is necessary, however, when the head fails to become engaged at the pelvic brim and there is reason to fear prolapse of the cord, when the presentation is uncertain, when the pelvic diameters and anatomical relations have not been determined previously, when the foetal heart sounds are feeble, in haemorrhage, and in abortion between the sixth and seventh months. Among forty-one cases in which the head was unduly mobile prolapse of the cord occurred seven times. Twice this accident was recognized by rectal examination, in the remaining five cases by subsequent vaginal examination. In nineteen cases the presentation could not be determined by external examination; the presentations were either of the head or breech in the majority of cases. In eight of these rectal examination sufficed, but in the remaining eleven cases subsequent vaginal examination was required. Rectal examination was sufficient in two cases that required pelvic exploration; in a third case subsequent vaginal examination was necessary. In eight cases of haemorrhage due to placenta praevia rectal examination failed; it also proved useless in the two cases of abortion. Baumm adds that rectal examination yielded negative or incorrect results in 26.7 per cent. of all cases. The results were incomplete and somewhat misleading in 55 per cent., and in only 17.7 per cent. was a correct diagnosis made after rectal examination alone.

Pathology.

555. Filterable Forms of Tubercle Bacilli.

A. FESSLER (*Zentralbl. f. Bakt.*, April 1st, 1926, p. 148) has examined the evidence on which French workers have concluded that there exist filterable forms of tubercle bacilli, and has made a series of experiments himself in an endeavour to confirm their results. He used eleven strains of tubercle bacilli of human, bovine, and avian varieties. Cultures varying from one to four months old were ground up thoroughly in broth and filtered through a Chamberland L3 candle. The filtrate was mixed with a liquid medium, such as glycerin broth or potato broth, and incubated at 38°C. In two cases there appeared a turbidity in the tubes after three

weeks, and on microscopical examination a number of threads were found, dotted with small granules; none, however, were acid-fast. The conclusion that these threads were bacterial forms was falsified by the discovery that a turbidity was also present in uninoculated tubes of medium which had stood in the incubator for some weeks; microscopical examination showed similar thread forms. It appeared, therefore, that these bodies were the result of precipitation of the peptone. Animals inoculated with them remained well. Further experiments were undertaken to ascertain if the filtrates of cultures of tubercle bacilli or of tuberculous pus were pathogenic to animals; with one exception all the results were negative. In the isolated instance one guinea-pig which had been injected intraperitoneally with the filtrate of a human culture died about three months later, and at autopsy a tuberculous condition of the lungs and tracheo-bronchial glands was found. That this had nothing to do with the injection but was due to an aerogenic infection was evident from the distribution of the lesions and from the fact that another guinea-pig injected intravenously with the same filtrate remained perfectly well. Fessler's general conclusions are that the evidence in favour of there being filterable forms of tubercle bacilli is so far quite insufficient and that the results of the French workers are perhaps due to faulty technique.

556. Sedimentation Rate of Red Blood Cells.

H. N. COOPER (*Journ. Lab. and Clin. Med.*, April, 1926, p. 615) has studied the rate of sedimentation of the red blood cells in a number of different diseases. The method he uses is to withdraw about 10 c.cm. of the patient's blood, mix it in a bottle with the residue left by the evaporation of three drops of 20 per cent. potassium oxalate solution, and to deliver 5 c.cm. into a graduated test tube. The tube is placed in a rack, and readings are taken of the level to which the cells have settled after periods of 5, 10, 15, 30, 45, and 60 minutes. The results are plotted on a graph in which the ordinates represent the height of the column of cells and the abscissae the time in minutes. In the normal person the height of the cell column after one hour varies from 2.5 to 4.5 cm. In acute inflammation there is an acceleration in the rate of deposit, apparently coincident with the rise in the number of leucocytes. A rapid rate of deposit therefore signifies a high leucocytosis and is of good prognosis. In tuberculosis, both pulmonary and non-pulmonary, the rate of sedimentation varies with the activity of the disease and the general condition of the patient. In the early stages the rate is little altered; later on it increases. The worse the involvement, the faster is the fall in the level of the cells. Cases that are recovering show a normal rate. In pregnancy the rate of sedimentation increases; the test has been used to distinguish this condition from myomata of the uterus. In one case examined by the author in which pregnancy was associated with eclampsia and acute nephritis the fall of the cells was extremely rapid. The sedimentation rate, however, diminished a week before her non-protein nitrogen began to fall, and was thus of prognostic value in her recovery. Lastly, in malignant conditions the rate of sedimentation is increased, apparently in relation to the degree at which the tumour is advancing. It will be seen that the sedimentation rate is increased in diseases attended by tissue degeneration and destruction. The increased rate is said to be dependent on an increase of cholesterol, globulin, and fibrinogen, in the blood.

557. Liver Function Tests.

S. S. BERGER, M. B. COHEN, and J. J. SELMAN (*Journ. Amer. Med. Assoc.*, April 10th, 1926, p. 1114) report the results of a comparative study of five methods of testing the liver function in a hundred clinical cases. The tests, performed simultaneously or within forty-eight hours of each other, were the van den Bergh test, the Widai test (haemoclastic crisis), Rosenthal's test, the examination of the urine for urobilin (Schlesinger's method) and urobilinogen (Ehrlich's reagent), and the Hay test for bile salts. The authors state that since these tests represent different liver functions, any one of which may be impaired, they do not give parallel results. It was found that when all the tests were positive liver disease of a clinically severe type with toxic jaundice was indicated; when four were positive and one negative clinical liver disease of a chronic type, such as that in Banti's disease, pernicious anaemia, or cirrhosis was present. In every case in which all the tests, except the Widai, were positive there was obstructive jaundice due to tumour, a finding of considerable value in differential diagnosis. When only three of the tests were positive it was impossible to correlate the findings with the clinical picture. The authors consider that the tests are of value chiefly in differential diagnosis, and in following the progress of a given case; they afford the greatest amount of information when they are all performed simultaneously and repeated often.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

558. Measles complicated by Gangrene of the Legs.

D. J. HISHON and J. D. ROLLESTON (*Brit. Journ. Child. Dis.*, January-March, 1926, p. 47) report the case of a male infant, aged 16 months, suffering from measles complicated by bronchopneumonia, who developed dry gangrene of both legs ten days after the onset. Death occurred five days later. At the necropsy both superficial femoral and popliteal arteries were found to contain ante-mortem blood-clots throughout their entire length. An infarct was present in the left kidney and a larger vegetation occupied the upper surface of the anterior aortic valve. Rolleston, who has collected eleven other cases from the literature, remarks that gangrene of one or more limbs, which is a very rare complication of an acute infectious disease, is one of the most interesting, as it appears alike to the physician, surgeon, and medical historian. Gangrene of the limbs occurring in fevers is mentioned by Hippocrates, and recovery of patients in the Plague of Athens, after loss of their hands, feet, and genitals, is recorded by Thucydides. Of the twelve cases of gangrene of the limbs following measles, all but two occurred in children aged from 11 months to 13 years. Six were males, five were females, and in one the sex was not recorded. In all but Mum's case, in which the hand was involved, one or both lower extremities were affected. Five recovered, five died, and in two the issue is not recorded. Operation was performed in six cases, four of which recovered, one died, and in one the result is not stated. The attack of measles was severe in all, and in five the presence of bronchopneumonia was noted. Although gangrene of the extremities as a sequel of an acute infectious disease is usually attributed to an antechthonous thrombosis due to acute arteritis, in the present case the origin of the gangrene was undoubtedly embolic, in view of the definite cardiac lesion and the infarct in the kidney.

559. Anaphylaxis following Administration of Serum.

C. A. STEWART (*Journ. Amer. Med. Assoc.*, January 9th, 1926, p. 113) has recently met with seven instances of anaphylactic reactions after administration of serum in children who had previously been immunized by toxin-antitoxin against diphtheria. The first case occurred after prophylactic injection of tetanus antitoxin in a child who had been given toxin-antitoxin one year previously, five others followed prophylactic injection of scarlet fever anti-streptococcus serum in children who had been immunized from eight to eleven months previously, and the seventh followed therapeutic injection of diphtheria antitoxin in a child who had received toxin-antitoxin three months previously. Although no deaths occurred, Stewart considers that the reactions should serve as a warning to use care in the administration of serums derived from horses in children who have been previously sensitized by injection of toxin-antitoxin. Larson has recently introduced a method of immunization against diphtheria without serum (*Epitome*, October 31st, 1925, para. 382), and Stewart thinks that the perfection and standardization of this method will prove a distinct contribution to medical science.

560. Alcohol and the Expectation of Life.

K. A. HEIBERG (*Ugeskr. f. Læger*, March 11th, 1926, p. 251) traces the influence of alcohol restrictions, adopted in Denmark during the war, on the death rate in Copenhagen, and states that in 1917 the death rate among men in the ten-year age group 45 to 54 was only 14 per 1,000, whereas in the period 1910-14 it was 19 per 1,000 in the same age group. With regard to the objection that this decline in the death rate might largely be due to abstemiousness in feeding enforced by the war, he explains that the food rationing implied a change rather than a reduction in the dietary of the Dane, and that in the same period and age group there was no decline in the death rate for women, who, on the other hand, were not so addicted to alcohol as the men. Statistics are also quoted by the author showing that, whereas the death rate is considerably higher in the males than in the females of most age groups, this difference has been greatly reduced of late within certain age groups. Thus, in the period 1903-07, the death rate for the age group 26 to 35 was 39 per cent. higher for males than for females. In the period 1923-24 this difference was completely wiped out for the same age group. Again, in the next ten-year age group, 36 to 45, the excess of the male over the female death

rate declined from 61 to 16 per cent. In the third ten-year age group, 46 to 55, there was a fall from 80 to 11 per cent. In the excess of the male over the female death rate. It is pointed out that the age group under review—that is, 26 to 55—is the one in which indulgence in alcohol by men is most common.

561. Spirochaetosis Icterohaemorrhagica and Paratyphoid Bacillaemia.

F. VIDAL and R. J. WEISSENBACH (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, March 18th, 1926, p. 434) report a case, in a boy aged 15, who developed a febrile jaundice of sudden onset with slight epistaxis, but no other haemorrhages. On the fifteenth day the temperature, which had been normal for over a week, rose again suddenly to 104°, and the patient complained of violent headache, without, however, showing any other meningeal signs. There were two subsequent recurrences of fever. The case was therefore a typical one of relapsing jaundice with a well developed febrile infective syndrome and abortive haemorrhagic manifestations. Laboratory examination showed the spirochaetal origin of the jaundice, and examination of the blood and urine showed the coexistence of an organism somewhat resembling *B. paratyphosus* A, but more closely allied to *B. paratyphosus* B. The presence of this organism did not aggravate the disease, as there was no typhoid state, and no rose spots, diarrhoea, or intestinal symptoms.

Surgery.

562. Tuberculosis of the Caecum.

J. W. LARIMORE and A. O. FISHER (*Annals of Surgery*, April, 1926, p. 496) find that primary tuberculosis of the intestine in the adult is comparatively rare; secondary to lung infection it is found in 60 to 90 per cent. of cases ending fatally. The ileo-caecal segment is the usual portion of the intestine affected. Caecal tuberculosis occurs in three pathological forms—fibrous, necrotic, and hyperplastic. The clinical symptoms of the primary type are not conclusive at first, but are chiefly those of partial obstruction. Tenderness and a palpable mass are usually late occurrences, as is also diarrhoea. Early diagnosis is essential for surgical treatment, and x-ray observations show alterations of the intestinal contour by filling defects, spasms, and disturbances of alimentary motility. In the secondary form an unfavourable prognosis is usually given. There appears to be no better treatment than the surgical. The authors report five cases operated on with four deaths. Surgical treatment in the hyperplastic form of intestinal tuberculosis is usually favourable, in contrast with the ulcerative type; this differs markedly from the secondary type associated with pulmonary lesions. In cases of resection the lower three or four inches of the ileum are included and after mobilization the part is brought out of the abdomen; the ileum is usually anastomosed to the transverse colon. The cases with extensive pulmonary disease were relieved; without operation their condition would have been hopeless. The authors conclude that in selected cases surgery is justifiable; with x-ray examinations such cases may be detected and the extent of the lesion determined.

563. Infectious Muscular Erosion.

M. WOLFSON and LL. BRYAN (*Boston Med. and Surg. Journ.*, April 1st, 1926, p. 586) record a case of infectious muscular erosion causing hernia of the large bowel in the lumbar region, and remark that the case is instructive, showing to what an undiagnosed appendix abscess may lead. A married woman, aged 38, was admitted to hospital complaining of pain in the right lower abdomen accompanied by a low-grade septic temperature. There was a history of Caesarean section seven years previously, and successful haemorrhoidectomy, trachelorrhaphy, and anterior and posterior colpoplasty a month ago. The x-ray examination and blood and urine analyses were negative, and she was discharged on a diagnosis of hysteria with post-operative adhesions. On two subsequent occasions she was readmitted with practically the same symptoms, together with a pain over the lower right lumbar region and an extremely hypersensitive area over the right iliac crest. Nine months later a tender swollen mass was detected in the right lumbar region extending from the right mid-axillary line to the spine, and a deep-seated abscess in

the lumbar muscles and under the iliac crest was opened, the discharge from which contained Gram-negative intercellular diplococci. Two months later an x-ray examination of the spine and pelvis was negative. The abscess recurred three times during the following nine months and for the next three years the patient was in poor health, and stated that the mass over the right hip frequently became prominent and subsided without treatment. On palpation slight pressure would cause it to disappear, only to return immediately on release and especially on coughing or straining. On x-ray examination with an opaque meal the ascending colon and caecum were found to extend through the lumbar muscles posteriorly into a large hernial sac, which was found at operation covered by a flap of fascia which had been eroded through by the old abscess. The sac was dissected down to the hernial opening over the right iliac crest, where the remains of an old perforated retrocaecal appendix were found, at the tip of which was a walled-off abscess the size of a walnut. The hernial opening was closed and the patient made an uneventful recovery.

564. Restoration of Ruptured Anterior Crucial Ligament.

G. PERTHES (*Zentralbl. f. Chir.*, April 3rd, 1926, p. 866) describes the various methods that have been employed for the repair of the anterior crucial ligament. In the period 1913-25 there have been 8 cases of rupture of the crucial ligaments admitted to the Tübingen Klinik; all were verified by operation. In 6 of these cases the anterior crucial ligament was involved; in 1 case the posterior ligament, and in 1 case both ligaments were ruptured. Perthes uses a vortical curved incision, commencing in the mid-line, 3 inches above the patella, carried outwards over the external femoral condyle, and then downwards and inwards to the tibial tuberosity; the quadriceps tendon, patella, and ligamentum patellae are all divided vertically. By this method the intercondylar fossa is fully exposed. The torn ends of the ligament are freshened and approximated by means of a thin aluminium-bronze wire passed transversely through the tibial portion of the ligament, and then through two canals bored through the external condyle at the site of the insertion of the anterior crucial ligament, the lower openings of these canals being 1 cm. apart. The two ends of the wire are drawn taut, thus approximating the freshened surfaces of the ruptured ligament, and are then twisted together over the outer surface of the external femoral condyle. The synovial sac is closed with catgut sutures and the two halves of the patella are approximated with tendon and silk sutures, the soft tissues are sutured in layers, and the joint immobilized in plaster splints for three weeks. Perthes has also performed Groves's operation—passing a strip of the ilio-tibial band through canals traversing the external condyle and the head of the tibia. The patient was a woman, aged 22; she had ruptured the right anterior crucial ligament four years previously. The operation was quite successful, but four months later she felt severe pains in her right knee, and the abnormal mobility of the joint returned. Perthes believes that the recurrence was due to atrophy and partial absorption of the fascial strip.

555. The Diagnosis of Lipomata.

AUVRAY (*Bull. et Mém. Soc. Nat. de Chir.*, March 27th, 1926, p. 328), in describing a somewhat rare case of lipoma of the palm of the hand, emphasizes the difficulty of diagnosis from tuberculous teno-synovitis, a condition which is comparatively common. Fluctuating tumours also closely simulate lipomata in some situations and their diagnosis may be difficult. When a bag of ice is placed over a lipoma the tumour hardens under the effect of the cold; it is the only tumour which is so affected. In a case Auvray demonstrated, of a patient with a tumour in the thigh, all who examined it thought it was a lipoma. It did not harden after the application of cold, and an operation showed it to be a tuberculous abscess, thus confirming the test. The cooling brought about by the evaporation of ether over a lipoma produces a similar effect. This procedure, which is extremely simple and little known, is said to be a sure means of diagnosis when any uncertainty exists.

565. Periarterial Sympathectomy in Surgical Tuberculosis.

G. ICHOK (*Presse Méd.*, April 7th, 1926, p. 435) collates recent reports on the treatment of tuberculosis of the bones and joints by periarterial sympathectomy, which causes dilatation of the vessels and a local hyperaemia as in the Bier treatment. Favourable reports have been reported by Gundermann, Lâwen, and Cotte, but Peitri and Sebestyén have not obtained any benefit by treating the nerves. Ichok thinks that the reports published so far indicate that the method has been useful in some cases and is worth further trial.

Therapeutics.

557-

Treatment of Pelvic Inflammation.

J. A. MCGILINN (*Therapeutic Gazette*, April 15th, 1926, p. 229) condemns all major surgical operations during the acute stage of pelvic inflammation, especially salpingectomy and the ligaturing of veins in infective thrombo-phlebitis. Diagnosis should, he states, be made on clinical evidence since it is dangerous to await a positive blood culture report. He advocates serotherapy, chemotherapy, and general treatment. He uses large intravenous doses of polyvalent antistreptococcus serum since small doses given intramuscularly or subcutaneously are useless. In two cases the intravenous injection of mercurochrome was so effective that McGilinn employs it in all severe cases. Nephritis, severe stomatitis, and other toxic sequelae have been encountered, but without fatal results. He has never found benefit result unless there was a severe reaction following the intravenous injection of any germicide. He considers that general tonic treatment is the most valuable aid to recovery—sunlight and pure air, morphine to secure rest, and alcohol when indicated. When anaemia is severe small and repeated blood transfusions are often useful, but may cause "protein shock reactions." Localized pelvic inflammation requires rest in bed and purely expectant treatment for the relief of pain and anaemia. The author cites numerous cases indicating that inflammatory exudates and adhesions often disappear completely. He strongly recommends non-specific protein treatment and uses pasteurized or, preferably, boiled milk. In the case of out-patients he uses one of the sterilized milk or casein products supplied in ampoules. These were found to produce milder reactions than did pasteurized or boiled milk. The severity of the reaction, however, appears rather beneficial than otherwise; it occurs from three to six hours after injection, and there may be a severe rigor followed by a temperature of 104° or even 106°, but this falls quickly with profuse sweating. Daily blood counts may show also a definite leucocytosis, persisting for several days; there is sudden relief from pain and a sense of well-being, and consequently the patients submit willingly to a repetition of the injection. He finds that previous protein tests are unnecessary and that anaphylaxis does not occur. The first injection was usually 5 c.cm., the next, given in five or seven days, was 10 c.cm. The number given depended on the extent and chronicity of the lesions; the maximum number was usually six injections. In cervical gonorrhoea there was usually a local reaction in the form of a profuse gonococcal discharge after the injections. The author now uses this treatment in all cases before resorting to surgery except for the evacuation and drainage of localized abscesses.

558. Vaccine Treatment of Chronic Gonorrhoea.

F. WOLFF (*Zentralbl. f. Gynäk.*, April 17th, 1926, p. 1069) publishes conclusions derived from treating resistant cases of chronic gonorrhoea by administration of (1) stock vaccines, (2) freshly prepared but not necessarily autogenous vaccines, and (3) living vaccines. He finds that stock vaccines supplied by manufacturing chemists are to a certain extent useful as an adjuvant to local treatment, are helpful in cases of adnexal inflammation, and may serve by provocation to make a latent gonorrhoea manifest; nevertheless they are not therapeutically effective in the absence of local treatment. Freshly prepared vaccines were found superior to all stock preparations. The author states that they should be prepared from a clinically virulent case of acute gonorrhoea or an acute complication (such as prostatitis or epididymitis) in an old-standing case, and should be given in high doses of from 500 million upwards twice a week. They speedily lose their efficacy with keeping and should be discarded after a few weeks. Focal and general reactions are said to occur much less frequently after injections of fresh than of stock vaccines, possibly because the latter are apt to contain liberated endotoxin. In cases in which acute and subacute symptoms and signs have subsided and in which after two or three months there is no tendency towards cure, Wolff has had excellent results from the subcutaneous injection of living gonococci, preferably derived from another patient, on one or if necessary two occasions. A culture not more than one week old from a virulent strain is used; three or four injections at a time of 0.1 to 0.2 c.cm. of a well shaken emulsion of a culture in 2 c.cm. of distilled water being given, the sites of infection being about 6 cm. apart. A painful phlegmon develops and sometimes an abscess; the second injection must not be given until these have almost subsided. No metastatic abscesses have been noted, nor signs of arthritis or endocarditis. This vaccine treatment alone sufficed in many cases to cure chronic uterine gonorrhoea; it did not appear to affect gonorrhoea of the mucous membranes such as urethritis, in which cases local treatment was also required.

569. Insulin in Diabetic Tuberculosis.

V. CORDIER and P. SÉDALLIAN (*Journ. de Méd. de Lyon*, April 20th, 1926, p. 205) state that there is still much divergence of opinion as to whether insulin should be employed in cases of diabetes complicated by tuberculosis. Some authorities assert that the administration of insulin lights up a quiescent tuberculous focus in a diabetic. Others, while agreeing that insulin has no directly beneficial effect on the tuberculosis, claim that the abolition of acidosis and the rapid improvement in the patient's nutrition which usually follows insulin treatment must increase the patient's power of resistance. The present authors, though agreeing that the number of recorded cases is too small to justify a dogmatic statement, consider that, in view of the uniformly fatal result in cases of post-diabetic tuberculosis, insulin should be given a more extensive and prolonged trial. Fibrous and progressive disease, however, constitutes an absolute contraindication. They give details of four cases in which the treatment proved beneficial, though death was not prevented.

570. Treatment of Gastric Dyspepsia.

F. L. APPERLY (*Med. Journ. of Australia*, March 27th, 1926, p. 354) has been investigating the conditions which interfere with the passage of food from the stomach into the intestine, and finds that before the intestine will accept chyme a certain salt concentration or osmotic value must have been reached. Any value above or below this causes rejection by the intestine of the food back into the stomach, where it remains until concentration is correct. The chyme should be about isotonic with sodium chloride in the blood. The administration of hydrochloric acid, sodium bicarbonate, or sodium chloride was found to have the effect of raising the salt strength of the food more rapidly to the required value, with the result that regurgitation of duodenal fluid was diminished, acidity was raised, and the stomach emptied more rapidly. The author believes that this explains why the use of sodium bicarbonate is valuable in some cases of achlorhydria with dyspepsia, and is followed by relief of pain and discomfort, while in others no benefit is obtained. The usual dose of sodium bicarbonate is from 15 grains to 1 ounce, given in about one ounce of fluid. In other cases hydrochloric acid was found more useful.

Radiology.

571. Radiological Diagnosis of Pulmonary Tuberculosis.

R. T. MONROE and E. S. EMERY, JUN. (*Boston Med. and Surg. Journ.*, April, 1926, p. 619) suggest that patients with vague symptoms of malaise, tendency to fatigue, and other possible indications of pulmonary tuberculosis may have the presence or absence of this disease definitely established by x-ray photographs, and that the inconvenience and expense of examining a large number of suspects fruitlessly may be avoided by a careful study of the symptoms rather than of the physical signs. The symptoms, signs, and x-ray findings of 107 patients were tabulated and examined statistically, and a comparison was made with another series of 500 patients of whom similar details were available. Considerable discrepancies between the physical signs and the x-ray picture were manifest in several cases; thus cavities were found present by x-rays in patients in whom the physical signs did not suggest their presence, and vice versa. In the 107 cases faulty diagnosis in 21 was attributable to the physical signs. Monroe and Emery therefore advise routine x-ray examination of the chest whenever the symptoms point to tuberculosis, irrespective of the indications afforded by the physical signs. Frequent examinations of the sputum, pulse, and temperature should not, however, be neglected, since a negative x-ray examination does not necessarily exclude tuberculosis. The authors mention that seven cases with negative x-ray findings had tubercle bacilli in the sputum.

572. X-Ray Treatment of Laryngeal Tuberculosis.

J. J. DEBICKI (*Journ. de Radiol. et d'Electrol.*, March, 1926, p. 120) reports most encouraging results following the x-ray treatment of laryngeal tuberculosis. He quotes a number of authors who have obtained similar results, particularly during the last five years; they all emphasize the anaesthetic effect of the treatment. Since 1921 Debicki has treated 33 patients with laryngeal tuberculosis, of whom 26 were completely cured. He employs a spark of 0.27 cm. and the filter is made of 4 mm. aluminium and 5 mm. cardboard or wood; the anti-cathode is placed at a distance of 0.23 cm. from the skin. The larynx is irradiated every week, alternately on either side. The treatment is repeated after an interval of four to six weeks according to the progress of the disease. The

author does not agree with those who consider that destructive lesions contraindicate x-ray treatment. Three of his patients were 52 to 62 years of age. Two patients were completely cured after treatment lasting for more than a year; in the other case a recurrence occurred after six months. The author states that while the most favorable results are obtained in early cases, serious destructive forms may be equally treated with success. The optimum dose is 5 Holzknecht units applied every week to each side alternately, and repeated after an interval of four to six weeks between each course. Apparent aggravations occurring during the course of treatment are not held to contraindicate its continuance. The treatment should be continued for some time after the disappearance of all symptoms.

573. X-Ray Treatment of Enlarged Prostate.

C. GUILBERT and R. D. GAVILLARD (*Urol. and Cut. Rev.*, March, 1926, p. 150) record their experience of x-ray treatment of 45 cases of enlargement of the prostate during the last four years. The results were as follows: 34 were cured by one treatment and 6 by two treatments. In 1 patient who refused a second treatment no good effect was obtained, 3 were subsequently operated on, and 1 showed a relapse during treatment. On conclusion of the treatment some patients developed bladder trouble owing to infection or deficiency of the bladder muscles, but these symptoms were independent of x-ray treatment. The authors maintain that irradiation of the prostate is a very mild procedure which does not exert any dangerous influence on the organ or interfere with surgical measures if these are required subsequently. It is important that irradiation should be instituted as early as possible, as a commencing hypertrophy is less sclerotic and more sensitive to x-rays and the vesical troubles are transitory and more curable. In order to avoid relapses the portal and general tension should be lowered in plethoric cases, and in infected cases the infection should be cured by vesical irrigation and vaccines.

574. Vesical Lesions Produced by Sodium Bromide Solutions.

ACCORDING to B. OTTOW (*Zentralbl. f. gynäk.*, May 1st, 1926, p. 1199) a 25 per cent. sodium bromide solution has now replaced collargol as a "contrast medium" in cysto-radiography, as it gives better images; but several writers have reported the occurrence of haematuria and of renal and vesical lesions following its employment. The author describes two cases of severe cystitis following intravesical injection of 200 c.cm. of a 25 per cent. solution of sodium bromide. The first patient, aged 41, had uterine myomata. Immediately after cysto-radiography she had dysuria and scanty urine, which persisted for four days. The vesical mucosa was partially detached and the trigone was deeply congested and of a dull blood-red colour. In the second case the bladder was anaesthetized with 50 c.cm. of a 2 per cent. alypin solution prior to the injection of 250 c.cm. of sodium bromide solution, which was followed by a sensation of burning and pressure. Two days later the patient had similar symptoms to the former. Cystoscopic examination two days later showed much damage to the vesical mucosa, ulceration, and bullous oedema. The author recommends that immediately after the skiagraphy the bladder should be emptied and it should then be irrigated with horic lotion. Since this procedure has been adopted he has not seen any similar injuries to the bladder wall.

Obstetrics and Gynaecology.

575. Persistent Occipito-posterior Presentations.

F. B. CRAIG (*Med. Journ. of Australia*, March 27th, 1926, p. 352) discusses the diagnosis and management of persistent occipito-posterior presentation. By abdominal palpation a correct diagnosis of the position of the foetus should be made after the thirty-sixth week, in time to correct malpositions. In occipito-posterior positions the breech occupies the fundus and foetal limbs can be palpated in the front of the uterus about the umbilicus. In the right occipito-posterior position the sinciput is easily felt above the pelvic brim, near the left ilio-pectineal eminence, and usually at a higher level than the occiput, which lies more deeply in the right side of the pelvis. In the left occipito-posterior position the sinciput is to the right in front and the occiput deeply placed to the left. By palpating these two points of the head it can be ascertained whether the head is movable or fixed in the brim. The foetal heart sounds are usually heard at their maximum above and lateral to the anterior shoulder, though a low uterine sonfile may interfere with their clearness. When the foetal spine has become slightly extended over the convexity

of the lower lumbar and upper sacral vertebrae of the mother, the foetal chest comes to lie close to the surface in the hypogastrum; the sounds will then be heard distinctly also near the middle line or even across it in the opposite iliac fossa, which may lead to a wrong diagnosis. During labour the foetal parts may be recognized between the pains, and the progress of the head estimated. When posterior positions are recognized before labour has started the head can be rotated into an anterior position by Buist's method. After the onset of labour it is unnecessary to interfere if the head is lying in the oblique diameter and is descending, provided that the condition of the mother and foetus is good. The mother should lie on the side to which the occiput points so that the breech may be dragged further over to the same side, the foetal spine being thus straightened, the occiput forced down, and its rotation to the front encouraged. Craig mentions four ways of dealing with arrested descent or backward rotation of the occiput. In multiparae manual flexion may be tried by pushing up the sacrum during a pain, but is seldom effective. When dilatation is complete the head may be rotated by the whole hand in the vagina after being pushed up to disengage it slightly. For this the patient is anaesthetized, placed in the left lateral position, and the right knee supported. In multiparae this may be all that is required when the pains are strong, but in most cases it is recommended that forceps be applied as soon as the head is in the correct position. A third method is rotation by forceps, with the minimum of force, the tissues being handled very gently. The fourth method, craniotomy, is usually only necessary when the outlet of the pelvis is contracted. Such a degree of deformity should, however, have been detected by an ante-natal examination and preparations made for Caesarean section.

576. Treatment of Repeated Abortion.

J. NOVAK (*Zentralbl. f. Gynäk.*, April 10th, 1926, p. 1003) records two cases in which healthy women, having (like their husbands) negative Wassermann reactions, had had five or six pregnancies in succession terminated by spontaneous abortion in the early months. In the ensuing pregnancy they were given small doses, about 20 drops, of a 0.05 per cent. potassium iodide solution daily, together with three Bland's pills. Healthy infants were born at term, as was the case also in two other patients who received similar treatment; one of these had previously given birth to a macerated foetus in the seventh month, and the other had suffered from recurrent pregnancy nephropathy with death of the foetus. In these patients also the Wassermann test was negative. The treatment was originally thought to be effective by reason of its action against a latent syphilis; Novak, however, regards it as probably affecting the endocrine glands, especially the thyroid.

577. Fibroma of the Cervix.

J. VANVERTS (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, April, 1926, p. 242) reports a case of the rare condition of fibroma of the cervix, the only one he has encountered in the course of practice during thirty years. The fibroma was as large as a small mandarin orange and had developed in the anterior wall of the cervix. It was sessile, and on section presented the characteristic structure. The body of the uterus contained a small interstitial fibroma in the posterior wall. The patient, aged 47, had had three confinements, the last three years previously. For some months the periods, which had been normal, increased until there was an almost continual loss of blood; considerable pain and tenderness followed. Abdominal hysterectomy was performed without difficulty, and the only other abnormal conditions found were that both abdominal openings of the Fallopian tubes were closed, their walls were thickened, and both ovaries contained numerous small cysts, of which some were haemorrhagic.

Pathology.

578. The Spirochaete of Tuberculous Haemoptysis.

F. BEZANÇON and E. ETCHÉGOIN (*C. R. Soc. de Biologie*, April 30th, 1926, p. 1056) have been studying the spirochaete that was first described in 1923 by Etchégoïn, who found it in the sputum of tuberculous patients suffering from haemoptysis. Attempts to cultivate it have at last been successful, though its isolation in pure culture has not yet been accomplished. The medium used consists of a mixture of horse serum, saline solution, and peptone water, covered with sterile oil, and heated for half an hour on three successive days at 56°C. Growth occurs best at 37°C., slightly at 29°C., and not at all at room temperature. The spirochaete is described as being a filamentous organism with four to nine

fairly sharp but irregular curves; the length of each individual spiral is 2.5 to 3 μ , and the length of the whole filament about 7 to 13 μ . The movements of the organism are very regular but not lively.

579. Immunization by Tetanus Bacilli in the Digestive Tract.

C. TENBROECK and J. H. BAUER (*Journ. Exper. Med.*, March, 1926, p. 361) find that tetanus spores are present in the stools of about one-third of the population of Peking; the disease, however, is relatively rare. The blood of these carriers was found to contain an appreciable amount of antitoxin, and it was assumed that it was this antitoxin that was responsible for immunity. To test this guinea-pigs were inoculated with about 1,000 spores in the muscles of the hind leg. The animals showed symptoms of the disease in four or five days, and succumbed on the seventh to the tenth day. Guinea-pigs without tetanus bacilli in the faeces were fed with old broth cultures; some were given Type 1, others Type 3, and others Type 5 bacilli; specific agglutinins appeared in the blood serum, and later an antitoxin was detached. After six months the amount of antitoxin was equivalent to 0.05 U.S.A. unit per c.c.m. These animals were then injected with tetanus spores of different types. The results were unexpected. It is known that agglutinins are specific for each serological type of bacillus, but that the antitoxin is common to all types. It was assumed, therefore, that guinea-pigs with antitoxin in the serum would be resistant to all types of bacilli, but it was found that they resisted only that type with which they had been fed. Thus, a guinea-pig with a considerable quantity of antitoxin was still susceptible to infection with tetanus spores of a type different from the ones used for immunization. When animals were fed with several types they became immune to these types. But though guinea-pigs which were carrying tetanus bacilli in the alimentary tract contained antitoxin in their serum, and were resistant to the injection of tetanus spores, they succumbed to the injection of tetanus toxin. Since there is apparently no relation between the amount of antitoxin in the blood and immunity to tetanus, the authors conclude that acquired immunity must be due to some other type-specific bodies which are elaborated.

580. The Cuti-Reaction and Vaccination.

L. RICCIARDI (*La Pediatria*, April 15th, 1926, p. 421) found that among 50 children whose cuti-reaction to tuberculin was intensely positive before vaccination the second reaction performed shortly after vaccination showed in 18 cases a distinct attenuation and in 3 cases was entirely absent. A third cuti-reaction performed a month later showed a return of the cuti-reaction to its original intensity. Ricciardi considers that this diminution or absence of reaction in vaccinated children is an indication that greater caution is required in performing vaccination on subjects who are living under unfavourable organic conditions or who are likely to be suffering from tuberculous infection, owing to the susceptibility of recently vaccinated children to tuberculous infection.

581. The Significance of Reticulation in the Red Corpuscles.

W. DAMESHEK (*Boston Med. and Surg. Journ.*, April 29th, 1926, p. 759) has made a careful examination during the last five years of the appearance of reticulated red corpuscles in the blood, using brilliant cresyl blue for his stain. One drop of 0.3 per cent. solution of the stain is placed at one end of a slide and allowed to dry; a drop of blood on a cover-slip is inverted on to the dye and the two allowed to mix for three or four minutes. Dameshek believes that the number of reticulated cells present indicates the degree of bone-marrow activity, and states that before and at the beginning of any remission or permanent rise in the red cell count the reticulated count exceeds 6 per cent. As the culmination of the rise is reached the count gradually falls again to the normal, which is 0.5 to 1 per cent. With bone-marrow aplasia the reticulated count was extremely low. He uses this count as a guide to prognosis in pernicious anaemia and believes that an elevation of the count up to 5 per cent. represents probably a process of regeneration coexisting with a greater extent of destruction, while a sudden rise in the count to above 6 per cent. foretells a coming remission. Continued low counts are said to be of very grave prognosis. The author considers that the relapse in pernicious anaemia is closely related to aplastic anaemia, which, with its evident bone-marrow failure, has an almost total absence of reticulated corpuscles. In purpura haemorrhagica the count increased before recovery and remained low when death from haemorrhage was pending. Dameshek adds that the marked reticulation in congenital haemolytic anaemia is of pathognomonic importance, distinguishing it from all other anaemias with large spleens.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

582. Ventricular Bradyrhythmia due to Septal Necrosis.
E. GERAUDEL, R. BÉNARD, and P. HILLEMANT (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, May, 1926, p. 281) describe a case of ventricular bradycardia and sudden death, which were not due to a lesion of the bundle of His, in a man, aged 67, who had oedema of the ankles, commencing orthopnoea, and cardiac asthma. The heart was dilated and there were general symptoms of cardiac failure—anasarca, ascites, pleuritic effusion, and albuminuria. The pulse varied from 36 to 24 a minute. After a transient improvement the patient died suddenly about three months after admission. Serial sections of the left ventricular wall showed an area of necrosis caused by endarteritis, blocking the branch of the right coronary artery which supplies the auriculo-ventricular node of Tawara and the bundle of His. The main trunk of the bundle of His was not involved, nor was the main trunk of the coronary artery, but this circulatory failure in the branch was the cause of the permanent ventricular bradycardia. There was a second necrotic area in the fibrous interventricular septum. The authors conclude that bradycardia, which is an important element in the Stokes-Adams syndrome, is due to a deficient blood supply in this artery; hitherto the Stokes-Adams syndrome has been regarded as being due to a destructive lesion of the bundle of His, such as a gumma or neoplasm of the interventricular septum.

583. Syphilitic Reinfection in Tabes.
POIRIER (*Bulletin Méd.*, April 4th, 1926, p. 665) reports a case of syphilitic reinfection of a tabetic patient. A man, aged 44, had had a chancre in 1903, and in 1916 complained of visual troubles, which proved to be due to optic atrophy. His Wassermann reaction was positive and he was treated with mercury intramuscularly; three years later the reaction was negative. In 1926, two weeks after coitus, a small ulcer appeared on the corona in the centre of a zone of cartilaginous hardness; the inguinal glands were enlarged. Poirier concluded that the lesion was a primary sore, and the first of a course of quinine iodohismuthate injections produced a typical roseola. The Wassermann reaction was found to be strongly positive. The patient had an old-standing tabetic optic atrophy; the pupillary light reaction was slow and feeble, and the accommodation reflex normal. The patient had been taking vesperal and adalin frequently, which may have affected the pupil reaction; the deep reflexes were present. Poirier suggests that this patient's first infection was due to the neurotropic type of syphilitic virus, and the second to the dermatropic type, if such exist. Bismuth was used owing to its almost selective effect on neuro-syphilis, arsenical compounds being avoided on account of their effect on the optic nerve.

584. Bilateral Popliteal Aneurysms.
A. W. HOYT (*Scientific Therapy and Practical Research*, February, 1926) reports a case of a man, aged 55, in whom fusiform popliteal aneurysms were found in both legs in the spring of 1922. Four Wassermann tests were negative and intensive specific medication was given without effect on the pain or the aneurysms. In December each aneurysm was 3½ inches long, and symptoms of intermittent claudication were very pronounced. Injections of 3 c.cm. of a 1 in 1,000,000 solution of the patient's whole blood in distilled water were given weekly. Four days after the first intravenous injection all symptoms of intermittent claudication had completely disappeared in both legs. A month later there was total absence of pulsation in the right popliteal aneurysm, and the right foot was warm, a satisfactory collateral circulation having been established on the day when the symptoms disappeared. Five months later the patient could walk without pain, but the right popliteal artery was pulseless and the left was pulsating strongly. Ten months subsequently the patient reported that he had been able to engage in strenuous exercise, including dancing, but he had recently had some pain over the left sciatic nerve, which suggested the existence of a deep thrombus. The skin over the first three toes of the left foot became yellow and dry gangrene subsequently occurred with severe pain. The gangrenous areas separated, leaving a healed surface. Six months later acute pain recurred in the left leg and foot, which were pulseless, and an area over the left patella became dusky. Dry gangrene appeared above

the left big toe, which separated from the foot, leaving a healed area. Three months later all pulsation in the left aneurysm had ceased, weekly intravenous injections of 2 to 4 c.cm. of the solution of blood in distilled water having been given during the attacks, and at three and four week intervals subsequently. In addition to these injections electric heat was used, a partial antidiabetic diet given, and the leg kept horizontal during the establishment of the collateral circulation, which was hastened by frequent massage. Complete recovery followed. Hoyt discusses the assumption of spontaneous cure in this case, as against the possibility that some undetermined part of the treatment was responsible for the favourable result. He draws attention to the age of the patient as an argument against the cure being spontaneous.

585. Aneurysm of the Heart.

H. NISHIDA (*Journ. of Oriental Medicine*, March, 1926, p. 60) suggests that aneurysm of the heart is not so rare as has been supposed; in the majority of cases clinical diagnosis is impossible. He has found records of about 120 cases observed since 1890 in Europe and America; only 4 cases have been recorded in Japan. He now reports the case of a woman, aged 58, who had had for ten months oedema of the face and legs, cough, dyspnoea, and slight pain in the chest. She was anaemic, the pulse was rapid but regular, the blood pressure was 100 to 160 mm., the Wassermann reaction was negative, and there was general anasarca. No obvious dilatation of the heart was present, but there was an apical systolic bruit and the second aortic sound was accentuated. Rhonchi were heard at both bases. The liver was somewhat enlarged and ascites was present. The urine contained albumin, indican, hyaline casts, and leucocytes. Three months later her appetite failed, her condition became worse, and she died a month later. The heart was generally dilated but the valves were normal; there was advanced atheroma of the aorta and of the coronary arteries. In the left ventricle, behind the mitral valve, there was a thin-walled aneurysm as large as a walnut. Nishida thinks that the aneurysm was caused by the interference with the nutrition of the wall of the left ventricle, due to the advanced atheroma of the coronary artery.

Surgery.

586. Cancer of the Skin.

J. J. MORTON (*Arch. of Surg.*, March, 1926, p. 653) finds that squamous-cell cancer of the skin occurs usually in patients aged 45 to 70. It is more common in men, since lip cancer is usually found in males, and there is the greater frequency of exposure to hazardous occupations. Anything that causes repeated injuries, such as a ragged tooth, may cause cancer, while it may arise in any of the common dermatoses. It may develop in scars and ulcers, while the various types of occupational cancer are due to chemical substances which set up irritation, as in tar and paraffin workers. An interesting group of this variety occurs in mule-spinners, due to irritation of the scrotum by mineral oil. The disease is seen in the face, trunk, and scrotum usually. The special danger of squamous cancer is its early metastasis. Treatment is by surgery or radiation; the primary growth should be removed, and also the dangerous secondary foci. Radium tubes may also be implanted after operation. Growths on the scalp and forehead do not usually require removal of the glands. A number of cases are reported, with illustrations of the growths.

587. The Acute Post-operative Toxaemia of Hyperthyroidism.

J. ROGERS (*Surg., Gynecol. and Obstet.*, April, 1926, p. 567) discusses the treatment of the acute post-operative toxaemia of hyperthyroidism, than which there are few more dangerous conditions. In his experience it occurs most commonly in patients with marked exophthalmos, especially those who have previously had a pallid or pigmented skin, or who show a perceptible muscular atrophy in the hands and forearms; it is more prone to occur in those with firm rather than soft thyroids. In such cases the danger apparently arises rather from an absence of thyroid secretion than from an excess, and consequently Rogers advises the subcutaneous administration of a boiled aqueous extract of the thyroid, known as

"thyroid residuo," in 20 to 30 minim doses every two hours, in the event of alarming symptoms arising during or immediately after operation. This appears to act by stimulating the terminal filaments of the vagus or parasympathetic portion of the involuntary nervous system, and therefore it does not increase the already alarmingly rapid cardiac action; while it intensifies the symptoms if administered to patients under medical treatment for severe hyperthyroidism, it appears to be beneficial in acute post-operative toxæmia. Notes of three cases are given in which its free administration averted a fatality or saved the patient from a very dangerous condition.

588. Treatment of Peritonsillar Abscess.

O. MAYER (*Wien. klin. Woch.*, April 29th, 1926, p. 508) describes two forms of peritonsillar abscess. The first points at the upper pole, and is most conveniently opened at Chiari's site by a horizontal incision from the mid-line at the base of the uvula; this incision should measure 2 cm. in length and depth; it extends towards the last upper molar. The tissues are much thickened, and care is necessary to avoid cutting the tonsillar artery or its branches. In such a case of damage to the tonsillar artery plugging with iodoform gauze failed to arrest hæmorrhage; Mayer performed an immediate enucleation and the bleeding ceased. This procedure causes collapse of the capsule with retraction of the wounded artery. The second form—namely, abscesses behind the lower half of the tonsil—may be recognized by the greater severity of the symptoms: dysphagia, tonsismus, persistent earache, and high fever. There is some paresis of the mandibular muscles and much swelling of the submaxillary and retromandibular glands. When the incision is made as described previously no pus appears. Mayer recommends enucleation under light ether anaesthesia, with the patient in a sitting position. If the abscess be not evacuated by enucleation at the right moment there is danger of the pus travelling downwards in the carotid sheath; it may even reach the mediastinum or cause erosion of the carotid. The abscess should be opened by an incision along the anterior border of the sterno-mastoid; free hæmorrhage from the tonsillar capsule or from the incision may be arrested by compression of the carotid or of the tonsillar bed. If the carotid be eroded, ligature of the common carotid trunk may be necessary.

589. Chronic Non-specific Synovitis of the Knee-Joint.

A. LÄWEN (*Zentralbl. f. Chir.*, April 3rd, 1926, p. 857), in 39 arthrotomies of the knee-joint, has often found that chronic synovitis resulted in fissural degeneration of the patellar hyaline cartilage and of the semilunar cartilages. He compares the inflammatory changes in the synovial membrane with those found in chronic peritonitis, and believes that many cases of dislocation of the semilunar cartilages, and of osteo-arthritis, originate from chronic arthritis. He therefore recommends that an exploratory arthrotomy should be made by a large anterior incision, preferably Payr's "S" incision. If the synovial membrane is thickened and adherent to the intercondylar fossa, or other bony surfaces, he excises redundant synovial masses and restores the normal outline of the synovial membrane by suturing the cut edges with fine catgut. He operates under strict hæmostasis; the tourniquet is removed after the suture of the cut edges of the synovial membrane, when a careful search for any bleeding points is made. He has excised the plica synovialis patellaris in nineteen cases.

590. Typhoid Abscess of the Breast.

P. O. SNOKE and J. L. GOFORTH (*Amer. Journ. Med. Sci.*, April, 1926, p. 555), who record a personal case, illustrate the rarity of typhoid abscess of the breast by the following statistics. Only four instances occurred among 1,626 cases of typhoid fever reported by Berg in 1895. Curschmann saw only two cases, one of which occurred in a male. Five cases were seen by Leadet in the course of twenty-five years. Madelung in 1917 found records of thirty cases, in only seven of which a bacteriological examination had been made. In three a pure culture of *B. typhosus* was found, in two others *Staphylococcus albus*, and in the other two no typhoid bacilli were present. The present case occurred in a negress, aged 18, who developed three post-lactation masses which probably represented periductal inflammation and may have afforded foci for the localization of typhoid bacilli. Subsequently a swelling developed in the right breast. No definite diagnosis could be made, and the breast was amputated. A large thick-walled abscess was found on section containing orange-coloured purulent material from which typhoid bacilli were grown. There was no evidence of glandular proliferation, tuberculosis, or syphilis. Histologically the picture was that of a chronic suppurative inflammatory process with abscess formation. Enlarged glands in the axillary fold proved to be periductal adenofibromata, presumably of misplaced mammary tissue.

Therapeutics.

591. Insulin Treatment in Non-diabetics.

R. FEISSLY (*Presse Méd.*, February 13th, 1926, p. 196) has treated six patients with non-diabetic malnutrition and debility, previously resistant to remedial measures, by injections of insulin. He gave them two or three injections a day half an hour before meals rich in carbohydrates, commencing with 5 units of insulin at each injection and increasing as rapidly as possible to 60 units a day. He maintained this treatment for three to four weeks. He found that the weight curve rose very steeply with the commencement of treatment, there being an increase of nearly 9 lb. in two cases in three and four weeks respectively. The appetite improved markedly even in those who had suffered from anorexia previously, and the patients required food at night as well as during the day. He stresses the point that the carbohydrate ration should be much in excess of the amount theoretically sufficient to neutralize the insulin; if the carbohydrate was restricted to a theoretical sufficiency the classic phenomena of hypoglycæmia appeared—namely, trembling, sweating, weeping, and nervousness.

592. Harmlessness of Toxin-Antitoxin Injections.

W. H. PARK (*New York State Journ. Med.*, April 15th, 1926, p. 347) states that probably over two million injections of toxin-antitoxin have been given in New York State alone, and no disaster has occurred. Only three serious accidents, to his knowledge, have ever followed the use of toxin-antitoxin. The first happened many years ago in Dallas, Texas, where, owing to a mistake, a toxic preparation was used. As the result of this occurrence the biological manufacturing plants, at the suggestion of the Hygienic Laboratory, adopted rules which must prevent this accident ever occurring again. The second was an accident which occurred near Vienna in 1924 (*JOURNAL*, October 24th, 1925, p. 757) and was at first attributed to changes in the toxin-antitoxin. According to recent information, however, the fatalities were due to the fact that through a mistake diluted toxin was used instead of toxin-antitoxin. The third accident (*JOURNAL*, March 8th, 1924, p. 454), which had no fatal results, occurred from the use of toxin-antitoxin immediately after thawing the frozen product. The new standardized preparation of toxin-antitoxin used in the United States contains only one-thirtieth of the amount of toxin used in the first preparation and is said to be absolutely harmless when used after freezing and thawing.

593. Intravenous Chemotherapy in Gonorrhoea.

H. JAUSON and M. VAUCHEL (*Presse Méd.*, February 13th, 1926, p. 193) report the successful treatment of gonorrhoea by chlorhydrate of diamino-methyl-acridine. Intravenous injections of 5 c.c.m. of a 1 in 50 watery solution of this dye were given three times a week until a cure was obtained. In some cases there appeared a yellow coloration of the skin and a subinflammatory puffiness, which disappeared in ten to fifteen days. The shock of the injection was negligible in most cases; a few susceptible individuals showed slight syncope after the first injection, but subsequent treatment was always well borne. Ordinarily fifteen to eighteen seconds after the injection the patient experienced a burning sensation, constriction of the throat, congestion of the face, and warmth in the perineum; this reaction only lasted five to ten seconds, but there was sometimes a local urticaria at the site of injection. In a few cases towards the fifteenth day a cumulative toxic effect was noticed—slight nausea, cardiac irritability, and colouring of the skin. The dye is fluorescent, and exposure of a patient to strong sunlight soon after injection caused in forty-eight hours an erythema of the exposed area, and sometimes even a papular eruption on the covered parts. This photo-sensitiveness is said to be most marked during May and June, and may be prevented by the administration of 0.25 gram of resorcin. Elimination is by the urine, 10 cc. requiring forty-eight hours; but there is little practical risk of cumulative effect with injections every other day, as 60 per cent. of the dose is eliminated in the first two hours. Of the 165 cases treated there was apparent cure, judged by both clinical and laboratory tests, in 153. The smallest number of injections necessary was five (in 22 cases), and the most twenty-five to forty (in 8 cases). One patient, however, required fifty-four injections for the cure of a metatarsalgia that had resisted all other forms of treatment. The only gonorrhoeal complication that arose after treatment had been established was iritis, which was cured in less than a week by further injections, together with the local instillation of atropine. The authors add that the advantages of this method of treatment are that it is ambulatory, no irrigations are necessary, there are no complications except the possibility of iritis, the effect on the general health is excellent, and there is better disinfection of the genito-urinary system.

especially in the female, than by any other method. They believe that the best results will eventually be obtained by the combination of a suitable mordant with the dye. The mordant with which they have been most successful up to the present is chromolin, which they combine with methylacridine, so as to get a 1 in 50 solution of the two products.

593. Iodized Oil in Bronchial Affections.

S. PRITCHARD, B. WHYTE, and J. K. M. GORDON (*Journ. Amer. Med. Assoc.*, April 10th, 1926, p. 1119) report upon the use of iodized oil in the diagnosis and treatment of bronchial affections. They used 40 per cent. metallic iodine with oil of poppy seeds so closely combined that no free iodine was present; the high iodine content rendered it opaque to x rays. By injecting the oil into the bronchi small bronchiectatic dilatations and enlargements were capable of detection radiographically. Three methods of introducing the oil were used: (1) supraglottic, in which 20 c.cm. of warmed oil was slowly syringed into the larynx under observation with a laryngeal mirror, the pharynx and the base of the tongue having been previously swabbed with a 10 per cent. cocaine solution; (2) transglottic, in which the tip of the cannula was passed through the glottis into the trachea; and (3) subglottic, in which the oil was injected directly into the trachea through a hollow curved needle passed through the crico-thyroid membrane after anaesthetizing the skin and subcutaneous tissues. The authors state that before injecting the oil 1 to 2 c.cm. of warmed 1 per cent. cocaine solution may be injected in order to anaesthetize the mucosa of the trachea and bronchi. The oil is directed into the right or left bronchus by inclining the patient to the desired side, and in order to fill the apical bronchi the patient must be placed on a tilting table with the affected side downwards, the distribution of the oil being determined by gravitation and the respiring power of the lung. In over 600 injections no ill effects had to be recorded, and it was found that the supraglottic method was quite as satisfactory as the others, required less anaesthesia, and caused less anxiety to the patient. As a method of treatment this particular compound of iodized oil, by allowing the slow liberation of iodine, was found to be of very great value in chronic affections of the lower respiratory tract, but in acute affections or in pulmonary tuberculosis the authors hesitate to use it for either diagnostic or therapeutic purposes. The technique is not difficult, but it is added that negative results afford no diagnostic proof that bronchiectatic dilatations do not exist.

Dermatology.

595. Lichen Nitidus.

H. W. BARBER (*Brit. Journ. Derm. and Syph.*, April, 1926, p. 143) discusses the signs, histology, and treatment of lichen nitidus, and gives a brief historical survey of the literature of the disease. The essential lesion is a minute papule not larger than a pin's head, flat, globular, and slightly raised; it is formed by a granuloma just below the epidermis, which is thinned above it, giving it the characteristic glistening appearance. In many cases the eruption consists only of such papules, which remain discrete and unaccompanied by any changes in the surrounding skin, with a limited distribution on the penis, lower abdomen, groins, inner surfaces of the thighs, the bends of the wrists and forearms, and backs of the elbows. In some cases the eruption is more widespread and loses its primary papular appearance in certain regions, though on examination of the whole body areas will be found where the papules are discrete and typical of the simpler form of the disease. Such a diffuse eruption particularly involves the joint flexures, such as the antecubital and popliteal spaces, the extensor surfaces of the knees and elbows, the submammary region, the groins and thighs, while the palmar and dorsal surfaces of the hands and feet and the buccal mucous membrane may be affected. No tubercle bacilli have ever been demonstrated, and its cause is unknown; Barber regards it as a definite entity and not a tuberculide. Resorcin and salicylic acid externally, iodine internally, and fractional x-ray doses have all been followed by improvement; spontaneous disappearance has been recorded.

596. Pruritus.

G. THIBERGE (*Journ. de Méd.*, April 10th, 1926, p. 229) discusses the clinical and therapeutic aspects of pruritus. The skin affections such as syphilis... Pruritus may exist with or without skin lesions, and it is always a question which of the importance of ascertaining which comes first. In cleanly people with long-continued pruritus, worse when in bed, it is essential to exclude

scabies, for in such patients the skin lesions may be very slight. Possibly the itching in parasitic diseases may be due to a toxin, and so come into line with the numerous toxic causes, such as uraemia, biliary affections, and endocrine inefficiency. Certain drugs, such as morphine, cocaine, chloral, and antipyrin, may cause pruritus; as also various foods, effervescent sweet wines, coffee, and tea. People of nervous temperament are especially predisposed. Acute pruritus is of toxic origin, and is not so chronic types. The cocaine relieves the feeling that some parasite is under his skin. Leukaemia sometimes induces troublesome pruritus, which can often be relieved by x rays. In the pruritus of the aged, often due to faulty urino elimination, relief usually follows a strict milk diet, with occasional doses of calomel and diuretics. Lotions should be warm and are better than ointments. A mixture of menthol, phenol, zinc oxide, and vaseline is useful. Cocaine externally is of little use as it is unabsorbed by the skin. Internally sedatives are advantageous, although in some cases tonics, such as glycerophosphates, are preferable. Attention to the diet is always essential, and a course of mineral waters or thermal baths in suitable cases is to be recommended.

597. Treatment of Infectious Skin Diseases.

H. H. YOUNG, JUSTINA H. HILL, and W. L. DENNY (*Arch. of Derm. and Syph.*, April, 1926, p. 465) have treated various infectious diseases of the skin by intravenous injection of mercurochrome-220 soluble, with the following results. High fever, occasionally marked gastro-intestinal disturbances, infrequently severe stomatitis, and rarely transient albuminuria, and casts might occur, but by beginning with small doses, such as 2 mg. per kilogram, and increasing gradually up to larger doses—5 mg. per kilogram—the patient could generally be given several injections without a marked reaction. Of 24 erysipelas patients so treated, 20 (83.3 per cent.) were cured; of 11 patients with boils or carbuncles, 10 were cured and 1 greatly improved; 4 cases of chancreoid ulceration all healed rapidly; of 36 patients with cellulitis and abscesses, 21 (58.3 per cent.) recovered promptly with no other treatment and 9 showed marked improvement; in 2 patients with gas gangrene the infection was eliminated; of 44 leprosy patients, 28 (63.5 per cent.) showed remarkable improvement. Good results were also obtained in cases of psoriasis, eczema, and syphilis. These results show that mercurochrome, administered intravenously, is a drug of great value in the treatment of infection of the skin with various streptococci, staphylococci, and bacilli, as well as in other types of infection.

598. Traumatic Psoriasis after Neosalvarsan.

P. H. VAN DER HOOG (*Nederl. Tijdschr. v. Geneesk.*, February 27th, 1926, p. 838) records the case of a woman, aged 27, who, after injection of neosalvarsan and mercury for a hard chancre, developed an arsenical erythema followed by psoriasis, from which she had never suffered before. Psoriasis-form syphilis was excluded by the clinical picture, which showed the characteristic appearance of psoriasis after methodical scratching; whereas in psoriasis-form syphilis purpura would have developed after this procedure. The diagnosis was also confirmed by histological examination. Similar cases of psoriasis following injections of salvarsan preparations have been recorded by Hesse, Pantrier, and Bonteller.

Obstetrics and Gynaecology.

599. Acute Post-partum Uterine Haemorrhage.

P. A. PETRIDIS (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, April, 1926, p. 221) reports a case of uterine inversion, which occurred in a primipara aged 27. Forceps delivery was necessary, but there was no perineal tear, and seventeen minutes after the birth of the child the placenta came away completely, though accompanied by considerable haemorrhage. Credé's method had been used very gently. The haemorrhage continued and gave rise to severe shock, which was unimproved by medicinal treatment. Vaginal examination showed the presence of a tumour, which was taken to be a fibroid. Vaginal tampons were inserted, but the haemorrhage continued, and it was not until a week later that a careful gynaecological examination revealed the presence of an inverted uterus, grey in colour, and suggesting the onset of gangrene. After prolonged treatment the uterus was restored to a healthy condition and replaced, and the patient subsequently became pregnant again, the child being born without a return of the inversion. Commenting on the case Petridis remarks that the cause of the inversion remains

obscure, as no traction on the cord or strong pressure on the uterus was exerted. The process of inversion continued progressively during the days after labour. It appeared that the anterior wall was first inverted, and that the rest of the uterus followed its descent. The slow reduction of the inversion by progressive vaginal tampons was probably due to decrease in size of the uterus after the relief of circulatory stasis and oedema. There was no constriction by the cervix, which was sufficiently large to permit the reduction of the inversion.

600. Pararectal Incision in Difficult Labour.

A. RIECK (*Zentralbl. f. Gynäk.*, March 27th, 1926, p. 773) reports the successful use of Schuchard's pararectal incision in difficult obstetric cases. The incision, which begins in the vagina about the junction of the upper and middle thirds and ends about the level of the tuber ischii, divides the sphincter vaginae and levator ani muscles. By this operation the length of the birth canal is diminished by approximately one-half and its axis becomes much less curved. Eight cases are mentioned in which Schuchard's incision was used. It rendered possible speedy termination of labour in four cases of pelvic and four of cephalic presentation in which labour had lasted several days. One case was that of a primipara in eclamptic coma with a temperature of 104°, whose child was born alive.

601. Conservative Treatment in Gynaecology.

ACCORDING to D. H. WESSELS (*Med. Journ. of South Africa*, March, 1926, p. 213), conservative treatment in gynaecology is often preferable to surgical operation, but while twenty years ago it was difficult to persuade patients to undergo an operation, they are now usually unwilling to adopt a conservative line of treatment. That enlargement of the uterus often occurs just before the menstrual period should be remembered when estimating the rate of development of a fibroid, and when dealing with atypical pregnancies or irregular haemorrhages. A pregnant uterus associated with irregular haemorrhages may, on examination, be found contracted and be mistaken for a myomatous uterus. The author gives details of a case of this kind in which hysterectomy was advised, but the diagnosis was corrected by a second examination when the uterus was fully relaxed, and a diagnosis of a four months' pregnancy could be established. Wessels considers myomectomy the operation of choice in treating fibroids during the child-bearing age, and has records of several full-term pregnancies after this operation, which in no case in his experience caused uterine rupture subsequently. He regards myomectomy as a more conservative measure than x-ray treatment. Haemorrhages due to fibrotic change of the uterus, whether associated with benign hypertrophy of the endometrium or not, are treated so satisfactorily by radium after a diagnostic curettage that hysterectomy is unnecessary. Discussing the ovary as the most frequent cause of unnecessary surgical intervention, he states that ovarian pain and tenderness are often due to inflammation elsewhere in the genital tract. He thinks that the flaccid and thin-walled Graafian follicle cysts do not require operation, as they often rupture spontaneously or on manual examination. In other cysts of the ovaries, unless they are malignant, it is frequently possible to shell out the cyst without sacrificing much of the ovarian tissue. Wessels gives details of a case of bilateral dermoid cysts in an unmarried girl; the cysts were shelled out from both ovaries, and the girl subsequently married and bore three children. The author considers that the operation of salpingectomy for the cure of a gonococcal pus tube is not only an unnecessary procedure, but also periculous, and he cites a case in which such an operation resulted in death subsequently, owing to abdominal adhesions. In many cases the pus in such tubes has been shown to be sterile, and in time the condition would clear up spontaneously.

602. Primary Syphilis of the Cervix.

R. S. CRON (*Amer. Journ. Obstet. and Gynecol.*, March, 1926, p. 378) reports two cases of chancre of the cervix, and discusses the apparent rarity of this lesion. In the course of the pelvic examination of some 4,000 women only six patients with primary syphilitic lesions of the genitalia were discovered; in two cases the infection was localized in the vaginal portion of the cervix. Cron believes that the apparent rarity of cervical chancre can be accounted for by the lack of symptoms, the rapid involution, and the absence of scarring. He suggests that routine visual examination of the cervix, especially in newly infected syphilitic women, will demonstrate a higher percentage of primary lesions. He adds that a negative Wassermann reaction is usually found during the primary stage and does not exclude syphilis.

Pathology.

603. Production of Antibodies by Artificial Pneumothorax.

T. YEGER (*Ch. R. Soc. de Biologie*, March 5th, 1926, p. 502) has estimated the antibody content of the blood and of the pleural fluid in tuberculous patients at various points during artificial pneumothorax treatment. The complement fixation test was used, with Calmette-Massol's technique and Boquet's methylic antigen. All patients giving a positive Wassermann reaction were excluded. The results showed that there was a marked rise in the titre of the blood during the characteristic crisis (fever, thoracic pain, and dyspnoea) which commonly precedes a pleural effusion; this was followed by a marked fall in the titre after the effusion, provided that the general state of the patients improved. The antibody titre of the pleural fluid always corresponded to that of the blood. In patients who had remained well for a long time after the effusion antibodies were absent both from the pleural fluid and from the blood. Since tubercle bacilli, either in an intact or in a broken-down condition, are present in pleural effusions, and since an antigen capable of fixing complement in the presence of a tubercle antiserum can likewise be demonstrated, the author infers that the sudden increase in the titre of the blood immediately preceding the development of a pleural effusion is due to the absorption into the circulation of tuberculous antigenic material through the pleura.

604. Action of Histamine.

J. H. BURN and H. H. DALE (*Journ. of Physiol.*, April 23rd, 1926, p. 185) have studied the vaso-dilator action of histamine, the substance supposed to be responsible for the vascular features of "shock." In the cat histamine causes a fall of blood pressure followed by a rise (secondary or pressor phase of histamine action), but after the suprarenal glands are extirpated this secondary effect does not occur. It is therefore concluded that the secondary phase is due to an output of adrenaline. This is corroborated by the following facts. If, before the injection of histamine, ergotamine (which antagonizes adrenaline) is injected, then only a fall of blood pressure is produced. The physiological converse of this is that very small doses of adrenaline, after an evanescent rise of blood pressure, produce a fall of it. This fall is attributed to the production of histamine, largely in the lungs. The authors conclude that the secondary pressor effect of histamine is due to accelerated output of adrenaline, and that the secondary depressor effect of adrenaline is due to the liberation of a histamine-like substance. The significance of these facts is discussed in relation to the balanced chemical control of capillary tone. O. INCHLEY (*ibid.*, p. 282) believes that histamine shock is best explained by venous constriction. He finds that histamine in low concentrations constricts veins but not arteries. This constriction leads to a passive dilatation of the capillaries.

605. Cardiac Changes Produced by Cod-Liver Oil.

E. AGDUHR (*Acta Paediatrica*, March 6th, 1926, p. 319) reports that important organic changes, such as atrophy, degeneration, necrosis, and haemorrhages, were caused in white mice by the addition of 0.1 c.cm. per day per animal of cod-liver oil to their basal diet. These changes specially affected the heart. In the cardiac muscle cells there usually appeared pigment atrophy, sarcocytolysis, and vacuolous, albinous, and waxy degeneration. Many muscle cells were destroyed and disappeared, the cardiac muscle being transformed into connective tissue. This change was more pronounced in the muscles of the ventricles, particularly in the outer walls of the right ventricle. When the changes were farther advanced small haemorrhages usually appeared in the cardiac muscles. On a basal diet inferior in vitamins and nutritive value excrescences developed in the heart, subendocardially, interstitially, or on the endocardium, probably after previous injury to the endocardium. They were most common in the auricles, but were also met with in the ventricles, in some cases being large enough to impede the blood flow. Associated with these severe cardiac changes were oedema of the lungs, subcutaneous oedema, and exophthalmos. The author finds that cats, dogs, and calves are even more adversely affected by cod-liver oil than mice, and raises the question whether cod-liver oil given to children over a relatively long period may not lay the morphological foundation for future cardiac disease. He quotes Mellanby's warning against giving large doses of cod-liver oil (*JOURNAL*, May 24th, 1924, p. 895) since tachycardia and cardiac discomfort may result. Agduhr believes that the organic changes in his experiments were due to poisonous substances ordinarily present in cod-liver oil, which could be removed without affecting the vitamin content of the oil. This is forming the subject of further investigation.

P. DOTTI (*Il Morgagni*, February 28th, 1926, p. 265) has examined the case sheets of 2,253 patients suffering from tuberculosis in Bologna between 1920 and 1924 and has classified them according to the degree of anatomical involvement of the lung. Patients in any stage of the disease who showed purely unilateral lesions were placed in group 1; those with bilateral disease, but with one lung more affected than the other, were placed in group 2; and patients with bilateral disease of equal extent in the two lungs were placed in group 3. Patients in the first group formed 34 per cent. of the total number; the lesion was in the left lung in 58 per cent., in the right lung in 42 per cent. of these. In group 2 the left lung was affected more severely than the right in 59 per cent. of 982 patients; the right lung more than the left in 41 per cent. The third group contained 485 patients; in these the lesions were of equal extent on the two sides. Combining the first two groups, it appears that of 1,768 patients, representing 78 per cent. of the total number examined, 772, or 44 per cent., were affected exclusively or more severely on the right side, and 996, or 56 per cent., on the left side. The author, therefore, concludes that tuberculosis begins more often on the left side than on the right. The reasons for this are to be found in the poorer ventilation of the left lung; in the less adequate blood supply, which leads to stasis and the consequent retention of gaseous and organized products; in its smaller size; and in its compression by the aorta. All these factors, he thinks, render the left lung a more favourable ground for attack by the tubercle bacillus than the right.

W. C. A. STEFFEN (*Arch. of Ped.*, January, 1926, p. 50) reports two cases of pertussis, one of which was complicated by pneumothorax in a girl aged 7, and the other by pulmonary abscess in a girl aged 5; both recovered. Only two previous cases of pneumothorax in pertussis have been recorded—by Mallinowski in 1885 and Golmo in 1860 respectively; and only one example of pulmonary abscess in pertussis is on record, which was described by Northrup in 1883. In view of the relative frequency with which a rupture of the lung into the mediastinum occurs, with its resultant subcutaneous emphysema, it is surprising that not more cases of pneumothorax have been recorded. Golmo's patient had an extensive subcutaneous emphysema, and at the necropsy a left-sided pneumothorax and consolidation of the upper lobe were found. Steffen maintains that pulmonary abscess in pertussis is more frequent than the reported cases indicate, as instances of non-tuberculous cavities of obscure etiology are often encountered in children.

A. RADOVICI (*Presse Méd.*, April 10th, 1926, p. 453), considering the difficulty that sometimes arises in distinguishing between peripheral and central facial paralysis, draws attention to a new diagnostic sign. He finds that when the palm of the hand, especially the thenar eminence, is irritated by a needle a reflex muscular contraction can be observed at the point of the chin. The persistence or exaggeration of this reflex on the affected side is in favour of a central lesion. The absence of the reflex on the affected side with presence on the sound side indicates a peripheral lesion. The absence of the reflex on both sides is of no diagnostic significance since this may occur in normal individuals. The presence of the reflex on both sides in a patient with facial paralysis suggests a central lesion. The author gives brief details of 25 patients where his observation was tested. In 10 cases of peripheral paralysis the reflex was constantly absent on the affected side; in 11 out of 15 cases of central paralysis the reflex was present on the affected side.

J. NOGUER MORE (*Ar. Médica*, February, 1926, p. 29), who records four illustrative cases, states that the rashes caused by sanocrysin have features common to eruptions due to other causes, such as salvarsan, but present certain peculiarities. The appearance of the eruption depends on several factors. In some cases the eruption is an index of the toxicity of the product, while in others it points to idiosyncrasy on

the part of the patient. More describes four varieties of sanocrysin eruptions—namely, scarlatiniform, morbilliform, urticarial, and lichenoid types. The urticarial and lichenoid types he regards as the final stages of the scarlatiniform type. The course of the eruption is as follows: after a prodromal stage which may be absent, characterized by intense itching and localized in different situations, but chiefly on the back of the forearms and wrists or outer side of the legs, there appear hyperaemic military or lenticular puncta, which are discrete at first, but later become confluent, forming patches on the elbows, knees, and elsewhere. The temperature is about 100.4°, and the patient complains of headache and prostration. In eight or ten days' time, before the eruption has faded, fine or coarse desquamation appears, and in fifteen to twenty days everything has disappeared. As the eruption fades, the itching, headache, and photophobia recur, the urine diminishes in amount, and an oedematous infiltration appears, being most marked on the forearms and legs, leaving the face unaffected, and lasting for eight days. The prognosis of these eruptions is generally good, and their appearance does not contraindicate the continuance of sanocrysin treatment.

G. BOENNINGHAUS (*Deut. med. Woch.*, February 19th, 1926, p. 322) states that though it is a familiar fact that palatal palsy is not an infrequent sequel of diphtheria, it is not so well known that after recovery from the organic paralysis children may in rare cases show a functional palsy due to a mere neglect of use of the no longer paralysed palate. It does not seem to be recognized that a functional palsy of this kind may take place in adults and recur periodically, as in the following case reported by Boenninghaus. The patient was a woman, aged 25, who since an attack of diphtheria two and a half years previously used to have recurrent attacks of nasal voice every two or three months, lasting for about eight days and then suddenly disappearing. The nasal twang was absent during singing and there was no regurgitation.

J. V. KLAUDER (*Journ. Amer. Med. Assoc.*, February 20th, 1926, p. 536), who records two illustrative cases, states that erysiploid, which received its name from Rosenbach in 1884, was first described by Tilbury Fox in 1873. The salient clinical features are as follows. The disease is most frequent from May to September. The infection can always be traced to contact with dead animal matter or to crab bites or contact with crabs. The incubation period is from one to five days. A distinctive feature of the erythema is its purplish-red colour. The disease is confined almost exclusively to the hands, and rarely progresses above the wrists. The surface of the involved parts remains smooth. The subjective symptoms are sensations of burning, pricking, itching, and pain. A relapse of the erythema is not infrequent. German observers hold that erysiploid and swine erysipelas are identical, erysiploid, in their opinion, being a mild form of swine erysipelas. The causal organisms of the two diseases are likewise regarded as identical, differing only in virulence. The symptoms of swine erysipelas in man are those of erysiploid in an aggravated form. The swelling is much greater, so that the fingers are frequently immobilized. The itching, burning, and pain are considerable. Lymphangitis and glandular involvement are frequent, and the disease is sometimes fatal.

J. ENNEKING (*Nederl. Tijdschr. v. Geneesk.*, March 13th, 1926, p. 1063) refers to the cases reported by Gondsmit, Hammer, and Wolff, and Schüffner and Rnys (*Epitome*, October 10th, 1925, para. 283), and records the fourth case of Weil's disease that has occurred in Holland. The patient was a man, aged 32, in whom the diagnosis of Weil's disease was suggested by well marked jaundice, fever, petechiae, epistaxis, and blood in the urine. His serum caused agglutination of a strain of *Leptospira icterohaemorrhagiae* in a dilution of 1 in 250 on the seventh day of disease and three days later in a dilution of 1 in 10,000. Death occurred on the same day, and the autopsy showed haemorrhages in the various organs. A guinea-pig inoculated with the patient's urine died in ten days' time with typical symptoms of Weil's disease. The patient had probably been infected by rats which infested the place in which he worked.

613. Prophylaxis and Treatment of Measles.

J. A. MUÑOYENO (*Arch. de med., cir. y esp.*, March 20th, 1926, p. 550) states that the difficulty in obtaining convalescents' serum for the prevention of measles has been obviated by using the whole blood of the fathers or brothers of children exposed to measles. The technique is simple. Blood is withdrawn with aseptic precautions from a vein in the forearm into a syringe containing 2 to 3 c.cm. of a sterilized 10 per cent. sodium citrate solution to prevent coagulation. An intramuscular injection in one or two regions is given at once. In the case of convalescents' serum the dose is 1 c.cm. for each year, or 1/2 c.cm. for each six months. If the blood of brothers or fathers who have had measles some time previously is used, the dose should be increased three times. If it is desired to prevent the disease entirely, the injection should be given before the sixth day of the incubation period, but if attenuation is aimed at with permanent immunization the injection should be given later. This form of prophylaxis should be employed in all cases in which it is expected that measles may assume a malignant character, such as in scrofulous and rickety children and in those convalescent from a severe illness, especially of the respiratory system. Therapeutically the method is indicated in all cases of measles with severe respiratory complications. In such cases convalescents' serum is best, but if it is not available, the whole blood of the fathers or brothers who have had measles should be used after a clinical and biological examination of the donor has been made. The amount of blood to be injected is three times that required in the case of convalescent serum, and if the attack of measles has occurred a long time previously it should be four times as much.

614. Atypical Typhoid Infections.

A. LANDAU and M. FEIGIN (*Arch. Intern. Med.*, January 15th, 1926, p. 32) record six illustrative cases, in patients aged from 27 to 60, of typhoid infection in various localizations entirely devoid of the clinical symptoms of abdominal typhoid and probably without its characteristic abdominal changes. They maintain that the existence of typhoid bacteriemia and a positive Widal reaction in so high a dilution as 1 in 400 or 1 in 800, together with a high temperature, is not always an absolute proof of abdominal typhoid, as such a syndrome may be observed in other localizations of typhoid infection, especially of the liver and gall bladder. Those states of typhoid infection, although in some ways similar to typhoid fever, differ from it in (a) the presence of leucocytosis with neutrophilia, (b) the absence of rose spots, and (c) the absence of changes in the lymphatic system of the alimentary tract. Leucopenia with neutropenia, which forms one of the most characteristic symptoms of abdominal typhoid, probably does not depend on the biological quality of the typhoid bacillus, but on its secondary seat in the lymphatic system of the alimentary tract.

Surgery.

615. Obstruction of Small Intestine.

J. MCKENTY (*Canadian Med. Assoc. Journ.*, March, 1926, p. 260) discusses the diagnosis and treatment of obstruction of the small intestine in adults, based upon a study of 95 cases. He considers that the high mortality is due to delay in operating, which in primary cases is the result of doubt as to diagnosis owing to inadequate knowledge of the early symptoms, which are scarcely mentioned in the textbooks. His observations show that pain, vomiting, and absolute constipation unresponsive to enemata warrant a diagnosis of obstruction, the clinical picture of primary acute obstruction during the first twenty-four hours consisting only of peristaltic pain, vomiting, and constipation, with a soft flaccid abdomen and rarely a mild degree of shock. During the second day slight abdominal distension occurred in 25 per cent. of the cases and an accelerated pulse in 30 per cent.; while during the third day the vomiting becomes stercoraceous, the pulse more rapid, and the distension more marked. In obstruction secondary to peritonitis the symptoms appear as an exaggeration or recurrence of those of the pre-existing peritonitis; unduly persistent "gas pains," recurrence of vomiting on the third or later post-operative day, and negative results after enemata, are diagnostic points. In the early stage of primary obstruction a release operation will effect a cure in 90 per cent. of cases; in the late stages with symptoms of severe toxæmia drainage of the proximal loop by enterostomy is essential. McKenty concludes that, while improved therapeutic methods and the more frequent use of enterostomy in the secondary and late primary cases will cause some decrease in mortality, any marked decrease can only come from earlier diagnosis and operation.

616. Tumours caused by Oil Injections.

R. MOUGNEAU and L. MAGHMEI (*Journ. de Méd. de Bordeaux et du Sud-Ouest*, March 25th, 1926, p. 257) report the case of a woman, aged 60, who had five firm painless tumours, ranging in size from that of a chestnut to that of a hazel-nut, on the outer surface of the middle third of the thigh. These tumours appeared two months after the injection of camphorated mineral oil during an attack of influenza. Each tumour was firmly adherent to the fascia lata and one was attached to and moved with the subjacent muscle. The tumours were of cartilaginous hardness, and consisted chiefly of fully developed fibrous tissue which appeared to invade the adjacent adipose tissue. In certain areas there were traces of granulation tissue containing lymphocytes, giant cells, and a few epithelioid cells. No trace of mineral oil could be found. The muscle fibres adherent to one of the tumours had been invaded by bands of fully developed connective tissue. SABRAZES (*Ibid.*, p. 258) reports two similar cases, in which pseudo-tumours of the abdominal wall appeared after injections of camphorated mineral oil. In some parts the tissue surrounding the oily deposits resembled that of an epitheliomatous metastasis; in other parts, giant cells, lymphocytes, and plasmocytes, such as are found surrounding a foreign body, were present. Sabrazes considers that these tumours cannot be regarded as true epitheliomata.

617. Surgical Treatment of Bronchial Asthma.

F. ERKES (*Zentralbl. f. Chir.*, March 20th, 1926, p. 718) finds in the scanty records of cervical sympathectomy for the relief of bronchial asthma that the operation was performed on the left side in the majority of cases. In a few instances, resection was performed on the right side, after failure of a previous resection of the left sympathetic cord. Hitherto no test to indicate which side should be selected for operation has been described by any writer, except that Hesse found in cases of cardiac asthma that signs of irritation of the branches of the cervical sympathetic occurred more frequently on the left side, indicating it as the site for operation. Hesse also states that in cases of the so-called "asthma cardiaca dextra" the indications of cervical sympathetic irritation and pain are entirely or predominantly found on the right side; this would appear to indicate resection of the right cervical sympathetic. Erkes records the case of a workman, aged 36, whose illness commenced in 1917 after exposure to cold while on active service. At first the attacks occurred at intervals of about four weeks, and each attack lasted for about an hour. They grew more severe and frequent, until by 1920 they recurred every eight or ten days, and each attack lasted four or five days. The patient was incapacitated for six months, being confined to bed during the attacks, which were accompanied by a sensation of strangulation. The pupils were usually equally dilated during the attacks, but occasionally the right pupil only was affected. Medicinal and x-ray treatment failed to give relief. The right cervical sympathetic from the superior to the inferior ganglion was resected by von Flörcken's method and the wound healed by first intention. After the operation the attacks were less frequent and of shorter duration. Histologically the ganglion cells showed no appreciable changes and the nerve fibres and connective tissue were apparently normal. Four months later the patient reported that there had been no severe recurrence; he was in good health, and fit for work.

618. Estimation of the Date of a Fracture.

O. ANDREI (*La Chirurgia degli Organi di Movimento*, February, 1926, p. 254) thinks that it is possible to determine the age of a fracture by radiography, and cites an experience of 140 cases of fracture of different durations. He bases his estimations on the opacity, volume, and delimitation of the callus, on the characters of the line of fracture, and on the reconstituted bony tissue. In simple fractures of the shaft without displacement of the fragments the first change noted is a blunting of the edges and of the bony spicules, which shows about the end of the second week. Callus begins to appear between the sixteenth and twentieth days; it is clearly delimited at the third or fourth month, and reaches the opacity of normal bone at the eighth or tenth month. In the first year the callus shows no lamellar structure. The line of fracture disappears between the sixth and eighth months to become more opaque later, in the second year. In fractures with displacement the callus does not become delimited until later, about the sixth or seventh month, and is not reduced so readily as in simple fracture without displacement. In fractures of the fingers, blunting of the edges is observed as early as the first week, and callus appears as a delicate white cloud between the second and third weeks; it becomes clearly defined at the end of the fourth month, and between the sixth and seventh months it reaches the opacity of normal bone.

619. Chronic Abscess of the Tibia.

AUVRAY (*Dull. et Mém. Soc. Nat. de Chir.*, March 20th, 1926, p. 321) records a case of chronic abscess in a patient, aged 24, who had received a kick on the lower end of the tibia some years previously. The pain lasted only a few hours and there was no bruising. Six months later there was an acute exacerbation of pain which compelled the patient to rest. Since that time there had been intervals of freedom from all trouble, alternating with attacks of pain. Radiograms taken at different times demonstrated no bony lesion. Two years later, when seen by Auvray, there was some swelling round the ankle, but the skin appeared normal. On palpation over the tibia there was a well marked spot of localized tenderness near the lower epiphysis; pressure here caused acute pain. The diagnosis was then made of a localized abscess of the bone, and this was confirmed by radiographic examination. At the operation the bone was opened and a chronic abscess with thick pus was found in the lower end of the tibia. The pus was sterile and gave no growth on culture. The condition appeared to be a chronic osteomyelitis, probably originating from the kick. The patient had some boils at that time, and it is suggested that the infection may have arisen from this source.

620. Extraction of Needles and Fish-Hooks.

O. SUSANI (*Zentralbl. f. Chir.*, March 27th, 1926, p. 791) describes a simple and easy method of extracting needles and fish-hooks if less than 2 mm. in diameter and more than 3 mm. in length. The method is inapplicable when there is evidence of active infection, or when the foreign body is close to easily injured structures, such as large blood vessels or nerves. After a preliminary x-ray examination to determine the position of the foreign body, a 2 per cent. novocain-adrenaline solution is injected; a Record hypodermic needle of suitable calibre and fitted with a pear-shaped or conical metal plug, which serves as a handle, is thrust with aseptic precautions through a layer of sterile gauze into the skin and with the assistance of the fluorescent screen is entered in the axis of the foreign body, which is engaged by the needle-point. With a little manipulation the foreign body is made to enter the lumen of the needle, and the needle is then withdrawn with the foreign body in its lumen. In the case of fish-hooks and other barbed foreign bodies a larger needle is guided to engage the barb; a small incision may then be made and the extraction completed with forceps. The author has removed needles from the knee-joint with complete success; in one case the needle was broken off at the border of the patella, and in the second case it was broken and lying free in the joint. Both patients recovered full and painless movement of their knee-joints.

Therapeutics.

621. Administration of Adrenaline.

B. L. VELÁZQUEZ (*Arch. de med., cir. y esp.*, March 27th, 1926, p. 585) states that administration of adrenaline gives rise to a series of reactions by which its efficacy can be estimated—namely, hyperglycaemia, glycosuria, rise of blood pressure, and change in the pulse rate. The most constant reactions are the changes in glycaemia and in the blood pressure. Administration of adrenaline by the mouth is accompanied by hyperglycaemia but not by any obvious change in the blood pressure, which justifies the hypothesis that the drug is conveyed to the liver, where it is destroyed. Hypodermic administration of adrenaline causes considerable retardation and diminution of its action, the proportion being 1 to 4 as compared with the intravenous route. Intramuscular injection is less efficacious still, its activity being 1 to 6 or 1 to 8 compared with the intravenous route. Rectal administration gives rise to a glycaemic rate which does not exceed or is even lower than that obtained by the gastric route, while the blood pressure rates are slightly above those obtained from administration of adrenaline by the mouth. In contrast with the intravenous route the activity of absorption of adrenaline by the rectal route is 1 to 20 or 1 to 25.

622. Ephedrine in Bronchial Asthma.

H. E. MACDERMOT (*Canadian Med. Assoc. Journ.*, April, 1926, p. 422) reports the results obtained from the use of ephedrine for a period of three months in a group of twenty cases of severe and recurrent bronchial asthma in patients aged from 14 to 60. He found that this alkaloid produced well marked antispasmodic effects, which lasted longer than those of adrenaline, and that the treatment might be repeated safely during a prolonged period. In some cases 25 mg. was found a sufficient dose, while 50 mg. caused sensations of quivering and nervousness, with some headache, thirst, and

giddiness; other patients required a dose of 50 mg. In most cases relief was obtained in from two to five minutes after swallowing a capsule of the remedy, with a feeling of relaxation in the chest, and in some cases a notable diminution in the mass of râles. The effect came more rapidly, as a rule, when the alkaloid was taken on an empty stomach. Many patients obtained an entire night of comfort after a single dose of ephedrine, or during the day were able to take exercise without distress. Protection appeared to last for about six to eight hours; little or no change in the blood pressure was observed. MacDermot recommends that the initial dose should be 25 mg.; this may be increased if required.

623. Ether in the Treatment of Suppurative Otitis Media.

G. B. MCAULIFFE (*Med. Journ. and Record*, April 21st, 1926, p. 503) recommends the use of ether in treating suppurating conditions of the middle ear. After cleansing the ear with a solution of boric acid it is partly dried and then filled with ether, the patient remaining recumbent until the ether has evaporated. This treatment is given twice a day. The patient is said to experience the same sensation as that given by hydrogen peroxide, and the method is described as being easy for home treatment. In the majority of cases it was found to be very beneficial and no ill effects were encountered. It is not applicable in cases of chronic mastoiditis, and is without value when the perforation in the drum is insufficiently large to allow passage of the ether. Short details are given of sixteen cases, and the author refers to Waterhouse's article on the use of ether in the peritoneal cavity and the bladder (*JOURNAL*, February 6th, 1915, p. 233).

624. Sanocrysin Treatment of Tuberculosis.

F. R. DE PARTIARKOYO (*Arch. de med., cir. y esp.*, March 6th, 1926, p. 433) reviews the literature, and records his observations on cases of pulmonary tuberculosis treated in the Guadarrama Sanatorium by sanocrysin. His conclusions are as follows: (1) If employed with caution sanocrysin does not usually give rise to any bad effects. (2) It does not appear to have any bactericidal action. (3) It seems to be principally indicated in recent cases with effusion. In fibrotic cases its action is nil. (4) The doses should be small at first (10 cc.) and gradually increased to a gram or more. The injections should be given at first every third or fourth day and at the end of the course every tenth day. (5) In order to form an exact estimate of the therapeutic value of the drug, it should be given, not at the beginning of the disease, but after some improvement has been obtained by a rest cure and the condition has become stationary. Otherwise sanocrysin might be credited with the disappearance of fever, diminution of expectoration, and improvement in the auscultatory and radiological findings, which are really due not to the drug but to hygienic treatment. (6) While sanocrysin is of some value in the cases mentioned, it is not indispensable in the treatment of pulmonary tuberculosis.

625. Hexylresorcinol.

H. M. N. WYNNE (*Minnesota Med.*, April, 1926, p. 156) reports his experience in the use of hexylresorcinol in urinary tract infections in women. He recommends its administration by gelatin capsules containing a 25 per cent. solution in olive oil, one being taken directly after meals three times a day for three days, and gradually increasing up to four capsules three times a day by about the eighth or tenth day. Of three cases of chronic *B. coli* infection treated by courses of from 200 to 400 capsules one showed but little improvement, while the other two obtained complete relief of symptoms and sterilization of the urinary tract. Cecal infections appeared to be more susceptible to the treatment than the bacillary, and clinically the drug was found to have a distinctly antiseptic action in the urine of patients suffering from either infection. Wynne adds that it is important to commence with small doses, increasing them gradually and continuing the full doses over a considerable period of time, during which alkalis should be avoided and the fluid intake regulated to allow of sufficient concentration of the drug in the urine.

626. Dichloramine-T in the Treatment of Wounds.

D. S. ADAMS (*Boston Med. and Surg. Journ.*, April 22nd, 1926, p. 737) reports his experience of using dichloramine-T in clean and septic wounds for nearly seven years. He adds to 25 grams of crystalline dichloramine-T enough chloroform to make 500 grams by weight, and he has found this 5 per cent. solution adequate for all purposes. The mixture was placed in 4-oz. brown bottles, and proved stable if kept cool and in the dark. Before its use the affected parts were shaved, cleansed with benzine, and 70 per cent. iodine applied. After excision of any foreign matter and the devitalized soft tissues the affected parts were thoroughly covered with dichloramine-T, and partial, or complete, skin closure effected. In

probably infected wounds, such as those due to street accidents, the deeper parts were packed with gauze strips saturated with dichloramine-T, and hot saline or saturated boric acid dressings were applied. The first dressings usually followed after forty-eight hours, the packs being removed and fresh dichloramine-T sprayed over the wound or applied to the surfaces on cotton swabs. Adams found that in head injuries dichloramine-T might safely be applied to dural and subdural structures; in abdominal injuries its use is not advised, nor for burnt surfaces, nor in suppuration of the pleura or peritoneum. He concludes that by this method a simple, uniform technique of wound treatment is easily obtained with a minimal expense, and a rapid formation of healing surfaces. The earlier dressings are associated with an unpleasant burning sensation which lasts for a few minutes, but is compensated by the absence of toxic symptoms. Favourable results were obtained in such bone conditions as osteomyelitis and compound fractures, and there was a total absence of infection with gas-forming bacilli.

Disease in Childhood.

627. Pneumothorax in Young Children.

A. MONCRIEFF (*Brit. Journ. Child. Dis.*, January-March, 1926, p. 37), who records a case in a male infant aged 1 year 10 months, states that the occurrence of pneumothorax in babies or young children is comparatively uncommon. He points out that though many of the recently recorded cases seem to have been tuberculous in origin, tuberculosis, especially in young children, is not a common cause of pneumothorax. In his own case the negative Pirquet reaction and favourable issue suggested that the case was not tuberculous but was probably caused by the rupture of a subpleural emphysematous vesicle in the course of a bronchopneumonic process in the right lung. The absence of any pus in the pleural cavity was against rupture of a subpleural abscess, which is the commonly accepted cause in post-pneumonic cases.

628. Nephrolithiasis in Children.

S. SIMONS (*Nederl. Tijdschr. v. Geneesk.*, March 27th, 1926, p. 1290), who records two cases, in a girl aged 5 and a boy aged 9 respectively, states that since 1900 only two examples of renal calculi and two of stone in the bladder have been met with in children at the Amsterdam University clinic for internal diseases. In Italy and Hungary, on the other hand, renal calculi in children is much less rare. Although the diagnosis can only be made with certainty by x-ray examination, as was done in Simons's cases, the possibility of nephrolithiasis should be considered in cases of renal haemorrhage in children for which no obvious causes can be found. Both Simons's patients were given 30 grams of glycerin a day mixed with equal parts of water. In the boy a stone consisting of calcium carbonate, and measuring 9 by 6 mm., was rapidly expelled. In the girl, however, in whom the stone, according to the skiagram, was much larger, the treatment had no effect, and the associated pyelitis was treated in the ordinary way. Although glycerin is not always of avail, it serves to expel small stones and thus helps to prevent the formation of large calculi.

629. Infantile Otitis Media.

DANA W. DRURY (*Boston Med. and Surg. Journ.*, January 21st, 1926, p. 96) has analysed the characters of otitis media as it occurs in very young babies. Otitis is favoured in infants by the fact that the tympanic cleft is filled with mucus and fluid, and both are excellent media for the growth of pathogenic bacteria. The upper part of the cleft is comparatively wide and there tends to be a large collection of inflammatory products in the attic region. In addition to this the cleft is incompletely divided into a number of small cavities by septa of mucous membrane. The Eustachian tube is very short and wide, its musculature is very flabby and ill developed, and it provides an excellent path for infection. Thus the middle ear in infants is very prone to be infected, and drainage is difficult owing to the anatomical nature of the cleft. It is often a matter of difficulty to localize the trouble in a small baby, but the ears of a child in pain should be examined. The drumhead is horizontal, the meatus often swollen, and a red engorged membrane may be covered and hidden by a layer of desquamated cells, making the examination difficult. There are usually signs such as tenderness, injection, and bulging, but any of these may be absent. Often there is a protruding white opaque membrane, and incision releases a quantity of mucus, indicating a low-grade infection. The temperature is usually raised in the evening but normal in the morning. Incision of the membrane is the correct

treatment and may have to be repeated. Persistence or frequent recurrence of the discharge points to a naso-pharyngeal focus of infection, and adenoids should be suspected; if present they should be removed at once. In infants the tendency is to antral and mastoid involvement rather than to intracranial or labyrinthine trouble. Once this is evident the antrum should be opened and drained, but enough time may be allowed for a protective zone to form. In certain cases there is formation of an abscess in the antrum without any infection of the middle-ear cleft. The best sign of mastoid infection is flattening out or sagging of the posterior wall of the external meatus.

630. Amoebic Dysentery in Children.

J. M. PARDO (*La Med. Ibera*, February 26th, 1926, p. 245, and *Arch. de med., cir. y esp.*, February 27th, 1926, p. 398), who records two cases in a brother and sister, aged 2 years and 9 months respectively, emphasizes the intensity of the intestinal symptoms in contrast with the low degree of fever. The urine in both cases showed a large quantity of nates. The heart always remained in a satisfactory condition. During the course of the disease a state of dehydration set in resembling uraemia owing to its being associated with oliguria and restlessness, but was readily overcome by hydrotherapy and ingestion of water. In the treatment of amoebic dysentery in children the dose of emetine should be gradually increased until 1/2 cg. per kilo of body weight is reached. The work of Benrrior, Clapier, and Marconix induced Pardo to associate stovarsol with emetine in doses of 0.3 cg. daily with satisfactory results.

Ophthalmology.

631. Metastatic Intraocular Mycosis.

F. H. VERHOEFF (*Arch. of Ophthalmol.*, May, 1926, p. 225) records a case of unilateral intraocular mycosis derived by metastasis from an undiscovered systemic focus, with hepatic and endocardial involvement. A man, aged 60, who was an inspector of cars which had contained cattle, complained of lassitude, weakness in the right hand, and fever; he later developed a metastatic purulent right endophthalmitis necessitating enucleation. He had chronic mitral disease, probably due to subacute bacterial endocarditis, with slight hepatic enlargement, and a small sore on the right shin was excised subsequently. The Wassermann and Widal tests were negative and blood cultures remained sterile. The ocular infection being confined to the interior of the eye was obviously metastatic in origin, and the persistent fever, enlarged liver, and endocarditis indicated the presence of other foci, though the portal of entry of the organism and the site of the primary focus could not be discovered. The micro-organisms, found only in the subretinal exudate, were closely related to the actinomyces group since they produced abscesses and consisted of filaments which formed granules and peripheral clubs, but they differed in that the filaments were more delicate, unbranched, and Gram-negative; they were also not acid-fast. Following enucleation of the eye the fever, enlarged liver, and endocarditis persisted, in spite of treatment, till death five months after the onset of the first symptoms. Although such ocular involvement is exceedingly rare Verhoeff considers it is possible that systemic infection of a milder type without ocular involvement may not infrequently occur and escape recognition because no lesions accessible for bacteriological examination are produced.

632. Charting the Visual Field.

M. U. TRONCOSO (*Brit. Journ. Ophthalmol.*, May, 1926, p. 280) advocates the adoption of a new method of recording the area of the visual field with a view to simplifying the present elaborate procedure. As mapped now, the findings in the perimeter have to be inverted twice; this method leads to confusion and misunderstanding, and is the outcome of a faulty mental habit violating the anatomical rule which requires the subject to be considered as standing in front of the observer. He points out how much easier it would be to follow this anatomical rule and consider the visual cones of the patient projected into the space in front of the observer—the right field in front of the right eye and the left in front of the left eye—recording the fields as they are found in the arc of the perimeter with only one inversion instead of two. This method does not involve any change in instruments except that the campimeter should be made of cloth so that pins may be inserted, and marking the limits and defects in the field on the side facing the operator. It would be advantageous also to standardize the notation of the meridians in the charts, which at present is confusing. Troncoso claims that as the result of these changes it will be easier to under-

stand and record the monocular and binocular fields of fixation than is at present the case after the inversion necessary for transferring them to the position of the observer's eye. Similarly, abnormalities in mobility of the eye will be rendered less difficult to define when considered in the standard anatomical position without reversing the findings.

633. Intraorbital Anaesthesia.

M. D. IGOVE (*Amer. Journ. Ophthalmol.*, April, 1926, p. 260) describes the technique and applications of intraorbital anaesthesia by the perineural injection of a 4 per cent. solution of novocain about the area of the ciliary ganglion in order to block the sensory nerves of the cornea, sclera, and iris. The injection is made through the skin at the junction of the lower and outer border of the orbit between the external and inferior recti, the needle being directed slightly upward and inward (for about 5 cm.) to avoid striking the floor of the orbit, and the entire amount of the novocain is injected posteriorly. Ample time must be allowed for absorption to take place, the best time to operate being about half an hour later. No toxic effects have been observed in over a thousand injections of novocain in amounts varying from one-half to 4 c.cm. From his own experience Igoe advocates its use in operations for cataract, glaucoma, enucleation, and when giving painful subconjunctival injections such as of mercury.

Obstetrics and Gynaecology.

634. Vaginal Hernia.

L. M. MILES (*Surg., Gynecol. and Obstet.*, April, 1926, p. 482) reports two new cases of vaginal hernia and discusses under the inclusive term "pelvic hernia" all hernias through the pelvic floor, subclassifying them as perineal, pudendal, or vaginal (anterior or posterior) according to the point of egress. Nine cases of vaginal hernia previously reported in the literature are considered. While they may be congenital the majority are acquired, following the trauma of pregnancy or child-bearing. Hernias between the rectum and vagina usually develop gradually; of those reported only two appeared suddenly, and only one showed signs of strangulation. Symptoms are more marked in the anterior variety than in the posterior, incapacity for work owing to the inconvenience of the protruding mass being the chief complaint rather than pain. The diagnosis from rectocele and cystocele constitutes the chief difficulty, there being no peritoneal sac in these latter. Since the internal ring is large these hernias disappear in the recumbent position, only to reappear in the erect posture or on straining or coughing, and replacement is accompanied by gurgling from the contained coils of intestine. The best method of treatment is by a perineal operation with excision of the sac and repair of the perineum combined with an abdominal operation to obliterate the cul-de-sac.

635. Spontaneous Birth of the Transversely Placed Head.

R. BRÜHL (*Zentralbl. f. Gynäk.*, March 13th, 1926, p. 646) records in detail the labour of a 2-para, aged 25, whose pelvis was somewhat flattened and had a true conjugate of 9.25 cm.; the previous labour had terminated spontaneously at seven and a half months. The head was delivered with the sagittal suture in the transverse diameter of the outlet (this diameter being of normal size) with the left arm behind and the right in front. Uterine contractions were forcible throughout labour, which lasted twenty-six hours; the child weighed 3.5 kg. and was 53 cm. in length. That the foetal head should pass through the pelvis with its long axis persistently in the transverse diameter appears not to be excessively rare; in the German records Brühl has found 22 such cases of vertex presentation, 4 of face presentation, and 23 of brow presentation. The etiological factors favouring such a mechanism of birth are not clear; many cases have been first labours, pelvic contraction has not commonly been present, the foetuses have been of very large as well as of very small dimensions, but as a rule the patients have been multiparae with flaccid soft parts at the pelvic outlet. According to Heinrichs 1 in 10 of brow presentations is characterized by persistence of the sagittal suture in the transverse plane.

636. Unusual Varieties of Extrauterine Pregnancy.

A. SCHWARTZ (*Paris Méd.*, March 27th, 1926, p. 297) reports some atypical forms of ectopic gestation. One patient complained of frequent copious uterine haemorrhages, persisting for one or two days, and recurring after a few days. In the intervals a large tumour could be felt to the right of the uterus; after a haemorrhage it disappeared. A diagnosis of

ectopic pregnancy was confirmed at operation. There was a right tubal pregnancy situated in the ampulla, the tube was dilated and permitted the blood to escape into the uterine cavity. In another case the patient complained of pain and metrorrhagia, preceded by amenorrhoea persisting for one month. The pain was particularly severe at the moment of defaecation. While under observation the patient had a severe haemorrhage from the anus. Median laparotomy was performed and a large tubal pregnancy was found attached to a coil of small intestine and closely adherent over a large area to the lower part of the sigmoid where it had perforated. The right ovary and tube were removed, the adhesions were separated with difficulty, and the sigmoido-rectal perforation sutured. A year afterwards the patient had a normal confinement. In a third case, the patient, previously quite regular in menstruating, had gone nine days beyond the usual time. This was followed by small daily haemorrhages. There was a fluctuating tumour to the right of the uterus as large as a foetal head. Laparotomy disclosed a tubo-ovarian pregnancy, almost filling the true pelvis. There was no intraperitoneal haemorrhage, but on puncturing the cyst 400 grams of almost pure blood was evacuated. The right adnexa were removed and the cyst wall sutured. The ectopic pregnancy had developed in a tubo-ovarian cyst. A fourth case was that of a patient operated on by the author in 1923 for a left ectopic pregnancy. In 1925 there was amenorrhoea for twelve or fifteen days followed by slight pain and uterine haemorrhage for eight days, when signs of collapse occurred followed by sudden recovery. The uterine cavity was so dilated that Lévy-Solul diagnosed very early uterine pregnancy. Under anaesthesia nothing abnormal was found in the pelvis. The uterus was cautiously curetted. Recurrent pain and haemorrhage necessitated laparotomy, and an ovum as large as a pigeon's egg, containing an embryo 12 mm. in length, was found with its membranes solidly adherent to the upper part of the rectum and neighbouring peritoneum—hence the absence of any pelvic tumour. This was a case of abdominal or tubo-abdominal pregnancy complicating an ordinary uterine pregnancy. The patient made a complete recovery. It is remarkable that in three of the above cases there was no trace of intraperitoneal haemorrhage.

637. Intrauterine Transplantation of Ovary.

R. B. P. MONSON (*Med. Journ. of Australia*, February 27th, 1926, p. 229) discusses intrauterine transplantation of the ovary and its clinical applications. He has found that the ovary can be successfully transplanted into the cavity of the uterus of the rabbit provided that its blood supply is preserved intact. Failing this, it was found that the transplanted ovary completely disappeared and definite uterine changes occurred, the body becoming flaccid, cylindrical, and elongated even to twice its normal length, and surrounded by dense deposits of fat with a change in colour to pale yellow. Monson refers to the results obtained by Tuffier and Estes in the human subject, the former opening the uterus on its posterior wall after previous dilatation of the cervical canal with tents for twelve hours, and then suturing the ovary into the uterine cavity so that one-third of it projects into the uterus. Estes adopts the method of suturing the ovary into the uterine cornu. Menstruation continued in all the twenty-nine cases operated upon by Tuffier, and one gave birth to a living child at term. Of twenty-seven cases reported by Estes, all but one continued to menstruate, while six became pregnant and four carried two pregnancies to a successful termination. No mortality has so far been recorded, and the operation appears to be justifiable in suitable cases when double salpingectomy is unavoidable and the patients wish to retain the possibility of child-bearing.

638. Diet in the Pre-eclamptic State.

V. J. HARDING and H. B. VAN WYCK (*Journ. Obstet. and Gynaecol. of the British Empire*, 1926, Spring Number, p. 17) have investigated the effect of various diets in patients showing evidence of the pre-eclamptic state as indicated by oedema, high blood pressure, headache, and blurring of vision. They find that protein or fat even in excess produces no ill effects, but by strictly limiting the intake of sodium chloride they were able in all cases to avoid the occurrence of convulsions. They agree, therefore, with the view recently expressed by de Wessclow and Wyatt that there is no necessity to restrict protein intake in the majority of pre-eclamptics. They advocate that the patient should be put to bed and given salt-free food until salt excretion in the urine reaches and remains at a minimum of 2 to 3 grams a day. The oedema becomes much diminished, and then 3 grams of salt, which is sufficient to maintain equilibrium, is added to the daily diet. It is said, therefore, that ordinary hospital or home diets can be used in the treatment of pre-eclampsia, provided they are salt-free. The albuminuria does not always disappear completely. Violent purgation

and forced intake of fluids are unnecessary forms of treatment. The authors are inclined to consider the oedema and nephrosis of the pre-eclamptic state as symptomatic of generalized vascular disturbance. They find that accompanying the progressive hydraemia of pregnancy demonstrated by Plass and Bogert's estimation of the plasma proteins there is a coincident increase (maximum about the seventh month) in the blood chloride concentration. The inclusion of one week in four on a salt-free diet is suggested as a measure which may be employed in the pre-natal clinic with the object of avoiding eclampsia and pre-eclampsia.

639. Anterior Abdominal Hysterotomy.

P. OGIZU (*Surg., Gynecol. and Obstet.*, April, 1926, p. 523) discusses the indications for anterior abdominal hysterotomy for the interruption of pregnancy and sterilization. He describes his technique, which he claims fulfils all the requirements of the ideal operation, since it is simple, can be performed at any time during the pregnancy, entails a minimum loss of blood, secures complete sterilization, and is capable of performance under any form of anaesthesia within half an hour. Through a mid-abdominal incision the uterus is opened anteriorly, and after delivery of the embryo and placenta 1 c.cm. of pituitrin is injected directly into its musculature and the wound closed by two continuous catgut sutures. One tube is then clamped at its isthmus portion and picked up so that a knuckle is formed, under the apex of which a silk ligature is passed and tied first over one limb and then over the other; the apex is then cut off and both raw surfaces cauterized. The same procedure is then repeated on the other tube. By this method the anastomosing circulation between the uterine vessels and the ovary is not interrupted. Ogizu considers that the operation is indicated for women suffering from chronic debilitating disease and in cases where a continuation of the pregnancy would endanger the patient's life. Such conditions are: (1) pulmonary tuberculosis accompanied by fever, rapid pulse, sweats, and loss of weight; (2) such cardiac diseases as aortic regurgitation and mitral disease with attacks of decompensation, and in auricular fibrillation and myocardial degenerations due to chronic infections; (3) chronic nephritis and hypertension; and (4) recurrent toxæmias, complicated diabetes, certain nervous and mental diseases such as chorea, such blood diseases as pernicious anaemia and leukaemia, and severe thyroid toxæmia. He finds that patients stand the operation well and recover rapidly.

Pathology.

610. Anaerobic Bacteria in Appendicitis.

M. WEINBERG, C. RENARD, and J. DAVESNE (*C. R. Soc. de Biologie*, April 9th, 1926, p. 813) have studied the microbic flora of the inflamed appendix, particularly the anaerobic bacilli of the gas gangrene group. Of these *B. perfringens* was much the commonest, being present in about 33 per cent. of cases; occasionally *B. sporogenes* was found, and *B. fallax* has been recovered recently on two occasions. In the course of an investigation into eight cases of appendicitis the authors isolated *B. histolyticus* twice and *V. septique* twice; in one case these two organisms were associated. In the first case—acute appendicitis and periappendicular abscess—the two organisms were present together with an anaerobic streptobacillus, an anaerobic Gram-positive bacillus forming zoogloea in liquid media, and *B. coli*. The strain of *B. histolyticus* was highly toxic to rabbits. In the second case—acute appendicitis during influenza—*B. coli*, a staphylococcus, and *V. septique* were isolated. In the third case—putrid gangrenous appendicitis in a child aged 3—an enterococcus, *B. pyocyaneus*, and *B. histolyticus* were found; the last two organisms were very pathogenic for guinea-pigs. From these results and from the work of other authors it is clear that the pathogenic anaerobes of the gas gangrene group are frequently found in acute appendicitis; the proportions in which each is present have yet to be worked out. The authors consider that these organisms are concerned in the etiology of the disease. In favour of this is the success that has attended the administration of polyvalent anti-gangrenous serum, advocated by Weinberg eight years ago. They believe that when the bacteriology of the inflamed appendix is fully known, the serum treatment of appendicitis should be even more valuable than at present.

651. The Cause of Acute Polymorphic Erythema.

C. LEVADITI, S. NICOLAU, and P. POINCELOUX (*Presse Méd.*, March 17th, 1926, p. 340) describe the isolation of an organism which they regard as the specific cause of acute polymorphic erythema. In March, 1925, one of the authors became suddenly ill with a septicæmic disease characterized by

three successive eruptions on the skin of macules, papules, and small nodules, accompanied each time by a fall in the temperature; there were also severe pharyngeal pain. Convalescence followed on the twelfth day, but the joints remained painful for a fortnight or more afterwards. Two blood cultures were taken, and the contents of a papule examined. In each case an organism was grown which they describe as being a non-capsulated, non-sporing, Gram-negative bacillus, 2 to 3 μ long by 0.5 μ broad, growing in chains, and showing marked pleomorphism. This was especially noticeable in artificial cultures, in which cocci and fusiform bacilli appeared. Growth was best in serum or aseptic broth to which a small fragment of rabbit testicle had been added; large flocculi formed on the walls of the tube, but the medium itself remained clear. On blood agar very small dew-drop colonies were seen. The organism is a facultative anaerobe; it was destroyed by heat at 60°C. in half an hour; it formed no toxin, and was found to be virulent to rabbits, guinea-pigs, mice, and monkeys. Injected intratesticularly into rabbits it gave rise to an orchitis followed by general peritonitis. Injected intravenously it might give rise to arthritis or to an erythematous eruption on the skin. Immunity was easily established. The authors consider that this organism is probably responsible for the polymorphic erythema and for erythema nodosum.

652. The Relation between Malta Fever and Infectious Abortion of Cattle.

G. FAVILLI (*Lo Sperimentale*, April, 1926, p. 41) contributes to the vexed question of the relation between Malta fever and infectious abortion of cattle. In 1924 and 1925 there was an epidemic of Malta fever in Florence and in other parts of Italy, where the incidence of this disease is normally very low. Many of the cases were traced to infection from goats, but in several others the method of infection remained undetermined. The author collected a number of strains of *B. melitensis* from human beings and made a comparative study of them with *B. abortus*. Neither morphologically, culturally, nor biochemically could any difference be made out between the two organisms. Their pathogenicity to laboratory animals was likewise similar. The subcutaneous injection into guinea-pigs of 1/4 to 1/2 c.cm. of a suspension of either organism, made by rubbing up a forty-eight hour culture in 5 c.cm. of saline, proved fatal in about a week; at autopsy the organisms were recovered in pure culture from the local abscess, the liver, spleen, and bile. In the hands of other workers, however, the pathogenicity of these organisms to guinea-pigs has proved very low. Whether these results of Favilli's are to be attributed to an increase in virulence is doubtful. Agglutinating serums were prepared by the injection of rabbits with six strains of *B. abortus* and five strains of *B. melitensis*. Cross-agglutination completely failed to distinguish between the two organisms; nor was the absorption test any more successful. The effect of heating the serums to 65°C. was tried, since this has proved of value in the hands of Fici and Alessandrini in distinguishing between the specific and group agglutinins. But the sole effect of the heating was to lower the titre about one-half; both organisms were agglutinated equally at the lower level. The author concludes that *B. melitensis* and *B. abortus* must be regarded as two varieties of one bacterial species, differing only in their adaptation to different animal hosts.

653. The Oxygen Consumption of Atrophied Muscles.

A. E. BERYL HARDING (*Journ. Path. and Bact.*, April, 1926, p. 189) has compared the oxygen consumption of an atrophied quadriceps extensor muscle in rabbits with that of the same muscle in the sound leg. It was found that whereas the average difference between the two legs of normal rabbits was 43.5 c.mm. of oxygen per 100 grams of muscle a minute; that between the normal and the atrophied legs of the experimental animals was as much as 405 c.mm., the oxygen consumption being greater on the atrophied side. Six rabbits in which a streptococcal arthritis of the knee had been artificially produced were taken, and their left legs put up in plaster for three weeks. Determinations made at the end of this time showed that the oxygen consumption of the muscles of the normal and experimental legs was approximately equal. It would appear, therefore, that a muscle which is undergoing atrophy as the result of arthritis consumes more oxygen than a healthy muscle, but that if it is immobilized this extra oxygen consumption is prevented. The author suggests that there are two different kinds of muscular atrophy; in one the muscle receives an abnormal number of impulses from the joint leading to an increased katabolism and associated with an increased oxygen consumption; the other, a pure disuse atrophy, in which the afferent stimuli are reduced and the oxygen consumption is not increased.

EPITOME OF CURRENT MEDICAL LITERATURE.

Medicine.

654. Paraplegia and Hodgkin's Disease.

F. PARKES WEBER (*International Clinics*, 1926, vol. i, p. 127) has collected details of twenty cases of Hodgkin's disease complicated by paraplegia, in which the post-mortem findings included tumours invading the spinal canal, syringomyelia, a band of cellular pachymeningitis interna, parenchymatous changes in the spinal cord, and tuberculosis. He raises the question whether deep x-ray treatment may give rise to transverse degenerative changes in the cord, with paraplegic symptoms, in the same way that the extensive use of x-ray treatment in mammary cancer may cause pulmonary fibrosis. The tumour-like growth present in Hodgkin's disease may also, he suggests, have a tendency to become malignant, a "Hodgkin's sarcoma" arising from a "Hodgkin's granuloma." The author reports a case in which a mediastinal tumour infiltrated the sternum, lungs, pericardium, and some of the ribs: the first evidence of the growth was found in a rib, and was regarded as sarcomatous or syphilitic, but the latter possibility was almost certainly excluded. A year and a half later the mediastinum was found to be extensively involved, and the lymphatic glands in the right axilla and on the left side of the neck were infiltrated. The blood count was not far removed from the normal. The anaemia and weakness increased, there was general cutaneous pruritus—a common symptom of Hodgkin's disease—and a swinging type of pyrexia. Death followed, due to the pressure of the tumour, which was found to have a structure resembling that of the growth in Hodgkin's disease. The author considers that such a malignant progress in Hodgkin's disease would afford a possible explanation of the paraplegia which sometimes appears.

645. Poisoning following the Oral Administration of Bismuth Subnitrate.

W. H. RESNIK (*Bull. Johns Hopkins Hosp.*, May, 1926, p. 323) reports a case of bismuth poisoning in a woman suffering from diabetes mellitus. Before admission to hospital she had been given in a fortnight about 5 to 7 oz. of bismuth subnitrate by the mouth. The symptoms comprised a bluish-black discoloration of the gums, which were swollen and inflamed; a similar discoloration of the tongue, most noticeable at the apex of the papillae and arranged in vertical striations along the lateral margins; a patchy, diffuse discoloration of the buccal mucosa; swelling and tenderness of the parotid glands; a moderate anaemia, the erythrocytes being 3,100,000 per c.mm., the haemoglobin 40 per cent., and the leucocytes 9,000 per c.mm.; and basophilic stippling of the red cells. The clinical picture, in fact, closely resembled lead poisoning. Bismuth was detected in the urine. Recovery followed the withdrawal of the salt. In discussing the features of bismuth poisoning the author states that the metal is excreted by the salivary and buccal glands, by the kidneys, and by the large intestine; hence the main lesions are stomatitis, nephritis, and colitis. When given by subcutaneous or intravenous injection in treatment of granulating wounds, of chronic suppurating sinuses, and of syphilis, the appearance of the first symptoms is generally within a fortnight of the commencement of treatment. Poisoning after the oral administration of bismuth subnitrate is apparently very uncommon.

646. Erythema Infectiosum.

T. P. HERRICK (*Amer. Journ. Dis. Child.*, April, 1926, p. 486) records 74 cases of erythema infectiosum. The evidence indicates that the disease is a distinct entity, is infectious, and results in the establishment of a specific immunity. The distinguishing features of the disease are its occurrence in epidemics, the lack of constitutional symptoms, the lack of any features distinctive of the other exanthems, the long course and characteristic progression of the rash, its evanescence at all stages, and particularly the irregular but brilliant outlines seen on the arms and legs in the third stage and in the recurrences. There are no prodromal symptoms. The first sign is usually a dusky flush, which appears on the cheeks. While distinctly outlined, the rash on the face has a slightly irregular edge and is definitely raised, as a rule. Frequently this first stage is overlooked, the first sign noticed being the second stage of generalized involvement. The generalized rash is usually well marked and slightly papular on the buttocks. The upper part of the arms also usually shows a papular rash. The trunk may be extensively involved with

a rash which is definitely papular, but often there are only a comparatively few faint macules. When the rash is not well marked the existence of any disease at this stage could easily be doubted. The second stage lasts from several days to a week, and passes gradually into the third stage, when the rash is limited to the arms and legs, and the outlines persist for another week or longer. The rash on the lower part of the arms may be the only manifestation of the disease noticed, and the appearance there when typical can scarcely be confused with any other disease. The rash starts on the back of the forearm, just above the wrist, and in the early stages cannot with absolute certainty be distinguished from sunburn. After a day or two it spreads farther towards the sides and up to the elbow, clear areas appear in the centre, and the outline is more irregular and more distinctly marked off from the surrounding skin. The rash spreads peripherally, and small clear areas appear in the centre, which increase in size and coalesce, thus giving rise to the bright red irregular outlines typical of this stage. By the end of a week the back of the arms will be clear, except around the elbow and near the wrist, and the irregular outlines will have spread over the sides of the forearm to meet on the flexor surface. These outlines were described by one mother as "lakes and rivers on a map"; they are the most distinctive features of the disease. No treatment is indicated. Isolation and quarantine might limit the spread of the disease, but the lack of serious symptoms or sequelae makes such a course unnecessary.

647. Narcolepsy as a Post-encephalitic Syndrome.

W. G. SPILLER (*Journ. Amer. Med. Assoc.*, March 6th, 1926, p. 673) states that since Géléneau first described narcolepsy in 1830 the recognition of this disorder as a distinct entity has been much disputed. By some it has been considered a symptom-complex occurring with epilepsy or hysteria. Redlich has recorded cases in which epidemic encephalitis was followed by short attacks of sleep, occurring several times daily, and refers to other examples in the literature. Spiller now reports three cases of narcolepsy in males aged 28, 22, and 15 respectively, in none of whom was there a clear connexion with epidemic encephalitis, though in one there was a history of an attack of influenza and diplopia, and in two the sleep at night was interrupted, suggesting the inversion of normal rhythm frequently observed in epidemic encephalitis. Spiller concludes that though it would be assuming too much to assert that narcolepsy is always a post-encephalitic syndrome, it may occasionally be a sequel of epidemic encephalitis.

Surgery.

648. Displacements of the Semilunar Cartilages.

P. LE BRETON and R. M. CLEARY (*Med. Journ. and Record*, May 5th, 1926, p. 576) consider the diagnosis and treatment of displacements of the semilunar cartilages, based on a survey of fifteen cases of removal. The account of the symptoms given by the patient is important, and, while locking is typical when present, inability fully to extend the knee is the most positive sign, though this is usually absent in recurring attacks. In the prone position there is sharply localized tenderness over the internal cartilage in front of the internal lateral ligament over the joint line an inch and a quarter to the inner side of the lower end of the patella. An enlarged retropatellar fat pad may simulate the condition, but the catch is slighter, with creaking beneath the patella and a distinct doughy thickening at the sides of the bone. A negative x-ray report eliminates chronic arthritis, and instability due to lax ligaments can be ruled out by comparing both knees. If the case is seen soon after the accident and the patient is walking on a flexed knee the cartilage may be reduced by flexing the leg on the thigh to about 45 degrees below full extension with the patient lying on his back. The leg is then rotated inwards and abducted and then suddenly extended while the inward rotation is maintained. Weight bearing may be allowed except in a marked case with first displacement, a Thomas heel helping to maintain abduction and inward rotation and so guarding against recurrence. For frequent displacements removal is necessary; the authors prefer the method of Sir Robert Jones. They state that the prognosis is excellent provided no arthritis, joint irritation, or lax ligaments are present, and they emphasize the fact that the method does not involve a stiff joint.

649. Cerebral Thrombosis following Ligation of the External Carotid Artery.

H. HERFARTH (*Zentralbl. f. Chir.*, May 1st, 1926, p. 1106) records three fatal cases of cerebral thrombosis occurring within a year after ligation of the external carotid as a preliminary to operations for epithelioma of the tongue. In the first patient left hemiplegia supervened sixteen days after the operation, and the patient died four days later. The external carotid had been ligatured as usual above the origin of the superior thyroid artery; a secondary thrombus filled the lumen below the ligature as far as the superior thyroid; a portion of this thrombus had broken away and had been carried to the middle cerebral artery. The internal carotid contained no clot. The mortality of this complication has been estimated at 1.54 per cent. The author observes that it is most important to use absolutely aseptic ligatures in this operation, such as Perthes's strips of fascia.

650. Vesical Lesions due to Urotropine.

O. GRAGERT (*Zentralbl. f. Gynäk.*, May 1st, 1926, p. 1195) observes that while urotropine has an undeniably powerful bactericidal action when given in acid solutions, it is very doubtful whether formaldehyde is evolved in the genito-urinary tract when the drug is given by the mouth or injected intravenously. When a 40 per cent. urotropine solution is given by the latter route, it is probable that any resultant improvement is due to the powerful diuretic action of the drug flushing out the bladder. The author describes three cases in which haematuria and severe vesical tenesmus followed the administration of urotropine. A woman who had already a *B. coli* cystitis was submitted to a supravaginal hysterectomy and right oophorectomy for myomata. The next day a dose of 10 c.cm. of urotropine was given intravenously. Immediately afterwards severe tenesmus with haematuria and excessive diuresis occurred. The bladder could scarcely hold 10 c.cm. of urine and the patient was obliged to urinate every ten minutes. Morphine gave but temporary relief. Haematuria ceased on the third day, but tenesmus and dysuria persisted for a week, in spite of irrigation with boric lotion. The second patient, a primipara, aged 31, after a difficult forceps delivery, had retention persisting for several days. Intravenous injection of 5 c.cm. of urotropine was followed by severe tenesmus and haematuria, necessitating irrigation of the bladder and prolonged sedative treatment. The third patient, who had had eclampsia during a confinement three years previously, had suffered subsequently from persistent pain in the right loin. The urine contained vesical epithelium, relatively few leucocytes, and no bacteria. Early right pyelitis was diagnosed, and the patient received 0.5 gram of urotropine by the mouth thrice daily; after twenty-four hours, when she had taken only 1.5 grams, she suddenly had severe tenesmus and haematuria and was obliged to urinate every five or ten minutes. This was relieved by atropine and local treatment. A cystoscopic examination showed many submucous haemorrhages. The urine flowing from the ureters was clear and free from blood and bacteria. Tests for tubercle bacilli were all negative. It is suggested that in one or more of these cases there was an angioneurosis or an idiosyncrasy for urotropine.

651. Prolapse of Rectum in the Male.

U. MAES and J. D. RIVES (*Surg., Gynecol. and Obstet.*, May, 1926, p. 594) describe a plastic operation on the levatores ani and pelvic fascia for complete prolapse of the rectum in adults, and give notes of three cases. Their procedure is based on the assumption that the cause of the defect is the presence of an abnormally long cul-de-sac, as suggested by Quénu and Moschcowitz, together with relaxation of the lateral ligaments, the levator muscles, and the sphincter ani. In the lithotomy position, after reduction of the prolapse, an inverted Y incision, with the arms extending round the anus, is made to expose the external sphincter, which is then freed from the central tendon of the perineum by cutting across the ano-bulbar raphe. The anterior quadrant of the sphincter is excised and the muscle sutured end-to-end. The levator ani is exposed by deepening the incision, and its median margins are separated by blunt dissection. With a guiding finger in the rectum its anterior and lateral walls are cleared by blunt dissection as far as the lateral ligaments. The prostate and seminal vesicles are pushed forward and any reflection of peritoneum carefully pushed up until the prostate is exposed in front and the adventitia of the rectum behind. The lateral wall of the space is now formed by the superior surface of the levator ani covered by the pelvic fascia, and, commencing at the apex, sutures are introduced to approximate the levator muscles and suspend the rectum, several transverse stitches being taken across the lateral and anterior aspects of the rectal walls. With three or four sutures the levatores are approximated and the rectum suspended, closing the depth of the cul-de-sac. A last suture

approximates the free margins without picking up the rectum, so that the anus is thrown backward to produce the normal angulation of the canal. The authors state that the procedure is not difficult, is without shock, and can be performed under spinal or local anaesthesia. They consider that it offers a satisfactory technique for cases free from complications and in which the prolapse is not extreme.

Therapeutics.

652. Calcium in Ovarian Insufficiency.

A. CRAINCICANU (*Presse Méd.*, May 1st, 1926, p. 545), as the result of careful research into the conditions underlying ovarian insufficiency, has found that the administration of calcium is particularly effective. He recommends the daily administration by the mouth of between 90 and 120 grains of calcium lactate in cachets, each containing about 20 grains. The treatment should be continued for ten days, and, if necessary, should be repeated after an interval of a few days. The total duration of treatment varied, but on the average amounted to about fifteen to twenty days. He reports that very satisfactory results followed the use of this salt in ovarian insufficiency. Alaphandary has obtained equally good results by intravenous injections, but the present author prefers the oral route as being easier and equally satisfactory. He finds that even in still stronger doses than those recommended calcium was well tolerated by his patients and produced no digestive trouble. The constipation usually present with ovarian insufficiency was dealt with simultaneously. The results of treatment were found to be permanent. Craincicanu discusses the production of ovarian insufficiency, both congenital and acquired, and relates it to a loss of tone, associated with sympathetic or parasympathetic disorders. He gives the details of five cases to illustrate the employment of calcium lactate after hysterectomy and in the treatment of amenorrhoea.

653. Treatment of Infantile Eczema.

E. FEER (*Rev. Méd. de la Suisse Romande*, March 10th, 1926, p. 137) divides the causes of infantile eczema into two classes—namely, predisposing and exciting. He describes two forms of the disease: (1) Generalized eczema, seen chiefly in young infants, is usually characterized by a seborrhoeic eczema, fatty crusts, and linterigo. It often appears in infants with severe digestive disorders and diarrhoea. The linterigo may suggest a syphilitic lesion. Among the more severe forms of this group must be included cases of desquamating erythrodermia. (2) Eczema of the scalp, often extending to the cheeks, is more common in older infants. Typically this form may be mistaken for impetigo, or the latter may be implanted upon it. The first point in treatment is to correct errors of diet; overfeeding should be stopped in fat infants. Breast-fed infants should have four or five feeds a day, one or two of which may be replaced by malted soup, infantmilk, or farinaceous soups. At 4 to 5 months fruit and vegetables may be given. Hand-fed children should have their ration of cow's milk cut down to 400, 300, or even 200 grams a day. With the milk farinaceous food, oatmeal, fruit, and vegetables may be given. In place of whole milk skimmed milk or buttermilk may be substituted. The diet should be so regulated that a fat infant should gain no weight over a long period, and if very fat should lose 1 or 2 kilograms. When the diet has been well regulated and not excessive it should not be cut down. For external application olive oil and cold cream are recommended. In papular eczema zinc oxide 25 per cent. and talc powder 75 per cent. are applied after the cold cream; for pruritus, 1/4 to 1/2 per cent. of thyroid or menthol in alcohol, painted on freely, or 2 to 3 per cent. of anaesthesia in powder form. For papular eczema and pruritus Feer advises equal parts of zinc oxide, glycerin, and talc powder up to 25 grams with alcohol and distilled water, of each 12.5 grams, a dusting powder being used after the application. When sleep is disturbed, chloral 0.1 to 0.2 g. is indicated. To prevent scratching, the hands should be bandaged. In eczema of the head a dressing of boric vaseline, not impermeable, should be applied and renewed daily; in two to four days the crusts should come off easily; they should not be pulled off for fear of causing hyperpyrexia, convulsions, or even sudden death. When the condition beneath appears moist, several layers of gauze soaked in a 1 in 10 solution of alum acetate, covered with cotton-wool, not impermeable, and renewed three to five times a day. When the inflammation and discharge have diminished, a paste of zinc oxide, talc, lanoline, and vaseline (of each 25 grams) should be applied, covered by a mask with openings for the eyes, nose, and mouth. The addition of 1 to 5 per cent. of léngaliol often diminishes discharge, and of 3 to 10 per cent. of tuménol eases pruritus. In certain cases of

moist eczema painting with 1 to 2 per cent. of silver nitrate before the application of the paste aids the cure. This method is also applicable in cases of intertrigo. The author has found coal-tar a most valuable remedy in cases of dry or slightly moist eczema. It is contraindicated in suppurating conditions. It should be painted on with a camel-hair brush, allowed to dry for a moment, then powdered thickly over with zinc oxide and talc powder, and covered with a porous dressing. The tar dressing will separate after a few days; portions may have to be helped off with olive oil. Occasionally there may be some oozing, when the author uses naphthalene 50 grains, zinc oxide and talc powder, of each 25 grains. When peeling commences he advocates zinc oxide and bismuth subnitrate in ointment preparations. Most cases should be cured in two to eight weeks. In chronic intractable eczemas arsenic should be exhibited in the form of Fowler's solution, 1 or 2 drops daily; alkaline waters are also of value.

Laryngology and Otology.

654. Tumour of the Auditory Nerve.

G. ZANETTI (*Arch. Ital. di Otol., Rinol. e Laringol.*, February, 1926, p. 92) describes a case of a woman, aged 75, who had a tumour of the right auditory nerve. It was the size of a small nut, appeared to be almost pedunculated, and sprang from the region of the internal auditory meatus, being lightly attached to the facial nerve and the pons. The structure of the brain did not show any appreciable change. A wedge-shaped piece of the cranium was removed, including the internal meatus and the tumour. The tumour, which had a clear-cut fibrous capsule, consisted of compact fibrillary fibrous tissue with numerous blood vessels; the latter were present to such an extent that the author describes the tumour as a fibro-angioma. He adds that it is usually very difficult to detect any true nerve tissue in these tumours, but it certainly occurs in some. The tumour may develop within the lumen of the internal auditory meatus, or it may spring from the free extracanalicular portion of the nerve; it arises from the sheath of the nerve and has a very wide area of attachment. In the present case there was no dilatation of the internal meatus, though this may occur to a marked extent. In life attention is drawn to these tumours by unilateral symptoms implicating the seventh and both parts of the eighth nerve.

655. Lymphoid Tumours of the Nasopharynx.

BARRET DE NAZARIS (*Rev. de Laryngol., d'Otol. et de Rhinol.*, February, 1926, p. 71) thinks that the rarity of any reference in the literature to lymphoid tumours in the nasopharynx is due to incomplete pathological examination. Lymphomas are hyperplastic tumours characterized by masses of lymphoid cells in the meshes of a distinct reticulum. They may be part of a disease of the whole lymphoid system, but Torretta and Forrer suggest an infective origin, though bacteriological investigations have so far proved inconclusive. The section shows a uniform appearance of lymphoid cells in compact mass, the traces of normal glandular structure having been lost; on higher magnification a very delicate stroma is distinguished, including a number of endothelial cells. The lymphoid cells consist of lymphoblasts and lymphocytes; macrophages are present, and their abundant and clear cytoplasm contains droplets of chromatin due to the digestion of cells of the tumour. The lymphoid cells sometimes pass into the circulatory system, but they never give rise to metastases. The disease is rarely seen in its early stages, and the first obvious signs are respiratory difficulties, deafness, or swelling of the carotid region. The orifices most frequently attacked are the choanae, the nasal orifices, and the communication between the nasopharynx and the oropharynx. Nasal respiration is quickly suppressed and Eustachian obstruction is an early symptom. Slight epistaxis and swelling of the glands of the neck appear early. On rhinoscopy the tumour is seen to consist of a smooth rose or violet coloured mass, soft to the probe, and moving with the palate; the whole of the nasopharynx is filled with an enormous mass of adenoid-like growth, with a doubtful site of attachment. The disease progresses rapidly in the whole of the neck and mediastinum, in a few months. In a child between an early lymphoma and adenoid growth, but later, when the cavity is completely filled, this difficulty does not exist. Fibroma of the nasopharynx is unlikely after 25; it is smoother, harder, and gives rise to serious haemorrhages. Epitheliomas are generally smaller, they bleed, and are ulcerated. Lymphomas are most easily confused with sarcomas of the pharynx, but in the latter there is no trace of invasion of the glands. Surgical intervention leads only to generalized hyperplastic degenera-

tion. MacBride claims to have cured two cases with arsenic. Temporary amelioration follows diathermo-coagulation or electrolysis. Radium and x rays are not very practicable owing to the scattered and diverse nature of the growth. Short wave-length radiations result in the rapid destruction of the nasopharyngeal tumour at first, but new glandular tumours develop with great rapidity and bring about an early fatal termination.

656. Chordoma of the Cervical Vertebrae.

W. S. SYME and D. F. CAPPELL (*Journ. of Laryngol. and Otol.*, April, 1926, p. 209) describe a case of a man of 59 who, two months previous to admission to hospital, had suffered from shooting pains in the neck when he moved his head from side to side. Pain was succeeded by stiffness of the neck, which was later accompanied by difficulty in swallowing and defective articulation. A tumour was found in the posterior wall of the pharynx extending up into the nasopharynx and down into the laryngopharynx. It was situated behind the pharyngeal wall, but there was no ulceration of the mucosa. The growth was exposed through an incision carried from the tip of the mastoid process downwards along the anterior border of the sterno-mastoid muscle. It was free from the pharyngeal wall, but was firmly attached to the vertebral column and was found to be invading the body of the third vertebra and adjacent portions of the second and fourth vertebrae, from which it was separated with difficulty. The deep part was curetted and the diathermy button applied. The patient made an uneventful recovery, but was readmitted to hospital six months later with recurrence in the site of the original growth. The growth was now ill defined and widespread, reaching up to the base of the skull and downwards to the fifth cervical vertebra, with numerous lateral extensions into the prevertebral muscles. It was removed as far as possible and the diathermy button again employed over the cavity, but the patient developed septic pneumonia and died three days later. The body of the third cervical vertebra was so much destroyed that only a thin shell of bone separated the growth from the spinal canal; there was, however, no evidence of any invasion of the spinal canal or meninges or of pressure on the cord. There was invasion of the second and fourth cervical vertebrae, and of the retropharyngeal tissues overlying the fifth and first. The brain substance was found to be healthy. Histologically the growth proved to be a cellular malignant tumour with broad strands of epithelial cells many layers deep, resting on a delicate connective tissue core, and solid alveoli of epithelial cells resting on a rather dense fibrous stroma. In the border areas of stroma which comprised the capsule of the tumour there were small cord-like structures closely resembling notochord in the earlier developmental forms in lower animals. The tumour cells presented very varying characters in different parts of the growth, but their general character was in conformity with their origin from notochordal remnants, reproducing the various stages in the ontogeny of the notochord. The authors have not seen any account of this feature in the previously published cases of chordoma. In the *BRITISH MEDICAL JOURNAL* of May 22nd, 1926 (p. 862), a case of sacrococcygeal chordoma was recorded by Mr. A. Richardson and Mr. A. L. Taylor of Leeds. The patient recovered after operation, but it was considered probable that recurrence would take place.

Obstetrics and Gynaecology.

657. Suprapubic Transperitoneal Caesarean Section.

A. BRINDEAU (*Presse méd.*, March 10th, 1926, p. 305) claims the following advantages for this method over the ordinary Caesarean section: (1) The skin incision need not be so long. (2) The haemorrhage is less severe. (3) The operative shock is less. (4) Cleavage of the uterine wound involves a zone which remains in a state of rest, whereas in ordinary Caesarean section the sutures are applied to the body of the uterus, which contracts vigorously for the first few days after delivery, and tend to cut through the uterine tissues. This does not occur when the lower uterine segment is sutured. (5) In case of infection of the peritoneum there is a greater likelihood of the infection being limited to the pelvic peritoneum. (6) Post-operative intestinal obstruction and adhesions to the intestine or great omentum hardly ever occur. On the other hand, the drawbacks of the low operation are as follows: (1) The operation takes a little more time and is distinctly more difficult than the ordinary method. (2) The delivery of the child is somewhat difficult and may require the application of forceps. The results of the operation are satisfactory. Of 1,200 cases collected by Marassy the mortality was only 3 per cent. The method is chiefly indicated in pelvic deformities and in haemorrhage due to placenta praevia.

658. Adenoma of the Cervix Uteri.

ACCORDING TO E. DOUAY and A. SOLMARU (*Gynecol. et Obstét.*, 1926, xxlii, 4, p. 245), it is important to remember that adenoma of the cervix uteri, although a benign epithelial tumour, not infrequently becomes malignant. When this is suspected care should be taken to remove a fragment for examination from the hardest and most readily bleeding portion. Most commonly adenoma of the cervix is found between the ages of 30 and 50 years, but it may occur after the menopause. It is not an inflammatory lesion and there is little evidence that precurrent inflammatory conditions have an important etiological relation with it. The histological lesions common to all its forms consist in hyperplasia of the cervical glands with intraglandular epithelial vegetations and penetration of the glandular cul-de-sac within the neighbouring connecting tissue. Mitotic figures are never seen. Macroscopically in about four-fifths of the cases there is diffuse adenoma, with a regularly hypertrophied cervix, dark red, firm, and elastic. The other or partial forms are localized vegetating adenoma, adenomatous polypus developing within the cervical canal, and cystic adenoma which in the early stages resembles Naboth's oviducts. The symptoms have an insidious onset with vague lumbosacral pain. A glairy discharge is invariably present and may be very abundant; it is transparent, but may have a rosy or amber tinge. To palpation the tumour appears firm, elastic, and granular. Purulent discharge is not present except after secondary infection. Adenoma of the cervix does not bleed readily; the occurrence of slight haemorrhage after coitus or medical examination is suggestive of carcinomatous metaplasia, and should lead to microscopical examination of a carefully excised fragment. In treatment the application of antiseptics is useless if not harmful; the effects of carbonic acid snow, radium, and diathermy are not permanent. The authors recommend complete destruction by caustic or cautery, or amputation of the cervix.

659. Diagnosis of Disease of the Urinary Tract in Women.

T. J. MCBEE (*Med. Journ. and Record*, February 17th, 1926, p. 242) states that the close anatomical and physiological relations between the urinary tract and the reproductive organs in the female warrant an examination of both systems when disease is suspected in either. A large percentage of what are termed "female troubles" in girls and young women are urological conditions or urological and gynaecological conditions combined. Investigation of a case of this kind should therefore include a careful study of the clinical history, complete physical examination, and the investigation, both macroscopical and microscopical, of the urine. The presence of blood in the urine demands a further examination by means of the cystoscope, if possible while blood is still present, and the functional ability of each kidney should be ascertained. Cystitis rarely, if ever, occurs as a primary infection, so that symptomatic treatment is useless unless the primary focus is also dealt with. Primary cystitis is unaccompanied by any rise in temperature. Catheterization followed by chills and fever is due to a previous existing pyelonephritis. McBee considers stricture of the ureters to be one of the most common lesions occurring in the female abdomen and advises their dilatation; from this treatment he has had many good results, large "tumour masses" being found to disappear following the dilatation. Tuberculosis of the urinary tract in a woman should always be suspected when the bladder is intolerant of warm bland fluids, if the urine is persistently acid, or if the bladder capacity is reduced to four ounces or less, if one half of the trigone is more involved than the other, or if there are obstinate ulcers on the bladder wall or marked distension of the ureteral orifices. Similarly, persistent pyaemia in a woman between 15 and 40 years of age with no pathogenic organisms detectable by ordinary methods should give rise to suspicion of tuberculosis; the urine should be examined repeatedly for tubercle bacilli and guinea-pigs be injected. Renal tuberculosis alone gives rise to practically no symptoms.

Pathology.

660. A Microscopical Precipitation Test for Syphilis.

B. S. KLINE and A. M. YOUNG (*Journ. Amer. Med. Assoc.*, March 27th, 1926, p. 928) give a preliminary report of a microscopic slide precipitation test for syphilis which they recommend on the grounds of economy of apparatus, simplicity, easier reading of results, and less serum required than in other tests. The results obtained by this micro-method were found to run parallel with those of the ordinary routine Kahn and Wassermann tests. Glass slides are washed with soap, well rinsed in water, placed in 95 per

cent. alcohol for a short time, dried and flamed. Four paraffin rings are made on the slides. The antigen is diluted and titrated as in the Kahn test; it should be used quickly, since some antigens lose their value after fifteen minutes, though most remain good for three-quarters of an hour. The serums are prepared as for the Wassermann test and heated for one hour at 56° C. Into each paraffin ring 0.05 c.cm. of undiluted serum is placed and then 0.015 c.cm. of Kahn's antigen dilution; the mixture is rapidly stirred, and a specially devised cover is placed over the slides to prevent evaporation. After ten minutes the first slide is removed and rocked and rotated by hand for about a minute. The reading is made under a 16 mm. objective with a 10 or 12.5 ocular, the light being cut out as in the examination of a urinary deposit. The result is expressed according to the size of the clumps formed. It is suggested that the test should be controlled by using various antigens. The authors believe that this test will be found of special value when only small quantities of serum are available, and in emergency blood transfusions for excluding syphilis in the donor.

661. The Intracutaneous Method of Testing for the Virulence of Diphtheria Bacilli.

M. KALNICKOWA and M. GLUSSMANN (*Centrabl. f. Bakt.*, May 5th, 1926, p. 308) report on the modification of the intracutaneous method of testing the virulence of diphtheria bacilli described by Havens and Powell. This modification consists in using the original mixed culture obtained from the patient, instead of purifying it before injection. The culture is inoculated intracutaneously into two guinea-pigs, one of which has been given a dose of immune serum some time previously; the reaction in the two animals is compared. A positive reaction is denoted by infiltration at the site of injection in the non-immunized guinea-pig, followed after three days by a typical necrosis; in the immunized guinea-pig there is no lesion at all. If organisms are present in the culture capable of giving rise to suppuration an abscess forms in both animals alike, but it is not followed by the typical necrosis unless virulent diphtheria bacilli are present also, and then only the non-immunized guinea-pig is affected. The authors plant the primary culture on inspissated horse serum, wash the growth off with saline, and standardize the suspension to 500 or 1,000 million organisms, depending on the number of diphtheria bacilli present microscopically. Of this suspension 0.2 c.cm. is injected intracutaneously into the shaved skin. The reaction can generally be read in twenty-four hours, and always within seventy-two hours. By this method they have examined in all 177 cultures, comparing the microscopical with the virulence tests. Of 60 microscopically positive cultures 4 proved to be avirulent; of 10 microscopically doubtful positives all proved to be virulent; of 13 doubtful negatives 2 were virulent; and of 86 definite negatives none were virulent. Since at least four to six tests can be made on a single guinea-pig it is clear that a considerable saving of time and money is obtained. It should be of special value in the testing of bacilli isolated from carriers.

662. The Prognostic Value of Lymphocytosis in the Sputum of Tuberculous Patients.

N. SANTANGELO (*Il Morgagni*, May 9th, 1926, p. 577) has examined the sputum, in many instances repeatedly, of 70 patients suffering from pulmonary tuberculosis. The extent of the disease was gauged by clinical examination, by radiography of the chest, and by bacteriological examination of the sputum. Films of the sputum were prepared and stained by the May-Grünwald-Giemsa method; cell counts were then made and the proportion of lymphocytes estimated. Of the 70 patients 50 were over 18 years of age. Of these the ones that showed progressive increase of the local lesion and a bad general condition contained less than 5 per cent. of lymphocytes in their sputum. On the other hand, those patients whose local and general condition was not deteriorating contained from 6 to 21 per cent. of lymphocytes. Patients who were becoming worse showed a progressive fall in the lymphocyte content of their sputum. The remaining 20 patients were under 18 years of age. The same observations were made, but the proportion of lymphocytes was considerably higher than in adults. The cases that were doing badly had a lymphocyte content of 10 to 12 per cent.; the cases that were doing well had a lymphocyte content of 12 to 23 per cent. Eight patients with combined tuberculous and syphilitic were found to have a much higher lymphocytosis than was warranted by the gravity of their condition. The author disclaims any diagnostic value for the test, but considers it useful for prognosis. The higher the proportion of lymphocytes in the sputum, and the greater the rise in the lymphocyte curve, the better is the outlook. Conversely a low proportion and a falling curve are of grave prognosis.
